Young cracticids, after they have left the nest, are fed for a variable period, probably from one to three months, although they often continue to beg noisily from adults for much longer. Pied Currawongs leave the breeding home range with their parents after about two months, and the family may join a mobile flock of adults and juveniles. Later, the young come together in a mobile, immature flock (see Movements). With the group-living cracticids, the juveniles remain with the group, gradually taking an increasingly greater part in group activities. In the case of Australian Magpies and Pied Butcherbirds, dispersal, if it occurs at all, does not generally take place until the young are approaching the second breeding season after the one in which they hatched.

Female Australian Magpies may breed for the first time when they are two or three years old. It is not possible to make a corresponding statement for males because of the high levels of extra-group copulations in which they indulge and the differences in group size among subspecies. Little is known of the age at which other members of the family first breed. The juveniles of those butcherbirds that are not generally group-living remain in the parental territory for most of their first year, some even staying long enough to assist in brood-feeding at their parents' first nest in the following year.

For those species for which the relevant information is available, the major causes of nest failure are predation by Australian Ravens (*Corvus coronoides*) and the loss of older nestlings in periods of bad weather with very windy conditions. Nests built in the outer canopy of tall trees are subjected to violent movement in strong winds. In a study of Australian Magpies in south-western Australia, for example, a number of strong cold fronts in late October in each of two years coincided with the second half of the nestling period, and several nests failed in the course of a few days. Once chicks leave the nest, they are susceptible to predation by foxes (*Vulpes*), domestic cats and dogs (*Canis*), and in towns and cities they are at risk from being struck by traffic, as well as being subject to the well-meaning attentions of people who "rescue" the helpless fledglings in their first few days out of the nest.

The main brood parasite of the cracticids is the Channel-billed Cuckoo (*Scythrops novaehollandiae*), recorded mainly from nests of the Pied Currawong and the Australian Magpie, and also a parasite of *Corvus* crows. There are a few records of butcherbirds being parasitized by the Common Koel (*Eudynamys scolopacea*), the main main hosts of which are large honeyeaters (Meliphagidae), particularly various species of friarbird (*Philemon*). In Wood's study in New South Wales, Pied Currawongs defended a small breeding territory, and 93% of attacks on intruders occurred within 40 m of the nest, although Channel-billed Cuckoos were attacked at 80 m and Australasian Goshawks (*Accipiter fasciatus*) at 50 m. Attacks involved dive-bombing, chasing, bill-snapping and alarm-calling.

Most information on nest success for this family relates to the Australian Magpie, supplemented by one study on the Pied Currawong. Annual variation in nest success can be considerable. Studies in most parts of Australia have found that, on average, about 50–70% of Australian Magpie nests succeed in producing at least one fledgling. In suburban Perth, in south-western Australia, the Rowley team studied 12–15 Australian Magpie groups of the race *dorsalis* over a nine-year period, during which a total of 289 nests was monitored. On average, 47% of nests produced at least one fledgling, with a mean of 0·74 fledglings per nest; over this period, the annual success rate varied from 27% to 83%. Because of the multiple nests in most groups, and some re-laying and renesting, however, 78% of groups produced at least one fledgling, with a mean of 1·7; about half of these fledglings survived their first year. It is difficult to calculate the survival rate of these yearlings to two years of age, as some apparent losses may be due to dispersal, but it was found that, for individuals more than two years old, average annual survival was 92%. Most groups included one or more adults at least ten years old; in 2004, for example, 21 of the 88 Australian Magpies in the 15 known groups had an age of ten years or more. The oldest individual in this study was at least 15 years of age when study of his group ceased. High survival of adults is probably common to all subspecies of the Australian Magpie. In the Australian Capital Territory, for instance, Carrick's study of the nominate race found a survival rate of 84% for adult males and 86% for adult females. For the Pied Butcherbird, the only other species for which there is corresponding information, Ann Robinson estimated adult survival of approximately 71%; 59% of fledglings survived to one year, and at least 82% of yearlings survived to two years.

*The breeding systems of the **Australian Magpie** vary geographically with race, from pairs assisted by yearlings to groups with several adult males and one or more breeding female, assisted by non-breeding adults and juveniles. Like the butcherbirds and the currawongs, Australian Magpies build a bulky, untidy, flattened bowl-shaped nest of twigs and sticks. The female alone does the building, over a period of 2–3 weeks, using mainly sticks and often exotic materials such as coloured electrical cable or fencing wire. The inner cup is lined with wool, grass and shredded bark. A female will frequently nest in the same tree in successive years, and several breeding females in a group may nest in adjacent trees.*

[*Cracticus tibicen tibicen*, Brisbane, Australia. Photo: Brian J. Coates]

Most species lay two to five eggs, with a mean clutch size of three in Australia, and fewer in New Guinea. Single eggs and single fledglings are reported for the two Peltops *species. Cracticid eggs vary in colour; those of the* ***Pied Butcherbird*** *may be olive to brown, buff, grey or green, with spots or blotches of brown of various shades, mixed with black dots, concentrated at the larger end. Only the female incubates. The male spends much of the time perched or feeding nearby; he may bring her food. However, the male may also absent himself, in pursuit of extra-pair copulations.*

[*Cracticus nigrogularis nigrogularis*, Toganmain Station, New South Wales, Australia. Photo: Graeme Chapman]

Movements

The cracticids for which detailed information on movements exists are the Australian Magpie, the Grey and Pied Butcherbirds and the Pied Currawong. For other Australian members of the family, an analysis by P. A. Griffioen and M. F. Clarke of data from the second *Australian Bird Atlas* is the only information available, in addition to anecdotal reports. Some information is derived from the recovery of ringed birds, but, apart from the four better-known species, the numbers of cracticids that have been ringed are low. Ringing data from the Australian Bird Banding Scheme are summarized by Higgins and colleagues, who also list many anecdotal accounts indicating that some members of the family move from place to place while others remain in a local area. Movements of the New Guinea cracticids have not been studied, but these populations appear to be more or less sedentary.

Cracticus species are generally characterized as sedentary, and are recognized as being territorial all year. Studies of marked populations of Australian Magpies and Pied Butcherbirds suggest that dispersal by immatures in their second year or later rarely extends over more than 10 km, and this conclusion is supported by ringing data. Of 16,022 Australian Magpies ringed over a period of 50 years, 91% of 1095 recoveries were made less than 10 km from the ringing site. Over the same period, fewer (877) Pied Butcherbirds were ringed, but 98% of the 158 recoveries were within 10 km. Analyses of the Atlas records by season shows no large-scale movements for the less well-known species. Nevertheless, genetic analysis of Australian Magpies from north of Brisbane, from eastern New South Wales, from western Victoria and from south-western Australia revealed a surprising lack of difference among populations, especially in southern and eastern Australia. If dispersal were always over small distances, less than 10 km, different populations would be expected to exhibit genetic differences; conversely, if there is gene flow between populations owing to long-distance dispersal, genetic differences between those populations would be slight. The lack of genetic differences between Australian Magpie populations in south-eastern Australia suggests that some long-distance dispersal does occur, and the few long-distance recoveries of ringed Australian Magpies indicates that this does happen on a small scale, enough to produce the observed genetic uniformity. The Australian Magpies from south-western Australia showed greater genetic differences from the south-eastern populations, from which they are separated by the extensive barrier of the Nullabor Plain.

Additional evidence that Australian Magpies are more mobile than would be expected from sightings of marked individuals in their territories comes from translocation studies undertaken by Jones and others. Some male Australian Magpies, in defence of their nests, attack humans, and it was decided, rather than destroy these birds, to capture some of them and translocate them various distances away from their territory. Surprisingly, most of these individuals returned home very rapidly from distances of up to 25 km. At distances greater than about 40 km, however, very few found their way back. This suggests that, although the birds were not able to navigate home from the longer distances, they were familiar with a much larger area, with a radius of up to about 25 km from home, amounting to nearly 2000 km^2. Jones and colleagues propose that even territorial birds travel outside their territory much more than had previously been thought, perhaps when investigating opportunities for extra-group copulations or looking for a better position in a territory than the one currently held.

The most mobile of the cracticids are the currawongs, especially the Pied Currawong, although the analysis of seasonal Atlas data does not reveal any evidence of large-scale movement. For the Pied Currawong, only the nominate race and the subspecies *nebulosa* of eastern and south-eastern Australia are well known. In south-east Australia, this species maintains breeding territories but, for the rest of the year, forms mobile flocks that move around a local area. Most of the information on its movements is anecdotal, and relates to the species' appearance or disappearance and its increase or decrease in numbers at certain times of the year. Some of the birds in these mobile flocks may be locally resident, whereas others may be altitudinal migrants which have moved to lowland inland or coastal areas from breeding grounds in the highland forests of south-east and east Australia. There is some evidence that the breeding adults remain in their highland areas, while it is the non-breeders and immatures that move to the lowlands. In New South Wales, J. R. Farrell's study of marked

*There is no information on the incubation period of the **Black Butcherbird**, but it is thought to be similar to that of the Pied Butcherbird* (Cracticus nigrogularis), *at 19–21 days. On hatching, butcherbirds may be naked, or covered with sparse down. For the first week, the breeding female broods the nestlings almost continuously. The male, and sometimes helpers from the group, deliver food to her, which she feeds to the chicks. When the nestlings have acquired a covering of feathers, she is able to leave the nest to forage, and the male and helpers then deliver food directly to the nestlings. Helpers may or may not be related to the brood they are feeding, and the benefit they derive from their behaviour is not yet understood.*

[*Cracticus quoyi rufescens*, Cardwell, N Queensland, Australia. Photo: Clifford Frith]

birds in the Blue Mountains, west of Sydney, clearly uncovered altitudinal migration, with immatures the most mobile. In lowland areas throughout their range, Pied Currawongs are considered to be resident, often with an influx of visitors in the autumn–winter period. Large flocks move out to feeding areas from communal roosts, and break up during the day into feeding parties, before coming together as they begin to move back to the roosting areas. A study by J. L. Readshaw of marked individuals in southern New South Wales and northern Victoria showed a regular southward shift in spring, to the south-eastern mountain forests, and a northward one in autumn, with a maximum distance of 320 km. With increased human populations in several towns and cities, for example Canberra, Sydney and Armidale, as well as the maturing of suitable nesting trees and food-bearing shrubs in many of the gardens in these expanding cities, Pied Currawongs which were once autumn and winter visitors are now remaining all year round, with a mixture of breeding and non-breeding individuals.

From pooled data on over 10,000 Pied Currawongs that had been ringed, 40, or 2·3%, were recovered more than 100 km from the ringing site, with a maximum distance of 360 km. In contrast, only eight of more than 16,000 Australian Magpies were recovered more than 100 km from the site at which they had been ringed.

Movements of the Black and Grey Currawongs are not so well known. In the case of the Black Currawong of Tasmania, some individuals are resident and others appear to be partial altitudinal migrants, leaving highland areas after breeding and appearing at lowland sites in the autumn and winter, when they can even turn up in gardens in Hobart. Highland areas of Tasmania are cold and wet or snowy in winter, and many other bird species leave the island altogether in the winter, migrating north to mainland Australia. The relatively few ringed Black Currawongs do not provide much information, because, of the 611 individuals concerned, only 96 were recaught, all within 10 km of the ringing site, and the chance of recovery of any that may have moved is very low. One marked bird was found dead 50 km away, and another was seen alive 3 km from the ringing site more than twelve years later. The subspecies *colei* and *parvior* on King Island and Flinders Island, in Bass Strait, are certainly resident.

Of the three *Strepera* species, the Grey Currawong is the one most generally considered to be sedentary. Even so, some populations in south-eastern Australia and Tasmania may undertake local or altitudinal movements, being present at some times and not at others, although it is not always clear whether this is due simply to seasonal differences in habitat use. Of 754 Grey Currawongs ringed, 126 were recovered, many several times; of 498 recoveries, all except two were at sites less than 10 km from the original ringing site, a good indication of their sedentary nature. One marked individual was recaptured at its ringing site 19 years later.

Relationship with Man

All of the cracticids with the exception of the two species of *Peltops* are relatively large passerines, confident and bold, which have adapted well to living with man and can become very tame. Butcherbirds, with their "perch and pounce" foraging, and the ground-foraging Australian Magpie have benefited from the clearing of forests for farming and grazing and from urban expansion. The Australian Magpie is one of the bird species which persist in cleared agricultural lands, nesting in the shade trees left for sheep or cattle and feeding on open pasture. Provided that enough substantial trees remain for nesting purposes, the older suburbs of large cities, with established parks, playing fields and gardens with shrubs, lawns and well-grown trees, are a mosaic of magpie and butcherbird territories.

The Australian Magpie, because of its wide geographical range, large size, terrestrial foraging in open areas, recognizable melodious song and propensity to become tame, is probably one of the best-known bird species in Australia. It is popular if the local group is a friendly one, but some groups are feared for their aggressive nest defence towards strangers. Almost everyone in Australia has a "magpie story". In suburban areas where magpies live, the territory of a pair or group of these birds probably encompasses several gardens, some of the owners of which are sufficiently interested in birds to put out food for them. Very soon, the magpies arrive at least once a day, scavenging around outdoor cooking areas, and gathering at the door while performing a

loud carolling chorus (see Voice) until food is provided. Many become tame enough to enter a house if a door is open; some groups are fortunate in having more than one provider of cheese or minced meat, or perhaps a place where a pet dog or cat is fed outdoors. In many areas, Pied or Grey Butcherbirds likewise come to be fed, becoming very tame.

Where Pied Currawongs now live in towns and cities throughout the year, they, too, can become tame, and readily visit feeders and picnic tables. Since they do not remain all year in a territory, however, there is not the same element of "ownership" on either side.

Australian Magpies, Pied Currawongs and Grey Butcherbirds, in particular, have in the past been regarded as agricultural pests, causing damage through their depredations of small fruit such as grapes and strawberries, and corn. In recent times, however, their value as predators of insects has come to be seen to be more important. Magpies are effective predators of in-ground insects, particularly beetles, but they also take grasshoppers and locusts (Acrididae) in significant numbers. In their natural forest habitats, currawongs prey on many of the insects that damage eucalypt foliage, and are regarded by foresters as being beneficial.

As well as positive relationships with man, most cracticid species are considered to have some negative features. In the case of the Pied Currawong, it is its role as a nest predator, particularly of small passerines, that is regarded as adverse. Observations at nests of Pied Currawongs showed that the parents fed significant numbers of small birds to their own nestlings; most of these prey were nestlings of House Sparrows (*Passer domesticus*) and Spotted Doves (*Streptopelia chinensis*), both introduced species, but some were of native honeyeater species. It is this perceived role in the disappearance of smaller passerines, particularly in urban and semi-rural areas, that has produced a long debate on whether Pied Currawongs should be culled. Moreover, studies of the nominate race of Gould's Petrel (*Pterodroma leucoptera*), which breeds only on Cabbage Tree Island, 1·4 km off the New South Wales coast, found predation by Pied Currawongs to be a significant cause of mortality in both adults and nestlings of this globally threatened petrel, the breeding success of which increased immediately from 20% to 60% after the currawongs were controlled. In this instance Pied Currawongs were the critical predator, but in most cases many other nest predators, including butcherbirds, are also involved.

So far as the Australian Magpie is concerned, its negative image is a result of its aggressive nest-defence behaviour. Each year in the breeding season, one reads newspaper reports of cyclists sprouting "Martian" antennae on their bicycle helmets, and more serious accounts from all parts of Australia of eye injuries to children who have been subject to magpie attack. The problem is analysed in detail by Jones in his book *Magpie Alert*, based on research by himself and colleagues on a significant human/wildlife conflict. Attacks usually begin with loud alarm and rally calls from the birds as a human intruder is detected near the nest tree. The first part of the attack is a swoop from behind, no contact being made with the intruder; this may be followed by closer swooping, when the magpie flies rapidly towards the head of the victim, from behind or from the side, with calling, loud bill-snaps, pecking and biting. Occasionally, more violent attacks occur, when the bird flies into the face or the chest of the human intruder, holds on with its claws, and pecks at whatever it can reach. Attacks are almost all confined to the period of the breeding season, and almost all are carried out by males close to the nest tree. The frequency of attacks increases during the incubation and nestling stages, but, once the young fledge, the attacks cease as the birds move away from the nest tree. Most Australian Magpies, however, are not aggressive towards humans, and, in the races living in large groups, very often only one of the males attacks the intruder. Further research on attacking magpies found that they were frequently selective, some individuals attacking only pedestrians, some only cyclists, and some only mail-deliverers.

The two most significant types of direct damage caused to humans by Australian Magpies are eye injuries and injuries to cyclists who fall off their bicycles. In Brisbane, 4–13 cases of eye injury are reported each year; repeated across the towns and cities of Australia, that indicates a serious situation. With better understanding of the problem, in particular the timing and the short duration of the attack period, it has become possible to manage it in ways that do not involve the shooting of the pair or group or the destruction of nests; these methods include bicycle helmets, helmets with extra projections or antennae, tall flexible rear poles fixed to bicycles, and, for pedestrians large hats or umbrellas.

Magpie attacks occur only in urban areas. In parks and playing fields, warning notices advising pedestrians to avoid the areas

Young butcherbirds remain in the nest for 25–30 days, though towards the end of that time they may leave the nest for short periods and sit in nearby branches. By the time they leave the nest all cracticids have acquired their juvenile plumage. They are unable to fly properly for 2–3 more weeks, and spend their time skulking in cover, on the ground, or on low branches. Like other cracticids, ***Black Butcherbirds*** *are very aggressive in defence of their nests and fledglings. In the Cape York region of NE Australia, the Trumpet Manucode* (Manucodia keraudrenii) *often nests close to this species, apparently taking advantage of its aggression against predators.*

[*Cracticus quoyi rufescens*, Cairns, Queensland, Australia. Photo: Atsushi Matsui]

Fledgling ***Pied Butcherbirds*** *are fed by group-members for at least a month after leaving the nest. In one study, all the young stayed with the group until they were nearly two years old. At the commencement of the breeding season, some then dispersed to join other groups. Social play among juveniles has not been studied in this species, but is likely to be similar to that of the Australian Magpie* (Cracticus tibicen). *Much of the play involves mock fighting, simulating the attacks and chases that will later be used in territorial and anti-predator defence, and the wrestling that helps establish dominance hierarchies within the group.*

[*Cracticus nigrogularis nigrogularis*, Hattah-Kulkyne National Park, NW Victoria, Australia. Photo: David Stowe]

for the few weeks of the breeding season can be effective. It should be remembered, too, that many reported magpie attacks are in fact carried out by butcherbirds, and it seems that, to many members of the public, one aggressive black-and-white "missile" looks much the same as another.

Status and Conservation

Of the twelve species in the family Cracticidae, eleven are currently considered not to be at any immediate risk. The twelfth is a Data-deficient species. This is the Tagula Butcherbird, which occurs only on the small island of Tagula, in the Louisiade Archipelago, off the coast of south-east New Guinea. It is possibly conspecific with the Hooded Butcherbird, but its biology and status on Tagula are little known, although its habitat has been degraded and heavily logged. Its geographical restriction to a single small island with a total area of about 866 km² does, however, suggest that it may warrant treatment as Near-threatened, if not Vulnerable. The forest of the eastern two-thirds of Tagula is already degraded, and logging remains a threat to all of the lowland forest. Indeed, uncontrolled and illegal logging in New Guinea and subsequent habitat degradation are widespread, affecting all species, whether threatened or not, and it will require a major political effort to rectify this situation.

Information about the Tagula Butcherbird's status would be a first step towards its conservation. Although its population and ecology are virtually unknown, as are those of most of the island's other endemic species, they are likely to be similar to those of the Hooded Butcherbird, which is a common and adaptable species, occurring in all forest-edge habitats, including gardens and savanna. Proposed conservation measures for the Tagula Butcherbird include surveys of potentially suitable habitat on the island and study of its ecological requirements, tolerance of habitat degradation and threats. The forests from Mount Riu eastwards are very important for the survival both of this species and of the endemic Tagula Honeyeater (*Meliphaga vicina*). Ten Tagula Butcherbirds were seen during a ten-day trek from the north coast up to Mount Riu in 1992, on the only recent visit to the island by ornithologists.

Although the eleven remaining species are not globally threatened, consideration of the 42 taxa covered by them reveals four which give cause for significant concern. Three of these are subspecies which, like the Tagula Butcherbird, occur on small islands and are therefore restricted in range and in population size. The subspecies *hercules* of the Hooded Butcherbird is found only in the Trobriand Islands and the D'Entrecasteaux Archipelago, at the south-eastern tip of New Guinea; although reported in 1970 as common on Goodenough Island, in the D'Entrecasteaux Group, despite the destructive agricultural methods used by the local residents, it is now restricted to just a few relatively small islands, and its future must be considered uncertain. Detailed surveys to determine its current status are a necessary step towards its conservation.

Two subspecies of the Pied Currawong are listed by Garnett and Crowley in their *Action Plan for Australian Birds*. These authors considered the population of the race *crissalis*, found only on Lord Howe Island, about 600 km north-east of Sydney, as stable but "endangered", estimated at 80 breeding individuals in an area of 12 km². A survey of the birds of Lord Howe Island, published in 2004, lists *crissalis* as rare, and suggests that molecular investigation of its relationship with the nominate race is warranted because of its long isolation, to determine whether it is a distinct species. Garnett and Crowley's recommendations for conservation action are for continued monitoring of the population by wildlife authorities, and to ensure that human residents on the island are aware of the significance of the subspecies, both biologically and commercially. Tourism is a major industry on Lord Howe Island, and visits by birdwatchers are a significant component of this. In addition, they list the mainland Victoria race *ashbyi* as "critically endangered" on the basis of its decreasing population size and range, but they stress that this is a precautionary assessment as a result of lack of information. No "pure" population of *ashbyi*, one without intermediate individuals (see Systematics), is at present known. Any efforts at conservation of this race depend on mapping the location of populations with individuals attributable to *ashbyi*, and the clear determination of morphological and genetic differences between *ashbyi* of west Victoria and *nebulosa* of east Victoria. Only then might it be possible to identify habitat barriers that could be used to prevent *ashbyi* from being overrun by *nebulosa*, if it is not already too late.

Another island currawong, the King Island race *colei* of the Black Currawong, is listed as "vulnerable" by Garnett and

The main brood parasite of the cracticids is the Channel-billed Cuckoo (Scythrops novaehollandiae), *here being fed by a* ***Pied Currawong***. *Currawongs attack adult cuckoos on sight, often going well outside the normal boundaries of their territory. One group of Pied Currawongs, which usually set upon intruders when they came within 40 m of the nest, attacked Channel-billed Cuckoos 80 m away. There are also records of butcherbirds being parasitized by the Common Koel* (Eudynamys scolopacea). *Intraspecific brood parasitism, in which the brooding female is not the mother of one or more young in her nest, has been found to be frequent among cracticids. Annual variation in nest success can be considerable. On average, 50–70% of Australian Magpie* (Cracticus tibicen) *nests produce at least one fledgling, while 59% of fledgling Pied Butcherbirds* (C. nigrogularis) *survive to one year, and at least 82% of yearlings survive to two years. For Australian Magpies over two years old, annual survival was 92%. Many groups of this species contain individuals over ten years old, and the oldest known Australian Magpie was at least 15. Groups led by these dominant older birds can be extremely stable, and are maintained by the retention of progeny, while being constantly refreshed by high levels of extra-group copulation.*

[*Strepera graculina*, New South Wales, Australia.
Photo: Neil Bowman/FLPA]

Crowley, on the grounds that it has only one population, of about 500 individuals, in an area of 500 km². The Tasmanian mainland and Flinders Island subspecies are thought not to be at any risk. At present, the King Island population is stable, but continued monitoring is necessary, as the expansion of the beef-cattle and dairy industries on the island is increasing demands for further clearing of the forest habitat.

The Black Butcherbird is widely distributed, with five subspecies in New Guinea and Australia. The recently described race *alecto* is found in southern New Guinea and includes birds found on the Australian islands of Boigu and Saibai, in the northernmost Torres Strait close to the New Guinea coast. Garnett and Crowley rated this race as "near-threatened", although it would be "vulnerable" on the basis of its small Australian range, limited to two islands with a combined area of 100 km². The islands are close to New Guinea, and there is likely to be genetic exchange, hence the downgrading of its threat status. Boigu and Saibai represent only a small part of the larger range of *alecto*, and are probably not of significance to the subspecies as a whole, but only in an Australian context. There appear to be no immediate threats to these populations, except perhaps the effects on low islands of rising sea levels for birds that live in mangrove habitat. It was suggested that birds such as the subspecies *alecto* of the Black Butcherbird could be used as a means of encouraging visits by birdwatchers, who would then contribute to the monitoring of habitats and numbers.

Apart from the Tagula Butcherbird, no New Guinea taxon in the Cracticidae is considered threatened or nearly so, and their status is insufficiently known for any realistic assessment of their true conservation status to be made. The two species in the genus *Peltops* are still poorly known, although both are widespread within that large island. The Lowland Peltops is perhaps more at risk, because of the extensive logging of the lowland rainforest that it occupies. This is likely to lead to a decrease in the extent of the species' occurrence and also in its population. The Highland Peltops appears to be even less known, there being few data on its breeding biology and little information on its population levels. Both species are assumed not to be threatened, but further fieldwork is required.

The main potential threat to all New Guinea taxa is likely to be the large-scale clearing of lowland and foothill forest for timber and wood chips. Owing to much illegal logging, the area cleared each year is greater than that allowed under permits granted. Butcherbirds are well known for their ability to co-exist with man, and in New Guinea they use the openings created by village gardens, but large-scale clearance of forest does not create suitable habitat. A further problem is the lack of information for West Papua (Irian Jaya), where the extent of recent clearing for timber and mining is not well documented. Even the information generated by bird tourism is sparse. Tourists are few in the west of New Guinea, and the high level of lawlessness in the east, Papua New Guinea, discourages many potential visitors, and restricts the travel of those who do make the trip.

For all cracticids, whatever their conservation status, habitat loss through land-clearing and fire is still a threat in New Guinea and parts of Australia. In Australia, the problems of drought, fire, introduced predators, and habitat degradation by grazing stock are significant everywhere, and regular monitoring is necessary in order to ensure that population levels remain stable, rather than declining. In times of drought, grazing pressure on understorey vegetation in uncleared timbered areas of private land and broad roadside reserves can be severe, removing the litter layer which sustains the insects and small vertebrates that are the basic food of butcherbirds and currawongs. The large-scale surveys involving amateur birdwatchers that have produced the first and second Atlases of Australian birds, in 1984 and 2003, respectively, provide some information on population trends, but they do not satisfy the need for detailed studies of individual species, especially those presumed to be at risk. Thus, in the Cracticidae, only the common and widespread Australian Magpie has been well studied, but the basic biology of butcherbirds and currawongs is in general poorly known, so that it is hard to identify those features of their life-cycle that make them vulnerable to threatening processes.

*The **Black Currawong** is a restricted-range species, confined to the Tasmania Endemic Bird Area. In spite of its rather limited distribution, it is relatively common in general, and its populations are mostly thought to be fairly stable. However, the race* colei, *of nearby King Island, is considered to be at risk, with a population of only about 500 individuals occurring in an area of 500 km².*

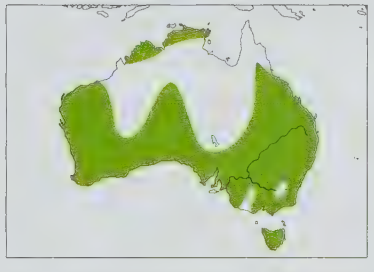
Genus *CRACTICUS* Vieillot, 1816

1. Black Butcherbird

Cracticus quoyi

French: Cassican des mangroves **German**: Mangrovemetzgervogel **Spanish**: Verdugo Negro
Other common names: Spalding/Rufous/Brown/Quoy Butcherbird, Black/Rufous Crow-shrike

Taxonomy. *Barita Quoyi* Lesson and Garnot, 1827, Dorey (= Manokwari), Vogelkop, north-west New Guinea.
Has at times been placed in a monotypic genus, *Melloria*. DNA evidence suggests that this species may be more closely related to *C. tibicen* than to others of genus, but more evidence needed. Race *jardini* intergrades with *rufescens* in region of Endeavour R (in NE Queensland). Geographical variation slight; some authors consider that species would be better treated as monotypic. Five subspecies currently recognized.
Subspecies and Distribution.
C. q. quoyi (Lesson & Garnot, 1827) – West Papuan Is (Waigeo, Salawati and Misool), Yapen (in Geelvink Bay) and mainland New Guinea (except Trans-Fly).
C. q. alecto Schodde & Mason, 1999 – SC New Guinea (Trans-Fly region from Princess Marianne Strait E to Daru I), Aru Is, and islands in N Torres Strait (Boigu and Saibai).
C. q. spaldingi Masters, 1878 – N Western Australia (Cambridge Gulf) E along coast, including Tiwi Is (Bathurst I and Melville I), to coastal Arnhem Land (to Blue Mud Bay, in Gulf of Carpentaria).
C. q. jardini Mathews, 1912 – coastal Cape York Peninsula S to Mitchell R in W and to Cooktown in E.
C. q. rufescens De Vis, 1883 – NE coastal Queensland from Cooktown area S to N Broad Sound (S of Mackay), with gap at Burdekin R.



Descriptive notes. 33–44 cm; 148–196 g (races unspecified), 180–220 g (*spaldingi*). Large, all-dark butcherbird with massive hook-tipped bill. Nominate race is black, brighter glossy blue-black on back, duller ventrally, and becoming duller with wear; tail long, appears square-tipped at rest but rounded in flight; iris brown; bill blue-grey or milky blue, distal third black; legs dark grey or black. Sexes similar in plumage, male (wing 180 mm) slightly larger than female (wing 176 mm). Juvenile differs from adult in having underparts dull black or brownish-black, iris brownish-yellow, bill pale grey, legs dark grey; immature like adult, but underbody and most of upperwing duller black-brown, contrasting with glossy head, neck and back, area of bluish colour at base of bill becoming more extensive with age. Races differ mainly in size and in bill morphology: *alecto* is larger than nominate (wing of male 190 mm, of female 181 mm), intermediate in size between following two, immature dull black; *spaldingi* is largest race (42–44 cm; wing of male 198 mm, of female 186 mm), with slender bill, immature dull black; *jardini* is smaller than previous (167 g; wing of male 181 mm, of female 176 mm), with short, slender bill, immature dull black; *rufescens* is smaller than last (33–38 cm; male 161 g; wing of male 174 mm, of female 166 mm), with short, slender bill, immature either rufous-brown or dull black (sometimes both types in same brood). Voice. Repertoire not well known; regional variation reported, but not well characterized. Vocalizations loud. Song a rich, melodious yodelling with some clear liquid notes, sometimes (e.g. dawn in breeding season) given in long bouts. Antiphonal duets by presumed males and female, especially at start of breeding season. In early morning, male gives clonking "gronk, gronk" call from perch in canopy.
Habitat. Nominate race occurs in most forest types and plantations in lowlands and hills, to c. 1300 m. In S New Guinea and N & NE Australia, mainly mangrove forests and riverine vegetation along humid coasts, also coastal rainforest and adjacent woodland, including open grassy woodland.
Food and Feeding. Invertebrates, mainly insects; also small vertebrates, e.g. small lizards and snakes, frogs, small mammals and birds (including nestlings), small crabs and fish; also some fruit. Sometimes feeds by pouncing to the ground, but in forest forages mostly at 8–30 m through subcanopy and lower canopy; also searches through litter. In mangroves, forages below canopy on trunks, branches, prop-roots and ground. Prey items too large to be eaten in one piece are wedged into a crack or fork or impaled on a spike, and then dismembered.
Breeding. Little known. Laying in middle to late dry season Aug to early Jan (mainly Sept–Oct) in New Guinea; eggs mainly Sept–Jan (mostly Oct–Nov) in Australia. Territorial, remaining on territory all year. Nest an untidy bowl of sticks and twigs, may be lined with rootlets and grass, one was 25 cm in diameter and 8 cm deep; in Australia placed in vertical fork 5–15 m above ground, or (in Western Australia) at 5–7 m in vertical fork of tall mangrove and often overhanging tidal creek; frequently in same area, although not same tree, each year; in NE Australia (Cape York) Trumpet Manucode (*Manucodia keraudrenii*) often breeds in vicinity of nest of present species, apparently benefiting from its aggressive nest defence. Clutch 2–4 eggs, usually 3; colour variable, cream to greyish-green, olive-grey or greyish-blue, with rich reddish-brown or darker dots, spots and blotches concentrated at larger end, dimensions c. 33 × 24 mm; no information on incubation and nestling periods.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Common and widespread in much of New Guinea; fairly common in Australia. Reported density of 3 birds/10 ha in rainforest near Port Moresby, in SE New Guinea. Australian population of race *alecto* rated nationally "Vulnerable" because of very small area of occupancy (islands of Boigu and Saibai, total area 100 km²); same race occurs also in S New Guinea and Aru Is. Main threat to Australian population of *alecto* is rising sea levels. Main potential threat to nominate race in New Guinea is logging of lowland rainforest habitat; for races on tropical coasts of N Australia, frequent fires lead to modification of grassy woodland habitats.
Bibliography. Amadon (1951), Barnard (1911), Barrett *et al.* (2003), Beehler *et al.* (1986), Bell (1982a, 1982b, 1982c), Beruldsen (2004), Blakers *et al.* (1984), Campbell (1901), Christidis & Boles (2008), Coates (1990), Coates & Peckover (2001), Diamond (1972), Ford (1983), Frith, D.W. & Frith (1995), Garnett & Crowley (2000), Higgins *et al.* (2006a), Johnstone & Storr (2004), Lavery (1986), Mayr & Rand (1937), McGillivray (1914), Mees (1964a), North (1906), Pizzey *et al.* (2007), Rand (1942a, 1942b), Rand & Gilliard (1967), Ripley (1964), Schodde & Hitchcock (1968), Schodde & Mason (1999), Schodde & Tidemann (1990), Simpson & Day (2004), Slater *et al.* (2003), Storr (1953), Tubb (1945), White (1922).

2. Grey Butcherbird

Cracticus torquatus

French: Cassican à collier **German**: Graurücken-Metzgervogel **Spanish**: Verdugo Acollarado
Other common names: Australian/Collared/White-winged (Grey) Butcherbird, Collared Crow-shrike, Clouded/Grey Shrike; Silver-backed Butcherbird (*argenteus* and *colletti*); Tasmanian Butcherbird (*cinereus*)

Taxonomy. *L[anius] torquatus* Latham, 1801, coastal south-east Australia.
This species and *C. mentalis*, which form a superspecies, have sometimes been placed in a separate genus, *Bulestes*. Races *argenteus* and *colletti* sometimes treated as a separate species, geographically separated from other races by significant desert barriers, and possibly at least as close to *C. mentalis* as to present species; *argenteus* shares some characters with present species and others with *C. mentalis*; further study, including molecular analysis, required in order to resolve true relationships. Race *colletti* often included within *argenteus*, but seems reasonably distinctive. Nominate race intergrades with *leucopterus* on W slopes of Great Dividing Range from S Queensland S to Otway Range, in Victoria. Proposed race *latens* (Uwins I, in N Western Australia) is a synonym of *argenteus*. Type locality of taxon *argenteus* is disputed; if this name is instead applicable to Arnhem Land form, Western Australian form then takes name *latens*. Five subspecies recognized.
Subspecies and Distribution.
C. t. argenteus Gould, 1841 – Western Australia (Kimberley region E from Yampi Sound and mouth of Fitzroy R) and marginally NW Northern Territory (E to mouth of Victoria R), S to Great Sandy Desert.
C. t. colletti Mathews, 1912 – coastal Northern Territory from Victoria R almost to E tip of Arnhem Land, S to N Tanami Desert in W.
C. t. leucopterus Gould, 1848 – S half of Australia S of 20° S (except for desert areas of Western Australia, South Australia, Northern Territory and W half of Queensland), in E extending N in E Queensland (W of Great Dividing Range) towards S Cape York Peninsula.
C. t. torquatus (Latham, 1801) – coastal SE Queensland S (mainly E & S of Great Dividing Range) to Victoria.
C. t. cinereus (Gould, 1837) – Tasmania.

Descriptive notes. 27–30 cm; 68–99 g, 112 g (male *cinereus*). Medium-sized butcherbird having strong bill with sharp terminal hook. Male nominate race has top and side of head black, sharply separated from bright white chin and throat, broad white half-collar on each side from throat towards middle of hindneck (the two sides not meeting), conspicuous white spot on lores; upperparts dark grey with some streaking and mottling, narrow white band across rump (prominent in flight); uppertail black with narrow white tip (tip usually abraded); upperwing mostly black, narrow white stripe through innermost secondaries, white patch in secondary coverts (visible in flight); underparts off-white, grey shading over breast, flanks and belly; underwing whitish, merging into brown on flight-feathers, undertail black or silver-grey with broader white tip; iris dark brown; bill pale blue-grey at base, sharp transition to black distal third to half; legs dark grey. Female is smaller than male, plumage variable, like male or variously with head duller brownish, back duller grey, loral spot off-white and larger (meeting eye), less white in wing, undertail always silver-grey (may be black on male). Juvenile is generally brown with buff streaks, head dark brown, streaked buff, throat off-white, loral spot, eyebrow and collar buff-white, upperbody dark brown with fine buff streaks, wing brown with buff stripe, underparts buff-white with diffuse dark brown streaking on breast and flanks, bill blackish, shorter, stubbier and less hooked than adult's; immature similar to adult, but head noticeably duller black or black-brown with buff streaks, buff eyebrow, collar dull off-white, upperparts duller and browner with lighter mottling (sometimes grey, similar to adult), underparts streaky brown-white, bill dull grey. Race *leucopterus* has longer tail than nominate, back lighter mid-grey, broader white band on rump, wider white stripe in wing, broader white tip of tail, male underbody white with faint grey bloom, female light cloudy grey; *cinereus* is larger and darker, with longer wing and tarsus, head greyish-black, back dull grey or brownish-grey; *argenteus* differs from nominate in having completely black head (no white on lores), black chin, front lower edges of hood extending as black "necklace" on to breast, paler silvery-grey back, scapulars and rump with darker shaft streaks, broader white tail tip, more extensive white patch in wing; *colletti* is similar to previous but smaller, with chin and side of breast white, no necklace, shorter white tail tip. Voice. Nominate race well studied. Three main song types: Territorial Song, heard all year, especially before dawn and in evening, given by male and female and any other group-members, as duet or group song, complex, vigorous, loud chortling containing both musical and harsh elements; Breeding Song, given Aug–Nov in breeding season, before dawn, by male, no harsh elements, each male has several versions each composed of a number of phrases with a series of simple elements, rising, falling, steady and warbling; Whisper Song (or Subsong), heard most of year, less in breeding season, usually in middle of day; given by male from special perch, soft, audible to 10–30 m, contains elements of Territorial and Breeding Songs, also mimicry of other birds, frequently given in long bouts (exceeding one hour). Other sounds include harsh "keerk" alarm calls, shrill distress calls, bill-snapping, begging calls by female in course of sexual behaviour or by fledglings when food-begging; also variety of soft warbling vocalizations at roosting or when feeding young in nest. Voice of *argenteus* and *colletti* little known, but that of former considered significantly different from that of nominate; recordings of *colletti* contain unhurried phrases of mellow ringing notes more like song of *C. quoyi* and *C. cassicus* than of present species; also some faster jumbled phrases like those of nominate race.
Habitat. Range of open habitats, mainly eucalypt (*Eucalyptus*) open forests and woodlands, including mallee woodlands and *Acacia* shrublands and woodlands, preferring open ground layer of

On following pages: 3. Black-backed Butcherbird (*Cracticus mentalis*); 4. Pied Butcherbird (*Cracticus nigrogularis*); 5. Hooded Butcherbird (*Cracticus cassicus*); 6. Tagula Butcherbird (*Cracticus louisiadensis*); 7. Australian Magpie (*Cracticus tibicen*); 8. Pied Currawong (*Strepera graculina*); 9. Black Currawong (*Strepera fuliginosa*); 10. Grey Currawong (*Strepera versicolor*); 11. Lowland Peltops (*Peltops blainvillii*); 12. Highland Peltops (*Peltops montanus*).

grass or scattered shrubs; also on farms, in rural towns and in parts of larger cities with well-grown trees in parks and gardens. In N of Western Australia and Northern Territory (races *argenteus* and *colletti*) mainly in riparian forest, especially of cadjeput (*Melaleuca leucadendra*), vine scrub, edges of rainforest patches, thickets at foot of cliffs, fringing vegetation such as pandanus (*Pandanus*) along creeks and rivers, forest and woodland in gorges and gulleys.

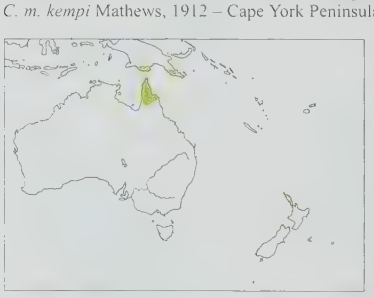
Food and Feeding. Invertebrates, mainly insects, also small vertebrates, especially small birds and nestlings; some fruit and seeds, and nectar. Forages from perch, pouncing on prey on ground, sallying to seize insects on branches or trunks of trees, or striking for flying prey such as bees (Apidae) or cicadas (Cicadidae). Reported as chasing small birds in flight, but more often seizes from behind small birds which are foraging on ground, killing them by powerful spear of bill to the head; association with mixed-species foraging flocks interpreted as a strategy to prey on other birds. Also robs nests of small birds. Prey too large to be eaten whole usually wedged in fork or impaled on thorn or twig and torn into edible fragments; surplus food cached in such sites. Seen drinking from ground pools and tree hollows. In Northern Territory, race *colletti* one of a number of opportunist nectar-feeders when nectar very abundant in dry season.

Breeding. Laying generally from early Aug to Jan (mostly Sept–Oct), but breeding recorded in all months, probably in response to rain in arid and semi-arid areas; laying Aug–Sept (end of dry season) in NW of range (race *argenteus*). Nests usually in simple pairs, sometimes with a helper, usually immature from previous year. Territorial; present in territory all year. Nest built by both sexes (reportedly lined only by female), a shallow, open untidy bowl c. 20 cm in diameter, external depth c. 10 cm, constructed mostly with thin twigs, neat internal cup c. 5 cm deep and lined with grass, rootlets, hair and other fine pliable materials, usually placed 2–12 m (mostly c. 5–6 m) above ground in horizontal or vertical fork in tree, usually living, most in eucalypt, some in *Acacia*, *Banksia*, cypress-pine (*Callitris*) or other native or introduced tree, often sapling used; in NW of range (*argenteus*) an untidy small bowl 18–23 cm across and 8–11 cm deep, internally 8·5–9 cm wide and 3–3·5 cm deep, of fine twigs, lined with spinifex grass and rootlets, usually in vertical or horizontal fork 5–15 m above ground in tree, including *Melaleuca leucadendra* and *Eucalyptus miniata*. Clutch usually 3–4 eggs, variable in colour, brownish-green with red, purple or brown spots, usually concentrated at large end, mean 32 × 23 mm, in NW of range (*argenteus*) 2–3 eggs, pale olive-grey or buff-brown, zone of reddish-brown spots and blotches on violet-grey at larger end, 29 × 21 mm; no information on incubation and nestling periods and post-fledging parental care of NW races; elsewhere, incubation by female alone, period c. 21 days; chicks fed by both parents, also by helper if present, nestling period 25–26 days; adults very aggressive towards intruders at nest; young fed by parents for at least one month after fledging, one record of male feeding fledglings from first nest while female built new nest; some immatures disperse after breeding season, but many remain with parents until start of next breeding season, and a few remain for at least part of breeding season and help to defend territory and to feed nestlings.

Movements. Sedentary. Many anecdotal reports of seasonal movements probably refer to post-breeding dispersal of immatures, but no detailed studies. Censuses in open forest near Darwin (Northern Territory) showed numbers of race *colletti* similar in wet and dry seasons, suggesting that birds remain in same area all year.

Status and Conservation. Not globally threatened. Generally rather uncommon and patchily distributed; more common in Tasmania. In some areas, numbers have declined because of clearing of open woodland habitats for urban development or for agriculture, as in wheat-growing area of Western Australia; in other areas, forest clearance has produced the more open habitats preferred by this species. Can co-exist with man, as suburban trees and parks mature to provide suitable habitat. Can become very tame and is often encouraged by householders, who enjoy its delightful song. In N Australia, main future threats are habitat alteration and loss resulting from current fire regimes and the possibility of a shift to more intensive agriculture in face of decreasing rainfall in S Australia owing to climate change. Current practice of yearly burning in late summer prevents regeneration of trees and leads to replacement of low grassy understorey with tall dense grasses unfavourable to butcherbirds.

(1926), Barker & Vestjens (1990), Barrett *et al.* (2003), Beruldsen (2004), Blakers *et al.* (1984), Carter (1996), Christidis & Boles (2008), Crawford (1979), Ford (1979), Ford & Mees (1987), Franklin (1999), Franklin & Noske (1999), Griffioen & Clarke (2002), Higgins *et al.* (2006a), Hindwood (1967), Johnson (2003), Johnstone & Storr (2004), Mathews (1912a), McCarthy (2006), Mees (1983), Pizzey *et al.* (2007), Robinson (1945), Saunders & Ingram (1995), Schodde & Mason (1999), Schodde & Tidemann (1990), Sedgwick (1947), Sibley & Ahlquist (1990), Sibley & Monroe (1990), Simpson & Day (2004), Storr (1991), Watts (2002).



3. Black-backed Butcherbird

Cracticus mentalis

French: Cassican à dos noir **Spanish**: Verdugo Dorsinegro
German: Schwarzrücken-Metzgervogel
Other common names: White-throated Butcherbird

Taxonomy. *Cracticus mentalis* Salvadori and D'Albertis, 1876. Nicura, south-east New Guinea.
This species and *C. torquatus*, which form a superspecies, have sometimes been placed in a separate genus, *Bulestes*. Two subspecies recognized.

Subspecies and Distribution.
C. m. mentalis Salvadori & D'Albertis, 1876 – S New Guinea in S Trans-Fly region (Merauke E to Balimo) and SE peninsula (Hall Sound E to Kupiano and inland to Sogeri Plateau).
C. m. kempi Mathews, 1912 – Cape York Peninsula, in NE Australia.

Descriptive notes. 25–28 cm; c. 74–100 g. Small white-throated pied butcherbird with hook-tipped strong bill. Nominate race has top and side of head and neck black, sharply demarcated white chin and throat, some black on chin at base of bill; black upperparts separated from black of head by white collar (broken in centre of upper mantle), rump grey; tail black with white tip; upperwing black, much white on scapulars and innermost secondaries, forming a long white band on folded wing, largely white primary coverts and some white at base of primaries together forming a patch on outer wing (seen from above in flight, black area of back separated from black and white outer wing by wide white band); entire underside white; iris brown; bill pale blue-grey with dark tip; legs black. Sexes similar. Juvenile has plumage pattern similar to that of adult, but black areas are dark brown, hood and mantle with buff streaks, underparts brown-tinged; immature similar to adult, but black areas duller, tinged brown, and some juvenile plumage in wings and tail. Race *kempi* smaller than nominate, with shorter wing, tail and bill, and narrower black region on back. Voice. Not well known. Song described as unhurried phrases of long and short, mellow ringing notes at low and medium pitches, interspersed with disyllabic yodels and croaks, somewhat similar to jumbled rollicking yodel of *C. torquatus* and *C. cassicus* but more languid, and unlike fluting song of *C. nigrogularis*; said to be an accomplished mimic. May sing antiphonal duets. Other vocalizations include explosive, rapidly repeated loud calls, "kya, kya, kya".

Habitat. Tropical savanna woodlands and open forest, generally dominated by eucalypts (*Eucalyptus*), also in paperbark (*Melaleuca*) woodland; prefers short grassy understorey. Occurs also in plantations, gardens and rural towns. In New Guinea, found in lowlands and foothills, to 600 m (on Sogeri Plateau).

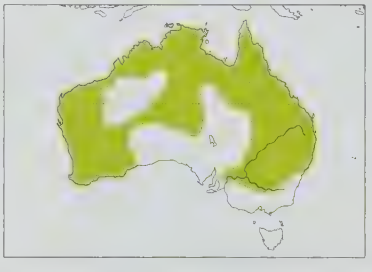
Food and Feeding. Chiefly insects, with small vertebrates (e.g. lizards), some seeds. In New Guinea, recorded as killing a Sacred Kingfisher (*Todiramphus sanctus*) and attempting to take fledgling Willie Wagtails (*Rhipidura leucophrys*). Feeds by pouncing and snatching, often after perching motionless for long period; forages also by moving slowly through canopy, gleaning and snatching. Few observations of feeding in Australia.

Breeding. Not well known; most information from New Guinea (nominate race). Territorial; present in territory all year. Laying Aug–Apr, from middle of dry season to middle of wet season, with most nests Oct–Dec; sometimes two broods. Nest built by female alone, a shallow bowl of sticks, lined with pliable stems of creepers and rootlets, placed usually 10–20 m above ground, sometimes much higher, in fork of tree. Clutch 2–3 eggs, usually 3, greyish-brown, spotted and blotched with reddish-brown in irregular ring at larger end, c. 29 × 22 mm; incubation probably by female alone, fed on nest by male, period c. 3 weeks; chicks fed by both parents, nestling period reported as c. 2 weeks; parents defend nest very aggressively.

Movements. Sedentary.

Status and Conservation. Not globally threatened. Rather uncommon to locally common, and restricted in distribution. The common butcherbird of Port Moresby, in SE New Guinea. Reported density near Port Moresby 2·5 birds/10 ha. Can co-exist with man in rural towns and cattle stations in Australia and plantations and gardens in New Guinea. Savanna habitat in Australia now subject to frequent fires, causing habitat change; few new young trees survive to replace old ones, and this species' preferred low grassy understorey is replaced with either tall grass or woody weeds.

Bibliography. Amadon (1951), Barnard (1911), Barrett *et al.* (2003), Beehler *et al.* (1986), Bell (1970c), Beruldsen (2004), Blakers *et al.* (1984), Christidis & Boles (2008), Coates (1990), Coates & Peckover (2001), Halliday (1987), Higgins *et al.* (2006a), Mayr & Rand (1937), Mees (1982), Pizzey *et al.* (2007), Rand (1942a), Rand & Gilliard (1967), Schodde & Mason (1999), Simpson & Day (2004), Storr (1953), Tubb (1945), White (1911, 1922).



4. Pied Butcherbird

Cracticus nigrogularis

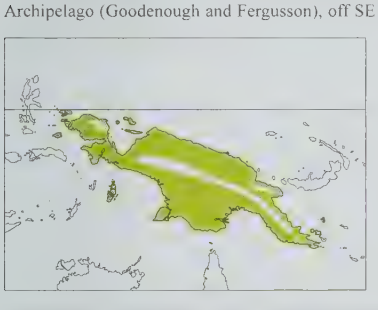
French: Cassican à gorge noire **Spanish**: Verdugo Gorjinegro
German: Schwarzkehl-Metzgervogel
Other common names: Black-throated Butcherbird, (Black-throated) Crow-shrike

Taxonomy. *Vanga nigrogularis* Gould, 1837, New South Wales, Australia.
Forms a superspecies with *C. cassicus* and *C. louisiadensis*. Races intergrade in N Queensland (SC Cape York Peninsula S to upper Georgina R and Diamantina R). Geographical variation partly clinal in W (race *picatus*), with gradual decrease in size from S to N; birds from W & C Australia sometimes recognized as race *kalgoorli* (described from Kalgoorlie, in S Western Australia), but probably part of this cline. Two subspecies recognized.

Subspecies and Distribution.
C. n. picatus Gould, 1848 – N & W Australia E to NW Queensland, S (except in main desert areas) to S Western Australia and NW South Australia.
C. n. nigrogularis (Gould, 1837) – E Australia from N, C & E Queensland S to E South Australia and N Victoria (Murray R).

Descriptive notes. 28–32 cm; 105–159 g. Fairly large butcherbird with strongly hook-tipped robust bill. Nominate race has black head, neck and upper breast forming distinctive hood, sharply divided from white collar and underbody; moderately broad dull white collar between hindneck and black "saddle", black grading into pale grey band on rump, adjoining broad white band on uppertail-coverts; tail black with broad white tip (above and below), white widest at edges; upperwing black, broad white band from point of shoulder (in flight, shows as white band between black back and black outer half of wing), white on innermost secondaries, inner greater coverts black, central ones white (or black and white), outer ones black, often with small white central tip, central median coverts white, outer ones black and white, small white patch on primaries at leading edge of outer wing; iris reddish-brown or dark brown; bill pale blue-grey, distal third black; legs dark grey. Female is similar to adult male, or differs in having head and saddle duller black or blackish-brown, collar narrower and tinged grey, smaller white patch on primaries (differences slight, most obvious if sexes seen together). Juvenile is similar to adult in plumage pattern but browner, with paler eyebrow, no collar, upper breast buff, underparts dirty off-white, bill brownish; immature brownish or buff where adult black, similar to juvenile, beginning to show signs of pale collar at sides of buff bib, underparts clean white, basal half of bill progressively more bluish-grey. Race *picatus* differs from nominate in having much broader, bright white collar and rump, narrow black area on back and little grey on rump, female with broad dull white collar, bill relatively longer than nominate, also S populations much larger than nominate. Voice. The most beautiful song within family of accomplished singers. Three main song types: Territorial or Day Song, heard all year, throughout day, as solos, antiphonal duets and choruses, a slow progression of extended flute-like notes, repeated, sometimes changing in pitch with either sharp break or sliding change (as if a flute-player were improvising slowly almost at random), in antiphonal duet each bird sings a series of notes (the two individuals at different pitches); Breeding Song, probably only by male, in breeding season, at daybreak and at night, in short bouts of 6–7 seconds over 10–20 minutes; Whisper Song (or Subsong) may occur in long bouts, up to 45 minutes, and accomplished mimicry of many other birds and other sounds may be included. Also gives variety of alarm calls, said to differ according to the type of threat.

Habitat. Open forests and woodlands, mainly eucalypts (*Eucalyptus*) or *Acacia*, with open shrubby or grassy understorey; also shrubland with some trees, and in N mainly in riverine habitats with riparian forests of paperbark (*Melaleuca*), casuarina (*Casuarina*), eucalypts, pandanus (*Pandanus*) and other trees. Also in modified habitats, farmlands, parks and gardens and playing fields with open grassy areas and mature trees.



Food and Feeding. Invertebrates, mainly insects; also small vertebrates; some seeds, fruit and nectar. No detailed studies of feeding behaviour. Forages largely on ground, pouncing from vantage point in tree or other elevated perch; also sallies from perch to chase flying insects. Wedges items into crevice or on to spike (such as twig or barbed wire) while dismembering it; may also cache food in such places.
Breeding. Laying in Aug–Dec (mostly Sept–Oct), occasionally also at other times, especially in more arid areas with unseasonal rainfall. Normally in group of 3–15 individuals (most frequently six), those other than breeding pair generally being young of previous years, most groups having only one breeding female (in a few cases a second female attempts to breed, but rarely successful); lives all year in territory of 13–22 ha, defended by all group-members; evidence of extra-group matings, and intra-group brood parasitism whereby female other than nest-owner lays in nest. Nest built by female, a deep, untidy open bowl of twigs and sticks, lined with rootlets, strips of bark and grass, fur and feathers, external dimensions 20–30 cm wide × 6–14 cm deep, internally 10·5–12·5 × 4–6·5 cm, usually 3–15 m above ground in vertical fork of tree towards outer edge of canopy and well shaded by foliage above, trees used dependent on habitat, include eucalypt, *Corymbia*, *Acacia*, casuarina, *Grevillea* and *Bauhinia*; new nest built for replacement or repeat clutch. Clutch 2–4 eggs, variable in colour, olive to brown, buff, grey or green, spots or blotches of brown, reddish-brown, blackish-brown, mixed with black dots, concentrated at larger end, 33 × 24 mm (nominate), 31 × 22 mm (*picatus*); incubation by female alone, period c. 19–21 days; chicks brooded by female alone, fed by female and some or all of other group-members, nestling period c. 30 days; fledglings fed by group-members for at least one month, many remain with group for several years, some disperse after about two years and join other groups. Records of brood parasitism by Pallid Cuckoo (*Cuculus pallidus*) and Channel-billed Cuckoo (*Scythrops novaehollandiae*).
Movements. Sedentary.
Status and Conservation. Not globally threatened. Locally common; rare in arid SW corner of Queensland and in NW New South Wales. In some areas, e.g. near Darwin (N Northern Territory), numbers have declined because of urban expansion. In SW Australia, has extended its range following clearance of forest for agriculture. Can co-exist with man near farms and in suburban areas with mature trees and extensive parks and gardens. Often becomes very tame and is fed and encouraged by residents, in part for the sake of its superb song.
Bibliography. Amadon (1951, 1962c), Anon. (1926), Barrett *et al.* (2003), Beruldsen (2004), Blakers *et al.* (1984), Brooker & Brooker (1989), Christidis & Boles (2008), Courtney & Marchant (1971), Donato & Potts (2004a), Franklin (1999), Hall (1974), Higgins *et al.* (2006a), Johnstone & Storr (2004), Jurisevic & Sanderson (1994), Lumsdaine (1996), McCarthy (2006), Mees (1961, 1964b), Pizzey *et al.* (2007), Plowright (2006), Robinson (1994), Saunders & Ingram (1995), Schodde & Mason (1999), Simpson & Day (2004), Slater *et al.* (2003), Storr (1991).

5. Hooded Butcherbird

Cracticus cassicus

French: Cassican à tête noire **German**: Papuametzgervogel **Spanish**: Verdugo Cabecinegro
Other common names: Black-and-white/Black-headed/Black-backed(!)/Pied Butcherbird(!)

Taxonomy. *Ramphastos cassicus* Boddaert, 1783, New Guinea.
Forms a superspecies with *C. nigrogularis* and *C. louisiadensis*; possibly conspecific with latter. Two subspecies recognized.
Subspecies and Distribution.
C. c. cassicus (Boddaert, 1783) – West Papuan Is, New Guinea and satellite islands (except those off SE coast), and Aru Is.
C. c. hercules Mayr, 1940 – Trobriand Is (Kailuna, Kiriwana and Kitawa) and D'Entrecasteaux Archipelago (Goodenough and Fergusson), off SE New Guinea.

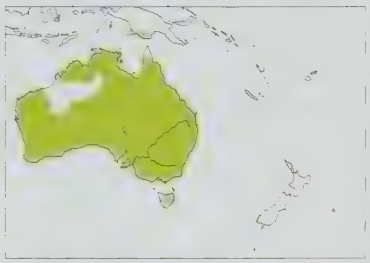
Descriptive notes. 32–35 cm; 130–155 g. Rather large butcherbird with black head and throat, and strong bill slightly hooked at tip. Nominate race has head and neck down to upper breast black; mantle and back variable, black, mottled or largely white depending on amount of white edging on black feathers (possibly varies with age), rump and uppertail-coverts white; upperwing black, conspicuous white patch formed by variable amount of white on upperwing-coverts and tertials; tail black, outer rectrices with white tips; underparts below upper breast white; iris dark brown or black; bill pale bluish-grey or milky blue, black tip; legs black. Sexes similar in plumage, male larger than female. Juvenile has black feathers of head, breast, back and wing-coverts tipped brown; bill grey. Race *hercules* is similar in plumage to nominate, but larger (wing 185 mm; nominate 170 mm). Voice. One of finest singers in family, but not studied in detail. Song described as loud jumble of bugling and yodelling, containing bell-like notes and liquid and rollicking phrases, with hoarse croaks, gurgles and musical notes, these varied phrases combined into songs which last for up to 6 seconds; bout of singing can last for several minutes, and include repetition of several different songs; song can include mimicry of other birds, including birds-of-paradise (Paradisaeidae), nominate race of Little Shrike-thrush (*Colluricincla megarhyncha*), Rusty Pitohui (*Pitohui ferrugineus*), Spangled Drongo (*Dicrurus bracteatus*) and Helmeted Friarbird (*Philemon buceroides*).
Habitat. Lowland forest and dense second growth, often near human habitation, to c. 650 m. Occurs in openings in rainforest, forest edge and gardens.
Food and Feeding. Feeds on large insects, larvae, spiders (Araneae) and fruit; also takes small vertebrates, including birds. Forages mostly in crowns of trees bordering open spaces. Usually in pairs or in small groups.
Breeding. Not well known. Many single records of nests suggest that breeding may occur at any time, with preference for late dry season. Reported that several pairs may nest close together quite amicably; one report of several adults feeding one nestling. Nest a bulky bowl of sticks and twigs, built 9–25 m above ground towards end of strong lateral branch of tree. Clutch 2–3 eggs, pale olive, tinged with brown, blue or green, with faint blotches of brown and some darker brown spots at larger end, c. 33 × 25 mm. No other information.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Widespread and common. Although present throughout most of New Guinea, and able to live in areas of human habitation, extensive logging of lowland rainforest is likely to lead to decreases in size and extent of populations. Race *hercules* restricted to mostly very small islands, has tiny overall range; also likely to be suffering the effects of logging.
Bibliography. Beehler *et al.* (1986), Bell (1970c), Coates (1990), Coates & Peckover (2001), Diamond (1972), Mayr (1940), Mayr & Rand (1937), Peckover & Filewood (1976), Rand (1942a, 1942b), Rand & Gilliard (1967), Ripley (1964), Schodde & Hitchcock (1968), Tubb (1945), Watson *et al.* (1962).

6. Tagula Butcherbird

Cracticus louisiadensis

French: Cassican de Tagula **German**: Louisiadenmetzgervogel **Spanish**: Verdugo de Tagula
Other common names: Louisiade/Sudest/White-rumped Butcherbird

Taxonomy. *Cracticus louisiadensis* Tristram, 1889, Sudest Island = Tagula Island, Louisiade Archipelago, New Guinea.
Forms a superspecies with *C. nigrogularis* and *C. cassicus*; possibly conspecific with latter. Monotypic.
Distribution. Tagula I, in Louisiade Archipelago, off SE New Guinea.



Descriptive notes. 27–30 cm. Rather large, dark butcherbird with powerful hook-tipped bill. Plumage is all black, except for white spots at sides of breast, white stripe on inner wing (formed by two partly white tertials), white uppertail-coverts, large white spots at tips of outer tail feathers, white lower abdomen, undertail-coverts and inner wing-coverts; iris dark brown; bill grey-blue, tip black; legs black. Sexes similar in plumage, male larger than female. Juvenile undescribed. Voice. No information.
Habitat. Forest and forest edge.
Food and Feeding. No information.
Breeding. No information.
Movements. Probably sedentary.
Status and Conservation. Data-deficient. Restricted-range species: present in Louisiade Archipelago EBA. Very poorly known. Ten were seen on the only fairly recent visit to island, during a ten-day trek from N coast up to Mt Riu in 1992. Forest of E two-thirds of Tagula (total area c. 866 km²) already degraded, and logging presumably remains a threat to all lowland forest. Population and ecology of present species virtually unknown, but thought likely to be similar to those of *C. cassicus*, a common and adaptable species occurring in all forest-edge habitats (including gardens and savanna). No current conservation measures known; proposed measures include surveys of potentially suitable habitat on Tagula and study of the species' ecological requirements, tolerance of habitat degradation and threats. Forests E from Mt Riu very important for survival of both the present species and the endemic Tagula Honeyeater (*Meliphaga vicina*).
Bibliography. Anon. (2008n), Beehler (1993), Beehler *et al.* (1986), Butchart & Stattersfield (2004), Coates (1990), Peckover & Filewood (1976), Rand & Gilliard (1967), Stattersfield & Capper (2000).

7. Australian Magpie

Cracticus tibicen

French: Cassican flûteur **German**: Flötenvogel **Spanish**: Verdugo Flautista
Other common names: Australasian Magpie, Piping Crow-shrike; Black-backed Magpie (*longirostris*, *terraereginae*, *eylandtensis*, *tibicen*); New Guinea Magpie (*papuanus*); Western Magpie, Varied Crow-shrike (*dorsalis*); White-backed Magpie/Crow-shrike (*tyrannicus*, *telonocua*, *hypoleucus*)

Taxonomy. *C*[*oracias*] *tibicen* Latham, 1801, New South Wales, Australia.
Often placed in a monotypic genus, *Gymnorhina*, partly on basis of adaptations for terrestrial foraging; inclusion in present genus supported by molecular studies. Races fall into three groups, the "black-backed group" (*longirostris*, *terraereginae*, *eylandtensis* and nominate) of NW, N & E Australia, the "white-backed group" (*tyrannicus*, *telonocua* and *hypoleucus*) of SE Australia and Tasmania, and the "western or varied group" (*dorsalis*) of SW Australia, the last possibly including *papuanus* of New Guinea; groups were formerly treated as representing three distinct species, but little congruence found between morphological variation and genetic variation. Races intergrade extensively: *eylandtensis* intergrades with *terraereginae* in C & S Northern Territory and NW Queensland, and latter race intergrades with all others (*tibicen*, *tyrannicus*, *telonocua*) where ranges meet; in SC Australia confusing intergradation involving *telonocua*, *terraereginae*, *tyrannicus* and *eylandtensis*; and *dorsalis* intergrades with *longirostris* over broad region of S Western Australia from Shark Bay E to SW edge of Great Victoria Desert. Proposed race *finki* (described from Horseshoe Bend, on Finke R, in Northern Territory) refers to an intergrading population between *eylandtensis* and presumably *terraereginae*; *leuconotus* (from South Australia) likewise relates to an intergrade. With so much complex intergradation and often only differences in size between races, recognition of so many races perhaps inappropriate; further study of differences between populations, including molecular-genetic analyses, is required. Nine subspecies provisionally recognized.
Subspecies and Distribution.
C. t. papuanus (Bangs & J. L. Peters, 1926) – S New Guinea (S Trans-Fly region from Princess Marianne Strait E to Oriomo R).
C. t. eylandtensis (H. L. White, 1922) – N Western Australia (Kimberley region) E through Northern Territory (including Groote Eylandt) to NW Queensland.
C. t. longirostris (Milligan, 1903) – Western Australia from Dampier Land S at least to Pilbara region (inland extent uncertain).
C. t. dorsalis (A. J. Campbell, 1895) – SW Western Australia (E almost to Eucla, S of Great Victoria Desert).
C. t. telonocua (Schodde & Mason, 1999) – S Northern Territory and South Australia.
C. t. terraereginae Mathews, 1912 – most of Queensland (except Gulf region and extreme SE) and New South Wales W of Great Dividing Range (including most of Murray–Darling basin) S to E South Australia (S, E of L Eyre, to Murray R) and N Victoria.
C. t. tibicen (Latham, 1801) – coastal SE Australia.
C. t. tyrannicus (Schodde & Mason, 1999) – N & E Victoria (mostly E of Great Dividing Range).
C. t. hypoleucus Gould, 1837 – E half of Tasmania.
Race *tyrannicus* introduced on King I (in W Bass Strait) and New Zealand (North I and South I); *hypoleucus* introduced on Flinders I (in E Bass Strait); nominate and *hypoleucus* (and possibly *tyrannicus*) introduced in Fiji.
Descriptive notes. 37–43 cm; c. 210–360 g (races combined), 212–325 g (*terraereginae*), 265–360 g (*dorsalis*), c. 300 g (nominate). Large black-and-white cracticid with long, heavy bill slightly hooked at tip, tail relatively short and square-ended, thighs feathered, long legs with large strong feet; wings long, broad at base, with pointed tip. Male nominate race is mostly glossy black, with

large areas of bright white on nape and back of head, rump, and most of uppertail except for black band c. 5 cm wide at tip; white vent and undertail-coverts; white secondary coverts forming large white shoulder patch, white primary coverts forming smaller patch at leading edge of folded wing; iris red-brown; bill bluish-white with black tip, area of white becoming more extensive with age; legs black. Female is like male, but white on back of head merges to light grey on collar and rump. Juvenile is like female in pattern, but plumage loose and fluffy, main colour mottled blackish-brown with buff or greyish-brown barring, smaller white areas in wing, flight-feathers brownish, has buff eyebrow, bill shorter and grey-black, pinkish gape, iris brown, legs grey-black; immature variable, some like adult female but less glossy, others more like juvenile with buff or greyish-brown streaking and barring and with pale fluffy plumage on belly, retains juvenile wings and tail and, sometimes, buff eyebrow, quickly loses pink gape, and bill may develop some white at base during first year, iris dark brown; in second year similar to adult female, but bill still not fully white. Race *terraereginae* is almost identical to nominate, but smaller, with shorter wing, tail and tarsus, and relatively longer bill, black tail tip narrower, some feathers on thighs may have white tips; *longirostris* has longer, more slender bill than previous, but plumage very similar except for white feathers on thighs; *eylandtensis* is small, with long slender bill, basic pattern similar to nominate except that black band across back of male much narrower (more white on back), thighs white or black; *tyrannicus* is very large with relatively short bill, male similar in pattern to nominate except that whole back is white, black tail tip very broad, thighs black, female and second-year immature like adult male but back milky grey with black streaks and white feather edging, back of head white, juvenile like that of nominate but back brownish-grey, barred black, with buff mottling; *hypoleucus* is very similar to last but smaller, with shorter wing, tail, bill and tarsus, black thighs, narrower tailband; *telonocua* is very similar to *tyrannicus* but smaller, and black tip to tail narrower, female has whitish patch on back of head and hindneck less extensive; *dorsalis* male is similar to preceding three races, but smaller than *tyrannicus*, with short black tip on tail, female wings, tail and underparts as for male, back of head and hindneck white, often blurred or scaled with grey, back black with narrow white feather fringes (giving scalloped effect), amount of white on back variable (little sign of white on some, on others white fringes broad and scalloping very obvious), juvenile similar to nominate except for buff fringes on back (scalloped appearance), first-year bird has back feathers dull black with variable white fringes, underside mottled grey, feathers darker-centred with paler fringe of light grey with buff tinge, especially on throat and chin (can be quite rufous), second-year has back black, variously scalloped white, underparts mottled, somewhat blacker than first-year, some have glossy black throat and upper breast, fully adult in fourth or fifth year; *papuanus* has dorsal pattern similar to previous, male white-backed (sometimes some black on mantle), female black-backed with white-edged feathers and grey rump, both with white feathers on thighs, juvenile more or less as nominate but brown tips on black back feathers, immature and subadult like adult female. Voice. Said to vary with locality and race. One of finest, best-known songbirds in Australia, with varied and complex repertoire. Well-known Carolling a series of loud, melodious flute-like yodelling calls, usually by pair or group, started by a senior male or female, others (including immatures) joining in, often performed on ground; used for advertising and defending territory, in border disputes or just as advertisement; given also when significant food source encountered. Warble Song (Subsong) by single individual from high but well-concealed songperch, a soft warbling incorporating mimicry, continuing for long periods (up to one hour), containing elements heard in Carolling but at lower intensity. Other warbling songs are Dusk Song, Dawn Song and Moonlight Song, the last two heard early morning and on moonlight nights before and during breeding season, singers probably males; gives many repetitions of a short phrase, for long periods. Wide range of alarm calls based on harsh "ka" sound at various intensities. Rally Call a loud descending whistle of two or three syllables, "hoo hoo hooooo", audible over long distance, serves to summon group-members to boundary dispute or to attack by predator. Nestlings and fledglings give loud insistent begging call at sight of adult with food.

Habitat. Open habitats with low ground cover such as grasses. Originally inhabited open eucalypt (*Eucalyptus*) woodlands, now found also in farmland and urban areas that provide open areas of grassland with mature trees nearby. Occurs in remnant vegetation patches, homestead trees, shelter-belts and windbreaks, along roads and rivers, also on edges of forest or woodland adjacent to farmland; in urban areas common in large parks, vegetation reserves and older suburbs with large gardens, lawns and well-grown trees. Not common in dense forests or pine (*Pinus*) plantations, except at edges and where large internal open areas present. Introduced population in New Zealand exhibits preference for open farmland with scattered trees.

Food and Feeding. Invertebrates, especially terrestrial insects; also small vertebrates, including frogs, lizards, small birds and small mammals. Will eat carrion if available, or take insects present on a carcass. Forages in groups, members of which spread out over quite a large area, rather than feeding close together. Feeds mainly on ground, by gleaning surface or probing with long bill; turns over litter, leaves and stones, also stands at base of trees and probes into loose bark on trunks. Walks slowly across foraging area, looking for prey on surface; can also hear subsurface prey, and probes for beetles (Coleoptera) in soil following auditory cues. Smaller prey consumed immediately; larger items held, shaken and bashed against ground, or may be held with feet and torn apart. Seen to cache food.

Breeding. Eggs recorded Jun–Mar (most laid Aug–Dec) in Australia, timing can vary with location and season, especially in N and inland areas with irregular rainfall; in New Zealand (introduced) eggs recorded Jul–Nov; female occasionally attempts second brood when group available to look after first brood. Breeds as pair or in group, maintaining territory throughout year; in urban area single territory can occupy several gardens, and in natural vegetation or farmland territory size varies with quality, c. 4–10 ha. Breeding system varries geographically (main difference is group size); in N & E Australia (races *terraereginae* and nominate best known) breeding unit a pair, and group includes only pair and immatures up to about one year; in S Australia (*tyrannicus* and *dorsalis* best known) group size larger, not all young disperse, breeding group includes multiple adult males, more than one adult breeding female, non-breeding adult males and females and older immatures; co-operative breeding recorded in some populations; some females in multi-female groups build nest and rear chicks with no assistance from other group-members until nestlings fledge. Evidence of high level of extra-group copulation; in urban population of *dorsalis*, more than 80% of nestlings were sired by extra-group males. Nest built by female alone, over period of 2–3 weeks, an untidy flattened bowl of sticks and twigs, with (in farmland and urban areas) fencing wire and coloured electrical cable often incorporated, inner cup lined with grass, hair, wool and shredded bark, external diameter c. 30–50 cm and depth 10–20 cm, internal diameter 13–16 cm and depth 5–10 cm; usually in vertical or horizontal fork in tall tree, in outer canopy of live tree, 2–20 m (average c. 10 m) above ground, eucalypt preferred if available, but in urban areas exotic trees also used; female frequently nests in same tree each year or in nearby one; in multi-female groups individual females may nest in adjacent trees. Clutch usually 3–4 eggs, blue or green with red-brown spots, blotches or streaks, average 38 × 27 mm; may lay replacement clutch if first nest attempt fails (unless failure very late in season); incubation by female alone, period c. 21 days; chicks brooded by female, fed by female, her male partner, and in some cases other group-members, nestling period c. 30 days; young out of nest initially unable to fly, spend time on ground, in low cover or in lower branches of tree, into which they clamber by hopping, can fly after 2–3 weeks, mother provides most food for first month, then young begin to forage independently, but continue to beg from mother or other adult (and may receive food occasionally) for up to six months, although largely independent by two months; in large groups fledglings may be fed by other group-members, in addition to mother and her male partner; some groups defend nest and fledglings very aggressively by diving at intruders, especially during late nestling stage; in small groups (only one pair breeding) young remain until dispersing at start of next breeding season, in larger groups young remain longer and many do not disperse; female may disperse when reaching sexual maturity at 2 years or may remain and breed in natal group; males may disperse in third year or some time later, but many do not. Nests parasitized by Channel-billed Cuckoo (*Scythrops novaehollandiae*), sometimes by Common Koel (*Eudynamys scolopacea*). Success varies with year and location, overall c. 70% of nests produce fledged young and pairs produce c. 1 fledgling per nest; in larger groups in Western Australia over ten years, groups with 1–5 breeding females produced 1·7 fledglings per group; main causes of failure are predation by crows (*Corvus*) and bad weather, especially rain and high winds when nests contain large nestlings.

Movements. Primarily sedentary. Non-breeding flocks formed by some races are more mobile within local areas, roosting several kilometres from feeding locations. Occasional long-distance movements of ringed individuals recorded, but no indication that such movement is frequent. Most dispersal only between local territorial groups, e.g. young male or female moving to nearby group that has vacancy. Race *hypoleucus* of drier E half of Tasmania, occasionally occurs in forests of NW and SW.

Status and Conservation. Not globally threatened. Generally common and widespread. Locally abundant in E Australia; less numerous in N & C parts. Fairly common in New Guinea. Has benefited from creation of more open grassy habitat by clearance of native vegetation for farmland and urban expansion. Able to thrive in towns and cities, where tall trees for nesting and roosting and grassy expanses for foraging meet its needs; moreover, most pairs or groups in urban areas are fed by at least one of the human residents whose garden they visit, and this food helps to maintain breeding success in poor seasons. No major threats to Australian races; in New Guinea, *papuanus* has very restricted range. Does not occur in rainforest habitat subject to logging, but could suffer from effects of fire, hunting, and overpopulation by humans.

Genus *STREPERA* Lesson, 1831

8. **Pied Currawong**

Strepera graculina

French: Grand Réveilleur **German**: Weißbürzel-Würgerkrähe **Spanish**: Verdugo Pío
Other common names: Scrub Currawong, (Pied) Bell-magpie, Pied Crow-shrike, Black/Mountain Magpie

Taxonomy. *Corvus Graculinus* Shaw, 1790, Sydney region, New South Wales, Australia.
Forms a superspecies with *S. fuliginosa*; sometimes considered conspecific, but differs in vocalizations. Geographical variation on mainland to some extent clinal, with general increase in size, decrease in bill size, greyer (less black) plumage, and decreasing white in wing and tail from N to S. Race *nebulosa* intergrades with nominate in N (from Mudgee S to Eden, in SE New South Wales) and with *ashbyi* in SW (W Victoria), possibly completely overlapping latter race (especially in Grampian Range), and continued existence of "pure" *ashbyi* individuals uncertain. Described race *grampianensis* (from Grampian Range, in W Victoria) based on juvenile specimen from intergrade zone; *riordani* (from near Geelong, in W Victoria) likewise an intergrade form. Six subspecies currently recognized.
Subspecies and Distribution.
S. g. magnirostris H. L. White, 1923 – E Cape York Peninsula S to about Laura (N Queensland), in NE Australia.
S. g. robinsoni Mathews, 1912 – coastal ranges of N Queensland on E slopes of Great Dividing Range (from Cooktown S to Ingham).
S. g. graculina (Shaw, 1790) – E Queensland (from Clarke Range, just S of Bowen) S, inland to W slopes of Great Dividing Range, to Blue Mts and SE New South Wales.
S. g. nebulosa Schodde & Mason, 1999 – SE New South Wales tablelands and E Victoria.
S. g. ashbyi Mathews, 1913 – S half of W Victoria (especially in Grampian Range) W of line between Ballarat and Cape Otway.
S. g. crissalis Sharpe, 1877 – Lord Howe I and offshore islands (including Admiralty Group).
Descriptive notes. 44–50 cm; male 259–385 g, female 243–324 g. Large, black passerine, like a *Corvus* crow but more slender, with long legs, long, heavy, slightly hook-tipped pointed bill forming almost straight line with flattened head top; long tail with rounded tip, long wings rather narrow,

with prominent "fingers". Nominate race is largely black (plumage appears browner when worn); prominent large white patch on wing formed by white bases of most primaries (patch crescent-shaped in flight), conspicuous white rump, broad base and tip of tail (above and below) and undertail-coverts; iris bright yellow; bill black; legs dark grey or black. Sexes similar in plumage, male slightly larger than female. Juvenile is similar to adult, but black areas brown, darker on back and wings, buff tips of wing-coverts forming wingbar, smaller white primary patch, lighter on belly with some streaking, bill with pale tip, gape yellow, iris dark brown; immature darker than juvenile, mainly blackish above (some with brown tinge), browner below (may have some streaking), buff wingbar contrasts with brown wings, primary patch small as on juvenile, yellow gape persists for about six months, iris yellow. Race *magnirostris* is of about same size as nominate, has short tail and massive bill, white wing patch larger and white tail base more extensive than nominate, narrow white tail tip; *robinsoni* is smaller than nominate, with short tail and short bill, white wing patch larger and white tail base more extensive, narrow white tail tip; *nebulosa* is larger than nominate, with long tail and short bill, back sooty black, sooty below, slate-grey belly, white wing patch and white tail base less extensive than nominate, broad white tail tip; *ashbyi* is similar to nominate in size, but with longer tail and shorter bill, back dark slate-grey, sooty below, slate-grey belly, white wing patch much smaller, white tail base very narrow (concealed by tail-coverts), white tail tip broad; *crissalis* is smaller than nominate, with proportionately long tail and bill, white wing patch small, white tail base and tail tip narrower than nominate. Voice. Most commonly heard call a loud ringing "curra-wong, curra-wong" (the Currawong Call), of two or three syllables, may vary with region or race, e.g. as "currah-currah-currong"; given in flight, when perched, advertising territory, chasing intruder, in presence of predator, and in communication with mate. Also harsh scolding alarm, and soft chittering calls in solicitation preceding copulation; food-begging call by female on nest similar to that of juvenile. Other calls made occasionally, but context not clear. Breeding Song different from other currawong sounds, heard only in breeding season, rendered as "ow-ooo, ow-ooo" or "kwee, koo-wee", repeated in phrases two or three times, and the sequence repeated in a series of short bouts before sunrise.

Habitat. Mainly eucalypt (*Eucalyptus*) forest and woodland; prefers older forest for breeding. N races also in rainforest; on Lord Howe I (race *crissalis*) in tall palm forest or rainforest. Widespread in E & SE mainland Australia in settled areas, farmland, country towns and parts of cities with parks, gardens and remnant areas of native vegetation.

Food and Feeding. Omnivorous; eats wide variety of fruit, seeds, insects and small vertebrates; also snails (Gastropoda). Most food collected by gleaning on ground and among foliage for insects and fruit. In winter, large flocks congregate at native and introduced trees and shrubs, feeding on such fruit such as lilly pilly (*Acmena smithii*), Moreton Bay fig (*Ficus macrophylla*) and various species of *Pyracantha* and *Ligustrum*. Observed to attack free-flying small birds, and to take eggs and chicks from nests, particularly when feeding own nestlings. Larger prey thrashed against hard object before eaten or fed to young; snail shells broken against rocks and flesh removed.

Breeding. Not well known. Season generally Aug–Dec in SE Australia. Breeds as pair, in territory established and maintained during breeding season. Most nest-building by female, over period of 10–14 days, with some help from male, nest an untidy outer framework 28–37 cm in diameter, of sticks and twigs, neat inner cup 15 cm in diameter and c. 5 cm deep, lined with dry grass, strips of fibrous bark and fine roots, placed in fork near end of outer branch, usually of tall eucalypt, in N Queensland sometimes of paperbark (*Melaleuca leucodendra*), in suburban areas introduced trees, especially pines (*Pinus*) used; often same tree used in successive years. Clutch usually 3–4 eggs, light brown with blotches of darker brown, mean 42–29 mm; incubation by female, may be fed on nest by male, period c. 21 days; chicks brooded by female only, fed by both sexes, nestlings leave nest for short periods after c. 31 days, fledge 1–2 days later. Nest parasitism by Channel-billed Cuckoo (*Scythrops novaehollandiae*) recorded.

Movements. Not well known. Some altitudinal migration, with post-breeding descent to lowlands E & W of Great Dividing Range, especially by immatures and non-breeding individuals; adults more likely resident. In non-breeding season, nominate race moves farther N & W and *nebulosa* disperses N & NW. In many coastal and lowland areas, small resident populations increased by influx in autumn and winter. Ringing studies revealed some movements of c. 300 km.

Status and Conservation. Not globally threatened. Locally common. Most races secure, except for those on Lord Howe I (*crissalis*) and in W Victoria (*ashbyi*). Race *crissalis* assessed variously as "Endangered" and "Vulnerable"; one population of estimated 80 breeding individuals in 18 km². Race *ashbyi* assessed as "Critically Endangered" on a precautionary basis; may already have been swamped by widespread and expanding race *nebulosa*, and no longer extant as a pure taxon. In some towns where this species was once only a non-breeding winter visitor, it is now resident, sustained by garden plantings, e.g. in Rockhampton (Queensland), Sydney and Armidale (New South Wales), Canberra (Australian Capital Territory) and Geelong (Victoria).

9. Black Currawong

Strepera fuliginosa

French: Réveilleur noir **German**: Tasmanwürgerkrähe **Spanish**: Verdugo Fuliginoso
Other common names: (Black/Sooty) Bell Magpie, Sooty Currawong/Crow-shrike, Black/Mountain Magpie/Jay

Taxonomy. *Coronica fuliginosa* Gould, 1837, Tasmania, Australia.
Forms a superspecies with *S. graculina*; sometimes considered conspecific, but differs in vocalizations. Three subspecies currently recognized.
Subspecies and Distribution.
S. f. colei Mathews, 1916 – King I, in W Bass Strait.
S. f. parvior Schodde & Mason, 1999 – Furneaux Group, in E Bass Strait.
S. f. fuliginosa (Gould, 1837) – Tasmania.

Descriptive notes. c. 50 cm; male 365–457 g, female 327–353 g. Large, dark passerine resembling a *Corvus* crow, with massive bill slightly hooked at tip and pronounced curve on upper mandible, flattened head top; long tail with rounded tip, long broad wings with "fingered" tips. Nominate race is almost entirely black (becomes browner with wear), white area at base of primaries forming white wingbar on underwing (and sometimes visible on upperwing), flight-feathers with white tips (broadest on outer five primaries), tail with rounded white tip; iris bright yellow; bill and legs black. Sexes similar, male larger than female. Juvenile is blackish-brown, streaked on breast, with pale areas of wing and tail off-white, bill greyish-white with pale yellow gape, legs dark grey; iris dull yellow; immature dark brown to black, similar to worn adult, wing and tail pattern as in adult but off-white, retains some juvenile plumage in wings, bill black, pale yellow gape persists into second year, iris yellow. Races differ only in size: *parvior* is smaller than nominate, with proportionately shorter tail; *colei* is smallest, with proportionately shortest tail. Voice. Not well known. Calls described variously as musical "kar-week, kar-week", long drawn-out rolling croak, and incessant chattering scream, possibly all variants of same call. Food-carrying adult gives long flute-like whistle. Soft whistles and croaks between members of pair.

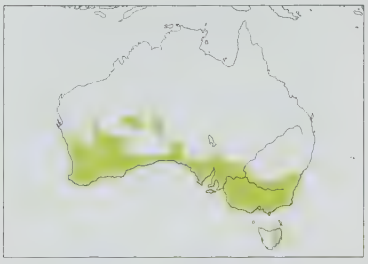
Habitat. In austral summer, inhabits moist mountain forests, especially cool temperate rainforests and wet sclerophyll (*Eucalyptus*) forests; also tableland habitats, e.g. heathlands, moors and sedgelands. In autumn and winter months, at least part of population wanders in flocks to lowland eucalypt forests and woodlands and urban habitats. On islands in Bass Strait lives in drier forested habitats all year, also coastal scrubs and beaches.

Food and Feeding. Mainly insects, and small vertebrates such as lizards, birds and mice; some fruit and seeds. Bass Strait races (*colei* and *parvior*) seen to feed in large numbers among piles of giant kelp (*Macrocystis pyrifera*) on beaches. Usually forages on ground, probing and gleaning and turning over bark and forest litter; will seize small birds in flight. Scavenges at picnic grounds and farmyards. May wedge larger prey in crevice or splintered log and tear off pieces to carry to nest or fledglings. Known to cache food.

Breeding. Little known. Season generally Oct–Dec; nestlings reported in Nov and fledglings in Dec. Breeds as pair. Nest built by both sexes, an untidy outer framework c. 40 cm in diameter, of sticks and twigs, lined with twigs, grass, rootlets and strips of bark, usually placed high in fork of tall forest eucalypt; may refurbish old nest of previous year. Clutch 2–4 eggs, purplish-buff with red-brown and purple blotches, generally at larger end, mean c. 44 × 31 mm; young fed by both parents; strong defence of nest. No other information.

Movements. Not well known. Some descend from cold and snow of upland areas during autumn and winter; others resident. After breeding season, may move in flocks closer to human habitation.

Status and Conservation. Not globally threatened. Restricted-range species: present in Tasmania EBA. Fairly common. King I race (*colei*) assessed as "Vulnerable" in Australia; main threat is clearing of native vegetation for farmland. Species is sometimes regarded as a pest in orchards and around poultry farms.



Bibliography. Amadon (1951, 1962c), Anon. (1926), Barrett *et al.* (2003), Beruldsen (2004), Blakers *et al.* (1984), Christidis & Boles (2008), Fletcher (1918, 1922), Garnett & Crowley (2000), Green (1989), Griffioen & Clarke (2002), Higgins *et al.* (2006a), Kinghorn (1928), Leach (1914), Pizzey *et al.* (2007), Plowright (2006), Ridpath & Moreau (1966), Schodde & Mason (1999), Sharpe (1877), Sibley & Ahlquist (1985a), Sibley & Monroe (1990), Simpson & Day (2004), Slater *et al.* (2003), Watts (2002).

10. Grey Currawong

Strepera versicolor

French: Réveilleur cendré **German**: Rußwürgerkrähe **Spanish**: Verdugo Cenizo
Other common names: Common Currawong, Grey Bell-magpie/Crow-shrike; Brown Currawong (*intermedia*); Black-winged Currawong (*melanoptera* and *halmaturina*); Clinking Currawong (*arguta*)

Taxonomy. *C[orvus] versicolor* Latham, 1801, Sydney region, New South Wales, Australia.
Races very variable in plumage colour and pattern, and for a long time regarded as forming four separate species, one in SE South Australia (*intermedia*), one in mallee and scrublands of SW New South Wales S to Kangaroo I and extreme NW Victoria (*melanoptera* and *halmaturina*), one in Tasmania (*arguta*), and one covering rest of range (*plumbea* and nominate); races, however, intergrade wherever they come into contact with one another, and better treated as representing a single species. Thus, *melanoptera* intergrades with nominate from South Australia–Victoria border E to Grampian Ranges in N and to Cape Otway in S; possible intergradation of *plumbea* with *intermedia* E through Great Victoria Desert uncertain but likely. Proposed race *howei* (described from Kow Plains, in NW) represents an intergrade population; *centralia* (from Everard Ranges, in NW South Australia) indistinguishable from *plumbea*. Six subspecies currently recognized.
Subspecies and Distribution.
S. v. plumbea Gould, 1846 – from SW Western Australia (S from Geraldton) E, discontinuously, to extreme SW Northern Territory (Petermann Ranges) and W South Australia (Musgrave and Everard Ranges, and in Great Victoria Desert).
S. v. intermedia Sharpe, 1877 – South Australia from Ooldea E along coast (S of Nullarbor Plain) to Yorke Peninsula.
S. v. melanoptera Gould, 1846 – SE South Australia (S Flinders Ranges S to Fleurieu Peninsula and Mt Lofty Ranges) E to mallee areas of NW Victoria.
S. v. halmaturina Mathews, 1912 – Kangaroo I, off South Australia.
S. v. versicolor (Latham, 1801) – SE New South Wales (from Hunter R) S, inland to W slopes of Great Dividing Range, to W Victoria (Grampians and, on coast, to Port Phillip Bay).
S. v. arguta Gould, 1846 – E Tasmania (E of line joining Devonport and Hobart).
Descriptive notes. 44–57 cm; 300–500 g. Large, like a raven (*Corvus*) but more slender, with long, heavy, conical bill only slightly hooked at tip and forming almost straight line with flattened head top; long narrow tail with rounded tip, long and broad wings with distinct white-tipped "fingers". Nominate race is mostly mid-grey, with blackish face, forecrown and throat, white undertail-coverts and tail tip; upperwing appears mostly grey, with white tips of flight-feathers, in flight wings blacker and with conspicuous patch formed by white area across bases of flight-feathers (visible from above and below); iris yellow; bill black; legs dark grey or black. Sexes similar, male larger and darker than female. Juvenile is much browner than adult, with body plumage softer and looser, face and throat not so dark, buff streaks and mottling on head, neck and upper chest, white markings

of wing similar to adult, pale fringes on upperwing-coverts (distinct buff wingbar), bill black with pale yellow tip and paler base of lower mandible, gape yellow, iris light brown; immature like adult, but head, neck, body and tail appear browner, may retain some streaking on throat and upper breast, wing as juvenile, gape remains yellow during first year, iris yellow. Races differ mainly in size, bill shape, colour tone of body plumage, width of pale tail tip, and amount of white in wing: *plumbea* is very like nominate, but plumage slightly darker, and bill tends to be slightly deeper with more decurved upper mandible; *intermedia* is smallest race, bill shape like that of nominate, plumage darker than nominate; *melanoptera* is similar in size and bill shape to nominate, but plumage darker (very like preceding race), slightly less white in tail, upperwing mostly blackish, lacks white tips of flight-feathers and white primary patch (sometimes indistinct greyish at bases of inner webs), wing-coverts darker; *halmaturina* is very similar to previous, but slightly darker, sooty-black, with bill longer and less broad, white on tail tip narrow; *arguta* is larger, longer-billed and much darker than nominate, dark sooty-grey, with faint dull grey tips to remiges and little grey at base of tail, also has large white wing patch, and more white on tail tip. VOICE. Best-known call, uttered in flight, "tew-tew" or "kling-kling" (usually described as the "Clinking Call"), typically of two syllables but often three, the third sometimes prolonged or changing in pitch, reminiscent of sound made by a gong or a hammer striking an anvil; can also give in flight a call similar to the "Curra-wong" of *S. graculina*. Also prolonged whistle-like call, likened to sound of a squeaking gate. Other calls described as like a toy trumpet, mewing of cat, growl and cough, but context not known. Food-begging calls by juveniles and by females in breeding season.

Habitat. Found in temperate forest to arid shrubland habitats. Eucalypt (*Eucalyptus*) forests and woodlands; mallee woodlands and shrublands with spinifex (*Triodia*) as understorey; may occur in farmland near forest, and in exotic pine (*Pinus*) plantations.

Food and Feeding. Omnivorous; no detailed studies. Wide variety of insects; also small vertebrates, including lizards, birds and their nestlings, small mammals; also fruit and seeds. Forages mainly on ground, but also above ground in fruiting shrubs or trees. Uses long strong bill to probe in litter on ground, in crevices and under bark, to turn stones and to split rotting wood. Known to be a nest predator.

Breeding. Little known. Eggs in Jul–Dec, varying with locality; fledglings to mid-Feb. Breeds as pair, in territory maintained all year. Nest built mostly by female, with some assistance from male, a shallow untidy bowl c. 36–46 cm in diameter, made with sticks, inner cup of grass, plant fibre, fine twigs and rootlets, usually placed high in tall eucalypt, often in fork at end of long branch in outer canopy. Clutch usually 2–3 eggs, colour variable, pinkish-buff or purplish-buff to brown, with dark brown, red-brown and lilac-grey spots and blotches, mostly at larger end, mean c. 44 × 30 mm; incubation by female alone, fed on nest by male, period c. 23 days; chicks fed by both sexes, leave nest at c. 32 days, remain with parents until next breeding season. One record of nest parasitism by Channel-billed Cuckoo (*Scythrops novaehollandiae*).

Movements. Sedentary at many sites. In Tasmania and highland areas of SE Australia, some possibly descend to lower altitudes in autumn–winter period, augmenting resident populations, but large flocks are not seen and apparent increase in numbers may simply be the effect of local birds foraging in more visible locations. In Tasmania, few records in higher-rainfall, heavily forested areas W of main range.

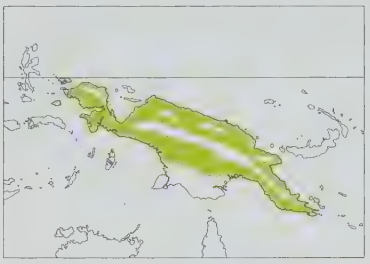
Status and Conservation. Not globally threatened. Locally common to uncommon. Has evidently declined throughout range. In Western Australia, range of race *plumbea* has decreased with clearing of forests and woodlands for farming; this race assessed as "Critically Endangered" in Northern Territory, with no sightings since 1960s; has been suggested that other populations of *plumbea* in C Australia and inland Western Australia have become rare and that the race is of conservation concern. Species is sometimes regarded as a pest in orchards.

Bibliography. Amadon (1951, 1962c), Anon. (1926), Barrett *et al.* (2003), Beruldsen (2004), Blakers *et al.* (1984), Christidis & Boles (2008), Condon (1951), Fletcher (1926), Ford (1971), Frith (1969), Garnett & Crowley (2000), Green (1989, 1995), Griffioen & Clarke (2002), Higgins *et al.* (2006a), Kinghorn (1928), Pizzey *et al.* (2007), Plowright (2006), Recher & Davis (1998), Schodde & Mason (1999), Serventy & Whittell (1967), Sharpe (1877), Sibley & Ahlquist (1985a), Sibley & Monroe (1990), Simpson & Day (2004), Slater *et al.* (2003), Storr (1991), Van Bael & Pruett-Jones (2000), Watts (2002).

Genus *PELTOPS* Wagler, 1829

11. Lowland Peltops

Peltops blainvillii



French: Peltopse des plaines **German**: Waldpeltops **Spanish**: Peltopo Llanero
Other common names: Clicking Peltops, Lowland Peltops-flycatcher/Shieldbill

Taxonomy. *Eurylaimus Blainvillii* Lesson and Garnot, 1827, Dorey (= Manokwari), north-west New Guinea.

Forms a superspecies with *P. montanus*. Monotypic.

Distribution. West Papuan Is (Waigeo, Salawati and Misool) and most of lowland New Guinea (apparently largely absent from Trans-Fly region).

Descriptive notes. 18–19 cm; c. 30 g. Smaller than butcherbirds, large-headed and stout, with large hook-tipped bill, shallowly forked tail and striking red, white and black plumage. Plumage is mostly glossy bluish-black, flight-feathers and tail with brown tinge; conspicuous white patch on side of head from behind eye to side of neck, few white feathers in mantle forming smudgy white patch; rump and uppertail-coverts red, and thighs, lower abdomen and undertail-coverts red; underwing white; iris red to dark red-brown; bill and legs black. Distinguished from very similar *P. montanus* by usually less extensive white on side of head, not reaching above eye level, and less white on back (also differs in some vocalizations). Sexes similar in plumage, male slightly larger than female. Juvenile is similar to adult but duller, with greyish-black plumage, and some white on throat and white tips of upperwing-coverts. VOICE. Song an unmusical series of clicks, described as similar to sound made by winding up a clock with a key; also described as three rapid pairs of notes all on one pitch, first note of each pair short and unstressed; may be repeated many times, singer throwing head down and forwards as each burst of notes uttered. Single loud, hoarse, upslurred "wheep" occasionally given; rarely, a high-pitched twittering call similar to common call of *P. montanus*.

Habitat. Canopy of lowland rainforest, especially at openings and edges; treefalls, road verges and river edges, and other disturbed areas, such as gardens. To c. 600 m. Replaced at higher elevations by *P. montanus*.

Food and Feeding. Mainly flying insects, including dragonflies (Odonata). Groups of three or four individuals spend long periods on high open perches, calling, and sallying after flying insects, sometimes almost down to ground level. Some insects snatched from foliage, especially in regrowth habitats. Prey taken to perch and consumed after little preparation.

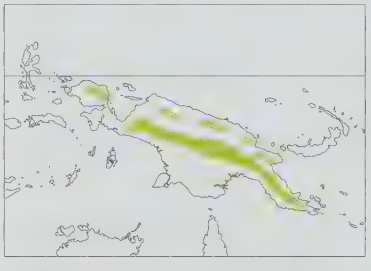
Breeding. Little known. Breeds probably in middle to late dry season. Territorial, present in territory all year. Nest reported as a small cup of twigs and rootlets, more than 6 m above ground in outer branches of tree at edge of clearing. Clutch size not known, but single nestlings and single fledglings reported; egg said to be yellowish-white with slight reddish sheen, and ring of dark brown spots at broader end. No other information.

Movements. Sedentary.

Status and Conservation. Not globally threatened. Widely distributed. Survey near Port Moresby found density of 2 birds/10 ha. Extensive logging of lowland rainforest likely to lead to decreases in size and extent of populations; nevertheless, able to live in ecologically disturbed areas and regrowth so long as high perches from which to forage are still present.

Bibliography. Beehler *et al.* (1986), Bell (1982a, 1982e), Coates (1990), Gilliard & LeCroy (1961, 1966, 1967a, 1967b), Junge (1953), Leach (1914), Mayr & Rand (1937), Rand (1942a, 1942b), Ripley (1964), Schodde & Hitchcock (1968), Sibley & Ahlquist (1984a), Stresemann (1923), Watson *et al.* (1982).

12. Highland Peltops



Peltops montanus

French: Peltopse des montagnes **German**: Bergpeltops **Spanish**: Peltopo Montano
Other common names: Mountain Peltops/Peltops-flycatcher, Singing Peltops/Peltops-flycatcher/Shieldbill

Taxonomy. *Peltops blainvillii montanus* Stresemann, 1921, Hunsteinspitze, Sepik Mountains, New Guinea.

Forms a superspecies with *P. blainvillii*. Monotypic.

Distribution. Highland New Guinea in Vogelkop (Tamrau Mts and Arfak Mts) and C cordillera from Weyland Mts E to Huon Peninsula and SE peninsula.

Descriptive notes. 20 cm; 27–36 g. Smaller than butcherbirds, large-headed and stout, with large hook-tipped bill, shallowly forked tail and striking red, white and black plumage. Plumage is mostly glossy bluish-black, flight-feathers and tail with brown tinge; conspicuous white fan-shaped patch on side of head from behind eye to side of neck, large white patch on back; rump and uppertail-coverts red, thighs, lower abdomen and undertail-coverts red; underwing white; iris orange-red to dark red-brown; bill and legs black. Differs from very similar *P. blainvillii* in slightly larger size, although bill same size (thus looks relatively smaller), white patch on side of head typically larger and reaches above eye level, larger and more conspicuous white patch on back (also differs in some vocalizations). Sexes similar, male slightly larger than female. Immature is similar to adult but duller, with white tips on some wing feathers and some white on chin and throat. VOICE. Most frequent call a very rapid series of 6–12 soft notes given in less than 1 second, descending slightly in pitch, likened to sound made by running a finger along teeth of a comb. Occasionally a hoarse upslurred "wheep", similar to that of *P. blainvillii*; also high-pitched repeated whistled "ti-chew".

Habitat. Montane rainforest; tall forest trees at edges of open spaces, in similar habitat to that of *P. blainvillii*. Seen near landslips, treefalls, along rivers or roads, in gardens; in virgin forest, observed in emergent trees or along ridges. Generally above 600 m, and to 3000 m; occasionally slightly lower, down to 550 m.

Food and Feeding. Food mainly insects, including beetles (Coleoptera) and adult bugs (Hemiptera), also large moths (Lepidoptera). Sallies out from conspicuous perch at 15 m or more above ground, returning to same perch or one nearby.

Breeding. Little known. Nest records indicate breeding during late dry season to early wet season, at least. Nest reported as a small cup of twigs and rootlets, placed 7–35 m above ground in horizontal fork at end of outer branch; two nests each held a single nestling. No other information.

Movements. Resident.

Status and Conservation. Not globally threatened. Widely distributed. Poorly known, but probably not uncommon.

Bibliography. Beehler *et al.* (1986), Coates (1990), Diamond (1972), Gilliard & LeCroy (1967), Lamothe (1979), Mayr & Rand (1937), Rand (1942b), Rand & Gilliard (1967), Ripley (1964), Sibley & Ahlquist (1984a), Stresemann (1923).

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family PITYRIASEIDAE (BRISTLEHEAD)

- Large passerine with short tail and very large hooked bill; plumage black and red, with orange "bald" crown.
- 22–26 cm.

- Borneo.
- Tropical rainforest.
- 1 genus, 1 species, 1 taxon.
- No species threatened; none extinct since 1600.

Systematics

Of the myriad birds with uncertain phylogenetic affinities and convoluted taxonomic histories, few can rival the Bristlehead (*Pityriasis gymnocephala*) of Borneo for the sheer number of taxonomic assignments and confusion with regard to its evolutionary history. Because of its unique appearance, the Bristlehead has been called "one of the strangest members of all the Oscines" by E. Mayr and D. Amadon. Described in 1836, this species was viewed by early taxonomists as a shrike (Laniidae) and, because of its large size and heavy hooked bill, it was placed next to the Australian genera *Cracticus* and *Gymnorhina* (subsumed into *Cracticus* in the present work), which were at that time also considered to be shrikes but are nowadays placed in the butcherbird family, Cracticidae. Towards the end of the nineteenth century, taxonomists suggested other possible relationships for the Bristlehead, most notably with the starlings (Sturnidae), particularly the large mynas (*Gracula*). R. B. Sharpe retained *Pityriasis*, along with *Cracticus* and *Gymnorhina*, in Laniidae, but he placed that family next to the helmet-shrikes (Prionopidae) and the vangas (Vangidae). In the mid-twentieth century, the Bristlehead was moved among several groups, including the starlings, the babblers (Timaliidae), the helmet-shrikes, the laniid shrikes (without the cracticids) and the wood-shrikes (*Tephrodornis*). Indeed, for much of the twentieth century, the common name of the Bristlehead was "Bald-headed Wood-shrike", suggesting a relationship with the true wood-shrikes. By 1980, the Bristlehead had been allied with no fewer than seven families, spanning much of the oscine radiation.

The uncertainty over this species' relationships appeared to be resolved in 1984, with the technique of DNA–DNA hybridization. Analyses by J. E. Ahlquist and colleagues indicated that the Bristlehead was closest to the cracticid genera *Cracticus*, *Gymnorhina* and *Strepera*, thereby supporting the earliest taxonomic treatments. The results of recent DNA-sequencing studies, however, appear to dispute this finding, and suggest that the Bristlehead is, instead, a member of a diverse group of shrike-like birds that are distributed across the Old World tropics. This group, which includes vangas, bush-shrikes (Malaconotidae), helmet-shrikes, wood-shrikes, philentomas (*Philentoma*), wattle-eyes (*Platysteira*), ioras (*Aegithina*) and assorted other genera, is evidently sister to the cracticids and the woodswallows (Artamidae). Within this purported group, the Bristlehead is not particularly close to any species, and it may have diverged from its nearest living relatives as long as 20 million years ago. The Bristlehead lineage has either diversified little over the past several millennia, or the species is the sole survivor of a more speciose radiation. Given the complexity of relationships and geographical dispersion of its supposed relatives, together with the unique characters of the bird itself, it is perhaps not surprising that efforts to classify the Bristlehead have led to such disparate conclusions.

The biogeographical history of the Bristlehead and, indeed, of the entire group of shrike-like birds to which it seems to be related is not at all clear. One of the main problems is that the group contains genera from several different tropical regions. For example, the helmet-shrikes, the wattle-eyes and the bush-shrikes are all restricted to Africa, the vangas to Madagascar, the philentomas, ioras and wood-shrikes to South-east Asia, and the cracticids to Australasia. The species within each of these tropical regions, however, are not necessarily closely related to one another. Bush-shrikes, for example, are more closely related to the Asian Bristlehead and ioras than they are to other African taxa. These convoluted geographical and phylogenetic relationships would seem to indicate that dispersal, extinction and other vagaries of evolution have played an important role in shaping the history of the shrike-like group. On a more local scale, in the Sundan archipelago, the Bristlehead appears to fill the "large-shrike niche", but it is unclear why it is restricted to Borneo, rather than being present also in Sumatra, Java and Peninsular Malaysia.

Morphological Aspects

One of Borneo's oddest bird species, the Bristlehead is a fairly large passerine, weighing 115–150 g and measuring about 25 cm in length. Its bulky yet compact appearance is due in part to its extremely short tail. The wings, on the other hand, are long and powerful. A particularly striking feature is the massive bill, the upper mandible of which has a rather prominent hooked tip.

The name *Pityriasis* is derived from the Greek and can be loosely translated as "suffering from dandruff". The specific name, *gymnocephala*, means "bald-headed" and refers to the most distinctive characteristic of the Bristlehead, the featherless patch on top of its head, which is covered with bright yellow to orange bristle-like protrusions. There are, in fact, no true bristles anywhere on the crown, which is, instead, covered with a dense

carpet of finger-like outgrowths of skin. Although these may resemble bristles in dry study skins, they are in reality specialized tubes or filaments 3–4 mm long, indicative of the most basic developmental level of feather growth. The Bristlehead also has distinctive dark grey, bristle-like modified contour feathers on its ear-coverts and upper breast. The remainder of the face, the neck and the thighs are bright red. Most of the rest of the body is black, the exceptions being the breast feathers and scapulars, which are charcoal-grey with black edges, giving the bird a scaled appearance. The wings are blackish, but have a white patch near the bases of the primaries, which is normally visible only when the bird is in flight.

Female Bristleheads are generally thought to differ from males in having red edges on some of the flank feathers, but although females always have some red on their flanks, some males also exhibit this characteristic.

Juveniles, at least in the early stages after fledging, show several features that permit them to be separated from adults. They have the head and neck more orange-red than in adults; the ear-coverts are red, rather than grey; the ear and breast contour feathers are not modified into bristles; the breast and flanks are mottled red and black; and the amount of red on the thighs is reduced.

Habitat

The Bristlehead occurs in a wide variety of habitats, and it is difficult to pinpoint one preferred type. It is found in undisturbed and disturbed dipterocarp forest, in upland heath forest (known also as *kerangas* forest), in coniferous lower-montane forest, in coastal swamp-forest, and in mangroves. It has also been observed in *Acacia mangium* plantations, both adjacent to and distant from primary forest. For many years it was thought to be strongly associated with peatswamp-forest, but in more recent times it has become clear that this was a misconception, as this particular habitat type appears to be relatively unimportant for the species. The Bristlehead is most commonly recorded in lowland and upland areas from sea-level to 600 m, but it has also been reported at about 1000–1200 m in the Maliau Basin, in Sabah, and at Mount Palung, in western Kalimantan.

The Bristlehead appears to be mainly a canopy species, sometimes feeding in emergent trees and rather less commonly descending to the middle storey. This would explain why it is rarely, if ever, mist-netted by ornithologists undertaking research within its range.

General Habits

Much of the life history of the Bristlehead is a mystery. The little that is known about this species has been pieced together from old specimen records and from a number of casual recent field observations. There have been no ecological studies of the species.

The Bristlehead appears to be a social species, virtually always occurring in flocks. Generally, groups consist of about six to ten individuals, although some coastal parties can be smaller, containing four or five individuals. These flocks are cohesive, their members staying normally within 20 m of one another. When a Bristlehead is injured or captured, other members of its flock congregate around the victim, while making a tremendous racket and approaching close to humans.

The movements of the Bristlehead are largely unpredictable. The literature is rife with anecdotes related by frustrated birdwatchers and ornithologists who, despite intense efforts, have failed to see the bird in the field. B. E. Smythies, author of *The Birds of Borneo*, managed to observe it on only five occasions between 1949 and 1956, and E. Banks, the former curator of the Sarawak Museum, saw it only once in a period of 20 years. Although the Bristlehead has been recorded many times in the Kabili-Sepilok Forest Reserve and in Danum Valley, both in Sabah, the chances of finding it on any given day are not good. The remarkable unpredictability of this species suggests that it probably forages over large areas. Observations from high-elevation lookouts confirm that flocks of the species move widely on a daily basis. There is a possibility also that it may undertake seasonal movements to some extent, as indicated by birdwatching records in Danum Valley (see Movements). When breeding, however, Bristleheads appear to remain in a single location, as would be expected. Those at the Brumas timber camp, in Sabah, which were carrying nesting material, were observed daily for a period of two to three weeks.

*Few birds rival the **Bristlehead** in the sheer diversity of its taxonomic assignments: no less than seven different families by 1980. DNA sequencing now suggests the Bristlehead is a member of a diverse group of shrike-like birds distributed across the Old World tropics. The biogeographical history of this group is unclear. The bush-shrikes (Malaconotidae) of Africa, for example, are probably more closely related to the Asian Bristlehead than to any other African taxa. The Bristlehead may have diverged from its nearest living relatives some 20 million years ago. In the Greater Sundas, the Bristlehead fills the "large-shrike niche", but nobody knows why it is restricted to Borneo and absent from Sumatra, Java and Peninsular Malaysia.*

[*Pityriasis gymnocephala*, Borneo. Photo: Severino Paulin, Jr]

Bristleheads often join with other forest species in mixed flocks. Species with which they associate include malkohas (*Phaenicophaeus*), trogons (of genus *Harpactes*), hornbills (Bucerotidae), woodpeckers (Picidae), babblers, Black Magpies (*Platysmurus leucopterus*), and drongos (*Dicrurus*).

Not surprisingly, nothing is known of the comfort behaviour and maintenance activities of the Bristlehead.

Voice

The vocalizations of the Bristlehead are distinctive, and are often the single thing that reveals the presence of these birds in an area. Flocks of Bristleheads constantly call with a variety of snorts and whistles. An unobtrusive nasal, whining contact call is regularly given by individuals in a flock that may otherwise be silent. Another contact call is a single loud whistle, repeated by each flock-member within the space of 2–3 seconds. In addition, a "pit-pit-peeoo", interspersed with a corvid-like chatter, is commonly uttered.

A particularly distinctive vocalization made by this species consists of a long high-pitched tone followed by a low even note of similar length, with a quick five-note staccato, and then a short trailing note.

Food and Feeding

The diet of this species consists largely of invertebrates. Recorded foods are katydids (Tettigoniidae), cicadas (Cicadoidea), stick-insects (Phasmida), beetles (Coleoptera), caterpillars (Lepidoptera), cockroaches (Blattodea), spiders (Araneae) and termites (Isoptera). The Bristlehead dismantles large insects, for which purpose it uses a branch as a brace against which to hold the prey; it then removes and discards the insect's wings and legs, before consuming the rest. Bristleheads will also seize small reptiles and amphibians when these are available, and they will occasionally take small to medium-sized fruits. They have been observed to feed on fruits the size of an olive (*Olea*) or a plum (*Prunus*), but these seem not to be a major part of the diet.

*The rather chubby appearance of the **Bristlehead** is partly due to its extremely short tail. Its wings, however, are long and powerful. The yellow or orange bristle-like features covering the featherless patch on its head are, in fact, finger-like protrusions of skin. The species also has distinctive dark grey, bristle-like modified contour feathers on its ear-coverts and upper breast. The face, neck and thighs are bright red, and the rest of the bird black and charcoal-grey; the grey edges of the scapulars giving the bird a scaly look. The massive bill has a prominent hook on the upper mandible. The Bristlehead appears to be mainly a canopy species, sometimes feeding in emergent trees, and less commonly descending to the middle storey. It is found in a wide variety of disturbed and undisturbed forest habitats.*

[*Pityriasis gymnocephala*, Sepilok Reserve, Sabah, Borneo. Photo: Sookiong Vun]

Bristleheads most often forage in flocks for insects, and they employ a variety of methods. They glean prey items from the foliage and twigs in the upper part of the forest canopy and, at times, in emergent trees. They may fly short distances in order to pounce on prey, and they occasionally take prey by sally-gleaning. Only rarely do individuals or groups remain in one feeding spot for more than a few moments.

When foraging, Bristleheads often move along large horizontal branches in an ungainly manner, making sideways hops, and their mode of advancing has been likened to that of a woodpecker. They also hop up lianas, turning 180° on each hop. Their movements are relatively acrobatic, although slow and heavy, making them look rather like giant tits (Paridae).

*The calls of the **Bristlehead** are distinctive, including a variety of snorts and whistles, and a long high-pitched tone followed by a low even note of similar length, with a quick five-note staccato, and then a short trailing note. The Bristlehead appears to be a social species, usually seen in flocks of six to ten birds, which keep together with a variety of contact calls.*

Breeding

Barely anything is known about the breeding behaviour and biology of the Bristlehead, and its nest remains undescribed. An oviduct egg of this species collected on 8th October, presumably in Sarawak, was described by E. Bartlett in 1896. It measured approximately 31 × 25 mm and was pure white, sparingly marked all over with circular and oval bright brown and slaty-grey spots of various sizes, the majority forming an irregular ring at the larger end. On the basis of data on specimen labels, Bristleheads appear to breed over a period of several months in eastern Sabah. This is revealed by the fact that a female from Brumas, in south-eastern Sabah, had enlarged ova and ruptured ovarian follicles, indicating recent egg-laying, on 18th May 1982; a specimen from Sapagaya Forest Reserve, near Gomantong, had an oviduct egg measuring 14 × 14 mm on 5th August 1983; and another, from Quoin Hill, had a 15-mm ovum, an enlarged oviduct and a well-developed brood patch on 4th October 1962.

Several lines of evidence suggest that Bristleheads are communal breeders, whereby groups of adults attend to the tasks of nest-building and caring for the young. Since the nineteenth century, ornithologists have noticed a high ratio of adults to juveniles in flocks of this species. Several members of a flock observed at Brumas in May 1982 were carrying nesting material, and two different individuals, both apparently female, were seen to feed a single fledgling at Mount Palung, in western Kalimantan. Some, but not all, of what appear to be the Bristlehead's closest relatives are also communal breeders, examples being the helmet-shrikes and the cracticids.

Movements

Insufficient information is available on this species to determine the extent of its movements. It certainly ranges widely while foraging (see General Habits), and its movements would appear to be governed by the availability of food.

Interestingly, records of Bristleheads in Danum Valley appear to be seasonal, at least to some degree, and this suggests that the species may perhaps make some seasonal movement in this region. The possibility of some altitudinal movement has been proposed.

Relationship with Man

No particular relationship is known to exist between the Bristlehead and the native peoples of Borneo. Indeed, prior to the growth in ecotourism, it was little known among native Borneans, perhaps because it was rarely encountered. As far as visiting ornithologists are concerned, however, the Bristlehead has a special significance, for it is generally the species most prized by birdwatchers in Borneo. As a result, its significance is now recognized, and the species is commonly "staked out" by local tour-leaders.

The Malay term for the Bristlehead is *Tiong Batu*, meaning "stone myna". It refers to the onomatopoeic name and sound, a loud "tiong", of the Common Hill Myna (*Gracula religiosa*), which resembles the Bristlehead both in size and in its possession of a white wing flash.

Status and Conservation

The Bristlehead is placed by BirdLife International in the category of Near-threatened. It is a forest-dwelling species restricted to Borneo, where its numbers are thought likely to be declining as a direct consequence of the increasingly widespread loss and degradation of forest throughout much of the island. Nevertheless, although virtually all lowland and upland forest in Borneo is disturbed, and large portions of forest have been destroyed, the effects of these habitat modifications on the Bristlehead are not fully understood.

As already noted (see Habitat), this species can be found in a remarkable array of habitats, from mangroves on the coast in Sarawak to coniferous forest in interior highlands of Sabah. It has even been observed recently in *Acacia mangium* plantations, including plantations that are far removed from primary forest. In none of these habitats, however, could it be considered a common species.

The main threat to the Bristlehead's survival is the continuing loss of its habitat. Rates of forest destruction in the lowlands have increased, especially in Kalimantan, where illegal logging and land conversion have become major threats, and all remaining stands of valuable timber are deliberately targeted. Although the magnitude of these threats may perhaps be lessened by this species' tolerance of logged forest, secondary forest and hill forest, detailed research is needed in order to determine its full habitat requirements.

The Bristlehead is known to occur in several protected areas. Examples are Tawau Hills National Park, Danum Valley Conservation Area, Kabili-Sepilok Forest Reserve and Sapagaya Forest Reserve, all in Sabah; Sepipong Reserve and Anduki Forest Reserve, in Brunei; Lambir Hills National Park and Samunsam Wildlife Sanctuary, in Sarawak; and Gunung Palung National Park, in Kalimantan. Even forest lying within the bounds of protected areas is not secure, however, as illegal logging takes place in these areas too.

Without greater knowledge of the foraging and breeding requirements of the Bristlehead, and in the absence of reliable estimates of its population size, no accurate statement on its conservation status can be made. Despite this, and in view of the marked lack of data on the species, it is advisable that repeat surveys be conducted in areas within and around those where it is known to occur in an attempt to ascertain rates of population decline or range contraction. Furthermore, there is a need for ecological studies aimed at improving our understanding of the Bristlehead's precise habitat requirements, its tolerance of secondary habitats and its response to habitat fragmentation.

PLATE 18

Genus *PITYRIASIS* Lesson, 1839

Bristlehead

Pityriasis gymnocephala

French: Barite chauve **German**: Warzenkopf **Spanish**: Gimnocéfalo
Other common names: Bornean Bristlehead, Bald-headed Wood-shrike/Crow, Bristled Shrike/Starling

Taxonomy. *Barita gymnocephala* Temminck, 1836, Borneo.
Relationships uncertain. Has in the past been considered closely related variously to shrikes (Laniidae), starlings (Sturnidae), helmet-shrikes (Prionopidae), vangas (Vangidae), butcherbirds (Cracticidae), babblers (Timaliidae) and wood-shrikes (*Tephrodornis*). DNA analysis indicated close affiliation with cracticid genera *Cracticus*, *Gymnorhina* and *Strepera*; more recent DNA-sequencing studies, however, suggest that present species belongs to a diverse group of shrike-like birds which includes vangas, bush-shrikes (Malaconotidae), helmet-shrikes, wood-shrikes, philentomas (*Philentoma*), wattle-eyes (*Platysteira*), ioras (*Aegithina*) and assorted other genera, this group being sister to the cracticids and the woodswallows (Artamidae). Monotypic.
Distribution. Borneo.

Descriptive notes. 22–26 cm; 115–150 g. Heavy-bodied passerine with massive hooked bill and short tail, giving top-heavy appearance, and long powerful wings. Male has unfeathered top of head bright yellow to orange with short outgrowths of skin, broad area of bare skin around eye pink-red, ear-coverts bristle-like and charcoal-grey, with remainder of face, neck and thighs bright red; most of body black, breast feathers and scapulars charcoal-grey with black edges (giving scaled appearance), sometimes some red in flank feathers; white wing patch resembling that of Common Hill Myna (*Gracula religiosa*), visible in flight; iris dark reddish-brown; bill black; legs pink to yellowish-pink. Female is like male, except that flank feathers always red (male variable in this characteristic). Juvenile, on fledging, is distinguished from adult by having head and neck more orange-red, ear-coverts red, rather than grey, ear and breast contour feathers not modified into bristles, breast and flanks mottled red and black, reduced amount of red on thighs, red eyering and greyish legs; subsequently, has black thighs, red ear-coverts, hindneck spotted with black, a few red feathers on bald head. Voice. Calls frequently, with variety of snorts and whistles. Unobtrusive nasal, whining contact call given regularly by flock-members; single loud whistle, repeated by each flock-member, also for contact; "pit-pit-peeoo", interspersed with corvid-like chatter, commonly uttered. Also, a distinctive vocalization consisting of a long high-pitched note followed by a low even note of similar length, then rapid 5-note staccato, and short trailing note.
Habitat. Forest. Often said to favour peatswamp-forest, but is probably most commonly associated with primary dipterocarp forest, and found also in various other forest types, including disturbed dipterocarp forest, upland heath forest (*kerangas* forest), montane coniferous forest, coastal swamp-forest, and mangrove; also *Acacia mangium* plantations (both adjacent to and far from primary forest). Lowlands to 600 m, locally to 1000 m.
Food and Feeding. Major food items include katydids (Tettigoniidae), cicadas (Cicadoidea), stick-insects (Phasmida), beetles (Coleoptera), caterpillars (Lepidoptera), cockroaches (Blattodea), termites (Isoptera) and spiders (Araneae); small reptiles and amphibians sometimes taken; small fruits occasionally consumed. Forages in canopy and subcanopy, sometimes also in emergent trees. Most food taken by gleaning, sometimes by sally-gleaning; will also pounce on prey at short distance. Forages in flocks of up to ten or so individuals; often with mixed-species flocks.
Breeding. Few data. Season apparently May–Oct, perhaps depending on rainfall and food availability. Possibly a co-operative breeder, several adults helping with nest-building and offspring care. Nest not described. No information on clutch size; one egg described as white, sparingly marked all over with bright brown and slaty-grey spots of various sizes, majority forming irregular ring at larger end, dimensions 31 mm × 25 mm. No other information.
Movements. No hard information. Foraging flocks wide-ranging, perhaps seasonally influenced.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Uncommon, and not often observed; population size and precise habitat requirements not known. Thought likely to be declining as a result of loss and degradation of forest throughout much of Borneo; habitat loss continuing, and fires also cause serious damage to habitat. Rates of forest loss in lowlands have increased, especially in Kalimantan, where illegal logging and land conversion now major threats, even in protected areas. This species is tolerant of logged forest, secondary forest and hill forest, but research required to determine its full habitat requirements; although extensive forest disturbance in Borneo likely to prove detrimental, its occurrence in a wide variety of habitats suggests some resilience. Occurs in several protected areas.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family PTILONORHYNCHIDAE (BOWERBIRDS)

- Medium-sized, compact, robust passerines, most with stout and powerful bill; adult males with strikingly diverse and often colourful plumage, females generally duller.
- 22–37 cm.

- New Guinea and Australia.
- Rainforest, also drier sclerophyll habitats.
- 8 genera, 20 species, 43 taxa.
- No species threatened; none extinct since 1600.

Systematics

The position of the bowerbirds (Ptilonorhynchidae) within the oscine passerines was unsettled through history until recent decades, reflecting uncertainty about bowerbird origins and their immediate relationship to other bird groups. As a result of several striking similarities in zoogeography, morphology, ecology, mating systems and the behavioural consequences of them, they were for a long time believed to be most closely associated with the birds-of-paradise (Paradisaeidae), and were often combined within the latter family. More recently, the results of several biomolecular studies have provided clear evidence of the discrete status of the Ptilonorhynchidae not only as a valid family, but also as a highly distinctive one relatively distant from, and basal to, the Paradisaeidae within the oscines.

Nowadays, it is widely acknowledged that the majority of Australasian passerines, about 85% of the total, are derived from a southern, or Gondwanan, origin. This major group, referred to as the "Corvida", radiated in Australia and New Guinea, and today it comprises three major lineages. These are the Menuroidea, which includes the bowerbirds, the Meliphagoidea, and the Corvoidea, which includes the birds-of-paradise. Extant bird groups considered closest to the bowerbirds are the Australasian treecreepers (Climacteridae) and the lyrebirds (Menuridae), the latter being considered the most primitive of the oscines. The recently mooted opinion that the Piopio (*Turnagra capensis*), a New Zealand endemic and sole member of the family Turnagridae, was in fact a bowerbird appears, from several lines of evidence, most unlikely to prove valid. Some taxonomists consider the North Island and South Island populations of the Piopio to represent two distinct species, both now, unfortunately, extinct (see HBW7, pages 52–53).

It is believed that the bowerbirds belong to a broad radiation of birds that occurred in Australasia during the past 60 million years, and it has been proposed that they diverged from the lyrebirds and the scrub-birds (Atrichornithidae) of Australia some 45 million years ago. Recent biomolecular researches, involving the application of hypothetical "molecular-clock" calibrations, suggest that their separation from broadly corvid-like relatives, including the birds-of-paradise, occurred about 28 million years ago and that the major lineages within the Ptilonorhynchidae arose approximately 24 million years ago. Such calculations, however, remain far from definitive, and the notion of a molecular clock is considered questionable by a number of scientists.

Contemporary consensus is that bowerbirds represent a basal, or primitive, group of Australasian oscine passerines. Supporting this view is the presence of a single corvoid pneumatic fossa (a depression or hollow) in the humerus bones of bowerbirds. Bowerbirds have characters of the legs, feet, palate, syrinx and sperm which, together, define them as a distinct family, but none of which is unique to them. While bowerbird anatomy is broadly typical of that of higher passerines, there are a couple of notable exceptions. The first of these is an enlarged lachrymal, which is part of the cranium bone structure, near the eye socket, and which represents a character unique to the Ptilonorhynchidae within the perching birds, and otherwise paralleled only by the lyrebirds. The second conspicuous difference is that the bowerbirds possess a greater number of secondaries,

Bowerbirds form a monophyletic family comprising 20 closely related species. Ten are restricted to mainland New Guinea, eight confined to Australia, and two found in both New Guinea and Australia. Ten races of ***Black-eared Catbird*** *are recognized, in New Guinea, Australia and offshore islands. The three species of catbird form a distinct subgroup, the genus* Ailuroedus. *Named after their cat-like calls, catbirds are monogamous, and neither clear courts nor build bowers. Recent biomolecular research suggests that catbirds diverged from other bowerbird genera about 24 million years ago.*

[*Ailuroedus melanotis maculosus*, Atherton Tableland, Queensland, Australia. Photo: Clifford & Dawn Frith]

The four silky bowerbirds forming the genus Sericulus *are among the ten bowerbird species that build avenue bowers out of parallel walls of sticks or grass stems. Bowerbirds measure 22–37 cm in body length, and weigh 80–200 g. In most of the polygynous species, females are slightly smaller than males, but females of the* ***Flame Bowerbird*** *and two other* Sericulus *species are the same size or slightly larger than their respective males. Size increases with altitude in New Guinea. The upland-dwelling Adelbert* (S. bakeri) *and Masked Bowerbirds* (S. aureus) *are larger than the lowland Flame Bowerbird.*

[*Sericulus ardens*. Photo: Clifford & Dawn Frith]

11–14 in total, including tertials, than most other passerines, which have only nine or ten. Bowerbirds typically lay small clutches (see Breeding), the 1–3 eggs being laid at two-day intervals. They have relatively long incubation and nestling periods for songbirds of their body weight, and the period over which the adults accompany the young after they have left the nest is extended, thus improving juvenile survival. These are features typical of some, but not all, Australian perching birds of Gondwanan origin, namely the Corvida.

Extant bowerbirds form a monophyletic family comprising 20 closely related species. Ten of them are restricted to mainland New Guinea, eight are confined to Australia, and two species are found in both New Guinea and Australia. Only the White-eared Catbird (*Ailuroedus buccoides*), the Black-eared Catbird (*Ailuroedus melanotis*) and the Great Bowerbird (*Chlamydera nuchalis*) occupy offshore islands, each of them being present also on the nearby continental mainland. Bowerbirds occur predominantly within the tropics and subtropics, only the Satin Bowerbird (*Ptilonorhynchus violaceus*) ranging significantly southwards into temperate Australia.

The eight genera currently acknowledged have largely been conservatively maintained throughout the history of the group. The three species of catbird form a distinct subgroup, the genus *Ailuroedus*; these monogamous members of the family neither clear a court nor build a bower as part of their reproductive behaviour. The catbirds were once grouped together with the Tooth-billed Bowerbird (*Scenopoeetes dentirostris*), which was at the time thought, erroneously, to be similarly monogamous. Recent studies have shown, however, that the Tooth-billed Bowerbird is a court-clearing polygynous species that constitutes a valid monotypic genus. Males of the remaining 16 bowerbird species, all of them also polygynous, build bower structures of two major types, the maypole type and the avenue type (see Breeding). Of the six maypole-builders, four are gardener bowerbirds, forming the genus *Amblyornis*, and the other two, each in a monotypic genus, are Archbold's Bowerbird (*Archboldia papuensis*) and the Golden Bowerbird (*Prionodura newtoniana*). The ten avenue-builders consist of the four silky bowerbirds, forming the genus *Sericulus*, the Satin Bowerbird, in its own genus, and the five grey bowerbirds, forming *Chlamydera*.

In 2008, a review and revision of the systematics and taxonomy of Australian birds was published. The authors, L. Christidis and W. E. Boles, applied all available evidence, including the results of recent molecular-genetic studies, and subsumed *Prionodura* into *Amblyornis* and *Chlamydera* into *Ptilonorhynchus*. Apparently inconsistent with this reduction to five bowerbird genera, however, is that the revision did not place *Sericulus*, too, into the newly enlarged *Ptilonorhynchus*, despite the fact that one *Chlamydera* species, Lauterbach's Bowerbird (*Chlamydera lauterbachi*), exhibits plumage characters clearly intermediate beween those of *Sericulus* and those of *Chlamydera*.

Recent studies have resolved most of the limited historical controversies regarding relationships among the various bowerbird taxa. The three catbird species are most obviously more closely related to one another than they are to any other bowerbirds; recent biomolecular research indicates that they diverged from other bowerbird genera about 24 million years ago, and that they are quite distinct from builders of avenue bowers. The Tooth-billed Bowerbird is as distinct from the catbirds as are other bowerbird subgroups and is, in fact, genetically closer to New Guinea gardener bowerbirds than it is to catbirds.

The status of the four gardener bowerbirds as species has been constant, each being associated with a distinctive maypole bower form. This situation has recently been complicated, however, by the discovery that both the Yellow-fronted Bowerbird (*Amblyornis flavifrons*) of the Foja Mountains, a very poorly known species, and populations of the Vogelkop Bowerbird (*Amblyornis inornata*) on the Fakfak and Kumawa Mountains, in the Bomberai Peninsula, build simplistic bowers, more like those of MacGregor's Bowerbird (*Amblyornis macgregoriae*). While Bomberai Peninsula bowers are quite unlike those of the Vogelkop Bowerbird in the Vogelkop Peninsula of north-west New Guinea, the birds concerned are thought to represent an isolated conspecific population, but this is not conclusively established. In the light of the otherwise highly species-specific form of bower shape within the family, it is not impossible that the taxonomic status of the bowerbirds in the Bomberai Peninsula may change.

Within the polygynous bowerbirds, two broadly distinctive clades are discernible. The species in the maypole-building genera *Amblyornis*, *Archboldia* and *Prionodura*, with the possible inclusion also of *Scenopoeetes*, constitute one clade and the avenue-building *Sericulus*, *Ptilonorhynchus* and *Chlamydera* the other. The close relationship among the genera of each of these clades is clearly emphasized by a review of numerous and obvious similarities in traits of their morphology, bower structures and decorations, courtship, nidification, and nesting biology. Recent biomolecular research indicates that the grey bowerbirds forming the genus *Chlamydera* split off from the Satin Bowerbird about 12 million years ago.

The five "grey" bowerbirds of the genus Chlamydera *include the largest member of the family, the* ***Great Bowerbird****. Both sexes of the Australian Great Bowerbird are brownish-grey; the male has an erectile, pinkish-mauve crest on the nape, which is much smaller or absent in the female.* Chlamydera *bowerbirds are avenue-builders. While most bowerbird species are confined to wet forests, the five grey bowerbirds have adapted to the drier, more open environments of riverine forests, open woodland, savanna, forest–grassland communities and, in Australia, to near-desert conditions.*

[*Chlamydera nuchalis nuchalis*, Kakadu National Park, Northern Territory, Australia. Photo: Hanne & Jens Eriksen]

Four intrageneric wild hybrid crosses are known, their existence emphasizing close genetic relationships between species. A unique skin specimen from Australia, collected near Brisbane, in south-east Queensland, in 1867, and which had disappeared by 1950, was considered by some authorities to be a hybrid individual between the Satin and Regent Bowerbirds (*Sericulus chrysocephalus*). A second, living, individual of this hybrid combination was photographed in 2003. Geographically restricted cases of hybridization have also been described, but only recently, as occurring between MacGregor's and Streaked Bowerbirds (*Amblyornis subalaris*) and between the Masked (*Sericulus aureus*) and Flame Bowerbirds (*Sericulus ardens*) in New Guinea, and, in Australia, between the Spotted Bowerbird (*Chlamydera maculata*) and the Great Bowerbird in northern Queensland.

The Satin Bowerbird is the only member of this family found in the fossil record, fossils of this species having been located in the east and south-west of the Australian state of Victoria from the geological epochs of the Pleistocene and Holocene of the Quaternary. These fossils testify to the previously far greater extent of wet forests, of Gondwanan origin, than can be found in present-day Australia, where this habitat is now restricted predominantly to the central-eastern and north-eastern seaboard of the continental island.

At the species level, the Black-eared and Green Catbirds (*Ailuroedus crassirostris*) are clearly closely related, but opinion on whether they constitute two distinct species or are conspecific has been divided. Morphological and geographical considerations, combined with equivocal protein-allozyme data, support their treatment as separate species, probably forming a superspecies. The subspecies *germana* of MacGregor's Bowerbird, found in the mountains of the Huon Peninsula, in north-east New Guinea, appears to build bowers that, at least in some cases, differ from those typical of the species. It has been suggested that *germana* might represent a separate species, the "Huon Bowerbird", but further study is required before such a decision is taken. In the case of Archbold's Bowerbird, living in the central mountain chain of New Guinea, it has for a long time been thought that the two subspecies might constitute distinct species, the adult male of eastern *sanfordi* being crested and building a "mat" bower, whereas the male of the western, nominate race was believed to be uncrested and possibly to build an avenue bower. Further study, however, has now revealed that both subspecies have crested adult males and both construct a maypole bower.

Morphological Aspects

Bowerbirds vary in total body length from 22 cm to 37 cm, and in body shape from being plump and stocky to being slender. The smallest is the Golden Bowerbird, which has an average weight of 80 g, although adult males have a total length longer than that of the *Amblyornis* gardener bowerbirds owing to their possession of a proportionately long tail. The largest is the Great Bowerbird, adults of which have a mean body weight of 200 g. Thus, the most lightweight member of the family has an average weight which is 40% of that of the heaviest. It is well known that, within bird species on the mountains of New Guinea, there is a general increase in body size with increasing elevation, and the bowerbirds broadly reflect this when species are compared. For example, upland Black-eared Catbirds are larger than lowland White-eared Catbirds, and the highest-altitude gardener, MacGregor's Bowerbird, is the largest while the one at the lowest elevation, the Streaked Bowerbird, is the smallest species. Archbold's Bowerbird, living at much higher altitude, is much larger than all true gardeners. Within the silky bowerbirds in the genus *Sericulus*, the upland-dwelling Adelbert (*Sericulus bakeri*) and Masked Bowerbirds are larger than the lowland Flame Bowerbird.

Adult female catbirds are on average nearly 10% lighter in weight than the adult males of the species. In most of the polygynous bowerbird species, the adult females are typically slightly smaller than their respective adult males, but adult females of three of the four *Sericulus* species have a mean size that is the same to slightly larger than that of the corresponding adult males. While most body proportions of adult bowerbird do not differ significantly between the sexes, there are a few exceptions. Adult male Archbold's and Golden Bowerbirds acquire a proportionately longer tail than that of their females, but adult females of the silky bowerbirds, of the Satin Bowerbird and of three of the five *Chlamydera* grey bowerbirds have a proportionately longer tail than that of the respective adult males. Juvenile and immature bowerbirds are generally smaller than subadults and adults of the same species, but there are, again, exceptions. These include younger males of the silky bowerbirds, of the Satin Bowerbird, and of the Spotted and Western Bowerbirds (*Chlamydera guttata*), all of which have an average tail length longer than that of the adults, and this situation is true also with regard to wing length in the case of the Regent Bowerbird. Adult

The avenue-building bowerbirds form one clade, and the maypole-building species another. Of the six maypole-builders, four are gardener bowerbirds, comprising the genus Amblyornis. *Each member of this genus is associated with a distinctive maypole bower form. Except in the* ***Vogelkop Bowerbird****, adult males of the otherwise brown gardener bowerbirds sport silky-textured erectile crests of bright orange or yellow, like that of* ***MacGregor's Bowerbird****. The sexes of the Vogelkop Bowerbird are alike in plumage, the female averaging fractionally smaller. Although the other congeners show sexual dimorphism in the presence or absence of the crest, nevertheless older female Streaked Bowerbirds* (A. subalaris) *may have one or several elongated narrow crown feathers, reminiscent of the male's crest. In MacGregor's Bowerbird, the subspecies* germana, *from the mountains of the Huon Peninsula, appears to build bowers that differ from those typical of other populations of the species. It has been suggested that* germana *might, in fact, constitute a separate species, the "Huon Bowerbird", but further study is required to confirm the details.*

Below: *Amblyornis macgregoriae macgregoriae*, Ubaigubi, EC New Guinea. Photo: William S. Peckover]

males of terrestrially displaying bowerbird species (see Breeding) typically have a shorter tail compared with that of their respective females.

Tarsus length in relation to wing length is typically uniform within a genus, the only obvious exception being that of the Regent Bowerbird. This has a shorter tarsus than that of its congeners, its tarsus measuring 26% of its wing length, compared with 29–30% for the rest of the *Sericulus* species. Bird species with proportionately longer legs are typically more terrestrial in habits, as illustrated by, for instance, the grey bowerbirds, whereas those with shorter legs, such as the Tooth-billed Bowerbird, are more arboreal.

Most members of the Ptilonorhynchidae have a relatively short, deep, robust bill and stout, powerful legs and feet. The four silky bowerbirds, however, are exceptional in having a relatively longer and finer beak, particularly so in the case of the Regent Bowerbird. The Tooth-billed Bowerbird is unique within the family in that it possesses a conspicuous notch, or "tooth", on the cutting edges of its upper mandible and several cusps and notches on the tip and cutting edges of its lower mandible. The bird uses the notched cutting edges to bite or tear leaf pieces and then to fold them into a compact wad prior to mastication; the functional cusps, which fit perfectly into indentations on the other mandible, are employed in a "chewing" action that enhances the digestibility of an item through crushing and grinding it.

The bills of the polygynous species are typically dark brown, blackish or black, but those of adult males of some sexually dimorphic species do display some colour. Adult males of the gardener and silky bowerbird groups have a pale bluish base of the lower mandible, while the entire bill is pale on adult male Satin Bowerbirds and is whitish on all adult catbirds. Adult male Regent Bowerbirds have a bright orange-yellow bill. The mouth colour of adult catbirds is black, but that of adult male Tooth-billed Bowerbirds is black with a sharply contrasting white anterior of the inside of the upper beak; females and immature males of the latter species have the mouth pale yellowish-flesh. The mouth of most other bowerbirds is orange-yellow or yellowish.

Generally, the iris colour of adult bowerbirds is dark to pale brown, that of juveniles being similar but paler and greyer. It is, however, red in adult catbirds and blue-grey in their juveniles. Adult males of the Golden and Satin Bowerbirds, along with the four silky bowerbirds, share a pale iris colour; that of the Satin Bowerbird being blue. While the iris of female silky bowerbirds is typically brown, that of some older individual females of the Regent Bowerbird may have variable amounts of yellow intruding into it. The legs and feet are typically dark brownish, olive-brown, olive, blue-grey or blackish, but those of the catbirds are a paler, brighter grey-blue, and those of the Vogelkop Bowerbird are distinctly blue, while Satin Bowerbirds have a much paler tan leg colour.

Bowerbird species are closely related to one another and, in terms of body proportions, postures, and general appearance, are generally more similar-looking than the member species of many other passerine families. Nevertheless, they do include strikingly diverse plumages. Within Ptilonorhynchidae there are some 50–60 plumages, as most species include a juvenile, an immature and an adult male and female, and some also a distinct subadult male stage. In the case of the catbirds, the Tooth-billed and Vogelkop Bowerbirds and the grey bowerbirds, the adult male and adult female are identical to each other, or nearly so. Thus, both sexes of all catbirds are similarly green above and spotted or streaked green to buff below, with conspicuous black and white facial markings, and both sexes of the Tooth-billed and Vogelkop Bowerbirds are generally brown. Other polygynous species are dramatically sexually dimorphic in plumage, adult males wearing brilliantly coloured feathering, decorated with an ornate crest or cape, while the females are drab. Excluding the Vogelkop Bowerbird, adult males of the other three, and otherwise brown, gardener bowerbirds in the genus *Amblyornis*, along with the all-black Archbold's Bowerbird, sport erectile crests of bright orange or yellow. Unlike closely related species, adult male Golden Bowerbirds are largely brilliant yellow, while the females and immature males are generally greyish-olive. Adult male silky bowerbirds, the *Sericulus* species, are brilliantly dressed in contrasting areas of black and intense reds or yellows, whereas the females and immature males are cryptically plumaged and with ventral barring. Other than being generally green, the plumages of female and immature male Satin Bowerbirds are intermediate in characters between those of the silky and the grey bowerbirds. The five *Chlamydera* grey bowerbirds are generally greyish to brownish.

Most bowerbirds forage alone, in pairs, or in small flocks. The Satin (Ptilonorhynchus violaceus) *and* ***Regent Bowerbirds*** *are exceptional in that they occasionally form aggregations of up to a hundred individuals; indeed, in the case of the Satin Bowerbird, groups may number several hundred birds. These large flocks are particularly associated with winter movements, when both species move to more open habitats in search of food. Usually these flocks are mostly of female-plumaged birds, which may include immature males, though up to 40 adult-plumaged males were observed in one flock. Smaller flocks may be mostly of a single sex.*

*Rainforest bowerbirds like the **White-eared Catbird** visit creeks and water-filled tree holes in order to bathe or drink. **Spotted Bowerbirds** visit water-holes and cattle troughs in their drier habitats. To maximize time at the bower, males drink water droplets from the forest floor and wet foliage. Water seems to be important for feather maintenance, as well as for drinking. When the Western* (Chlamydera guttata) *and Great Bowerbirds* (C. nuchalis) *are found in suburban gardens, there is usually water nearby. In a study of Tooth-billed Bowerbirds* (Scenopoeetes dentirostris), *males that rarely went more than 60 m from their bowers, travelled up to 400 m to find creeks to drink or bathe. After a brief rain shower, one adult male Golden Bowerbird* (Prionodura newtoniana) *foliage-bathed by flying into a wet sapling and briefly fluttering and hovering among the leaves. Other maintenance activities include preening, anting and sunning. Preening bowerbirds typically head-scratch indirectly, by raising a leg over the drooped wing on the same side, but Golden Bowerbirds also do so also by bringing a leg up directly beneath the wing.*

Males of the polygynous species advertise court or bower sites with special songs and other calls. These include vocal mimicry of other birds' calls, and other sounds from their environments. This ***Tooth-billed Bowerbird*** *is singing from a perch above his display court. The song of this species includes single squeals, screeches and chuck notes, and continuous babbling and mimicry. It is an excellent mimic, and at least 40 bird species, as well as frogs, fruit bats, crickets and cicadas have been identified among the sounds imitated. The Tooth-billed Bowerbird is silent during the winter. By contrast, all three of the socially monogamous, pair-bonding catbird species give their loud cat-like wailing and sneezing territorial songs throughout the year, although with far more insistence during breeding. Among males, the repertoire and quality of mimicry improve with age. Some species, such as the Satin Bowerbird* (Ptilonorhynchus violaceus)*, repeat a repertoire of the calls of other bird species in a specific order, and older males have been found to produce longer bouts of higher-quality avian vocal mimicry than younger ones. Females select the males which perform this mimicry well and also in the preferred order. Vocal mimicry by female bowerbirds at the nest is currently thought to be typical only of the avenue-builders, especially the Satin Bowerbird and the grey bowerbirds. Such mimicry is mostly, but not always, of predatory birds, and also non-avian sounds, including the mewing of cats. These calls could have the function of distracting a predator, or attracting other birds to mob it. They could also be a way of teaching offspring to recognize the calls of predators. Note that the "toothed" indentations on this bird's lower mandible are clearly visible.*

[*Scenopoeetes dentirostris*, Paluma, N Queensland, Australia.
Photo: Marie Read]

Vocal mimicry can be temporary and opportunistic. The male ***Golden Bowerbird*** *is among the species that mimic the call of another species in immediate response to hearing it, or even upon merely sighting an individual. Imitations of at least 20 bird species have been identified in the song and subsong of the Golden Bowerbird, along with mechanical noises. As well as domestic animals and human voices, sounds imitated by bowerbirds may include stock-whips, wood-chopping, Emus* (Dromaius novaehollandiae) *crashing through wire fences, and, increasingly among species in New Guinea, the sounds of chainsaws and of trees falling.*

[*Prionodura newtoniana*, Mount Lewis State Forest, Queensland, Australia. Photo: Günter Ziesler]

Colourful adult male plumage may involve one of several distinctive features. Thus, the four gardener bowerbirds and Archbold's Bowerbird possess an extensive and elongate brightly coloured, silky-textured, erectile crest, and the Spotted, Western and Great Bowerbirds have a similar but short crest restricted to the nape; males of the silky bowerbirds exhibit a strikingly contrasting black and brightly coloured plumage, and those of the Golden and Satin Bowerbirds have a brightly coloured glossy plumage. These features are presented during courtship displays (see Breeding). Forward-pointing loral feathering covers the nostrils of adult male Satin Bowerbirds, an unusual character that makes the bill appear short. This character is shared with some adult male gardeners and the Golden Bowerbird, but not Archbold's Bowerbird.

Juvenile plumage is much like that of the respective adult females, but is slightly duller and softer-textured, and is more barred ventrally in *Sericulus*, *Ptilonorhynchus* and *Chlamydera*, the ten species constituting the avenue-builders. An immature plumage even more like that of the adult female replaces the juvenile one in the first annual moult. In only a few species is this plumage discernible as being that of a young male, rather than that of an adult female.

Males of most perching birds, and possibly including the catbirds, acquire their adult plumage and breed within their first year or two of life. In contrast, males of those polygynous bowerbird species that do acquire brightly coloured adult plumage typically do so at five to six or seven years of age. This may involve some adult plumage colour intruding for a season or two into the female-like immature plumage worn for the preceding five or six years, the result being a subadult plumage, or the full adult plumage being gained by means of a single moult. Thus, promiscuous males of the bowerbirds, like those of other passerines that court at traditional focal displaying sites, exhibit delayed acquisition of visual adult male characters; young male Tooth-billed Bowerbirds, for instance, have a pale mouth interior for four or more years before the black colour typical of adults appears. So, males live among their conspecifics for half a decade or more before any sign of adult plumage becomes apparent. A subadult plumage, if worn, signals that the individual is not yet fully part of the highly competitive adult male community. Such a prolonged period in immature plumage could perhaps enhance a young male's opportunity to move within otherwise aggressive adult male society while gaining valuable experience. Moreover, as immature male plumages are cryptic, the deferral of adult plumage, which may be conspicuously colourful, presumably reduces the risk of attracting predators.

While bowerbirds have ten primaries and six pairs of rectrices, as do most passerines, they appear also to have between 11 and 14 secondaries, including the tertials, but further study is required in order to confirm this for all ptilonorhynchid species. Anything of significance with regard to bowerbird moult is known only for the Satin Bowerbird and, to a lesser extent, the Black-eared Catbird and the Tooth-billed and Golden Bowerbirds. As with most passerines, the primary moult of bowerbirds starts with the first, innermost primary and progresses in an outward direction from the body, simultaneously in both wings, the primary coverts being replaced in the same sequence as that of their corresponding primaries. Moult of the secondaries, including the tertials, begins when the first four or five new primaries are fully or nearly fully grown, again simultaneously in both wings. The tertials are replaced irregularly, and before the true secondary moult is completed. Tail moult begins during the early stages of the primary replacement, and is completed before all primaries have been renewed; it begins with the central rectrices and progresses simultaneously outwards to each side. The moult of the head and body feathers begins before the wing and tail moult commences, often finishing after the flight-feather moult is complete.

Habitat

Most bowerbirds, including the three catbirds, the Tooth-billed, Golden and Archbold's Bowerbirds and the *Amblyornis* gardeners, are predominantly confined to wet forests, or rainforests. The silky group and the Satin Bowerbird also occupy rainforest, but are strongly associated with rainforest edges, and the latter species also with adjacent sclerophyll wet woodlands. The five *Chlamydera* grey bowerbirds are the only real exceptions, as they have adapted to the drier, more open environments of riverine forests, open woodlands, savanna, and forest–grassland communities and, in Australia, to near-desert conditions. Lauterbach's Bowerbird of upland New Guinea and the Fawn-breasted Bowerbird (*Chlamydera cerviniventris*) of lowland New Guinea and extreme north-eastern Australia exhibit a preference for intermediate habitats, typically living at the edges, or within mosaics, of rainforest–grassland and rainforest–woodland communi-

Bowerbirds eat a great diversity of plant and animal foods. The food of adult ***Satin Bowerbirds*** *is mostly fruit and flowers when in season, and some animal food, mainly insects. But during the winter, when less fruit and fewer arthropods are available, leaves form a major part of the diet. This species "chews" leaf matter before swallowing it. During winter months, Satin Bowerbirds can be found in flocks of up to 200 individuals, which fly to pastures to graze on grassy shoots, white clover leaves and herbaceous plants. They also visit gardens, where they sometimes feed on green vegetables.*

[*Ptilonorhynchus violaceus violaceus*, Bunya Mountains, Queensland, Australia. Photo: Raoul Slater]

ties, respectively. In a few cases in which the ranges and habitats of two closely related polygynous bowerbird species overlap, hybridization between them may rarely occur (see Systematics).

In Australia, six ptilonorhynchid species live in the tropics and subtropics, mostly within rainforests at varying altitudes along the eastern escarpments and summits of the Great Dividing Range and the coastal lowlands to the east. The four grey bowerbirds found in Australia inhabit drier habitats predominantly to the west of the Great Divide. Many species are not adverse to exploiting human environments, including suburban parks, gardens, orchards and homesteads, if water and/or suitable foods are available.

It is within the Australian rainforests that most members of this family occur together, both monogamous and polygynous ones being involved. Tropical upland rainforests provide habitat that is shared by the Black-eared Catbird, the Tooth-billed and Golden Bowerbirds, and the small northern subspecies of the Satin Bowerbird. The last three of these are mostly confined to areas of the wet tropics over 600 m above sea-level, where they live sympatrically. The Black-eared Catbird occurs also in lowland areas, including Hinchinbrook Island, off the Queensland coast, and farther north on the eastern Cape York Peninsula. In contrast, the Golden Bowerbird can be found above about 350 m, but far more typically 680 m, and at up to 1260 m on Mount Bartle Frere, at the highest altitude for any bowerbird in Australia.

The Green Catbird shares subtropical rainforest with Regent and Satin Bowerbirds. The Green Catbird and the Regent

Seasonal availability of food, is the most important factor influencing bowerbirds' annual cycles. They do not use their feet to manipulate foods, and therefore eat predominantly fruits of the simple drupe or berry type. Species with overlapping ranges and habitat preferences may select different fruits, or use different forest strata when foraging. The Great Bowerbird (Chlamydera nuchalis)*, which is sympatric with the* ***Spotted Bowerbird*** *in northern Queensland, forages especially in fruiting fig* (Ficus) *trees. The Spotted Bowerbird forages more generally in fruiting trees and shrubs, and also visits gardens.*

[*Chlamydera maculata*, New South Wales, Australia. Photo: Greg & Yvonne Dean/ WorldWildlifeImages.com]

Bowerbird inhabit primarily rainforest interiors within the subtropics, whereas the Satin Bowerbird there is mostly a rainforest-edge species that lives also in adjacent eucalypt (*Eucalyptus*) sclerophyll forests and woodland. Green Catbirds and Regent and Satin Bowerbirds occur in both subtropical uplands and lowlands, the last-mentioned extending farther south into the temperate rainforests of the Otway Ranges of southern Victoria.

As already seen, the four grey bowerbirds living in Australia inhabit drier tropical and subtropical sclerophyll habitats, mostly west of the Great Dividing Range. Their habitats vary from eucalypt-dominated open forests to woodlands with paperbarks (*Melaleuca*), sclerophyll shrubs and/or a grassy understorey. The landscapes are dissected by river systems lined with denser to sparse riverine vegetation. The Fawn-breasted and Great Bowerbirds are sympatric in the northern Cape York Peninsula of north-east Australia. The Fawn-breasted is essentially a New Guinea species with a small outlier distribution in this extreme north-east part of Australia, where it inhabits pockets and galleries of vine forest, eucalypt woodlands and mangrove–grassland mosaics. At locations where the two species occur together, the Fawn-breasted Bowerbird is more frequently found in mangroves or adjacent *Melaleuca*-dominated habitats, while Great Bowerbirds prefer open woodland. The latter occurs extensively across the Australian tropics, as well as extending farther south in north-eastern Australia, on the east of the Great Divide, where suitable habitat exists. Its bowers are commonly built in riverine vegetation adjacent to riverbeds, which typically dry out seasonally. The Great Bowerbird is sympatric with the Spotted Bowerbird in some areas of northern Queensland where the favoured habitats of the two species overlap.

Spotted and Western Bowerbirds occur in the more semi-arid to arid habitats that extend south from northern Queensland into the subtropics of central and western tropical Australia. Spotted Bowerbirds favour open woodland with low dense shrubbery, under which the males build their bowers. The Western Bowerbird replaces the Spotted Bowerbird in central and western Australia, the former favouring areas close to water, such as river gorges with shady copses and the presence of rock figs (*Ficus platypoda*). Fig-fruit availability may to some extent dictate the distribution of Western Bowerbirds in more arid areas, as figs represent an important food resource.

One or both of the catbird species found in New Guinea may occur together with one or more species of polygynous bowerbird in a single habitat. Four pairs of closely related polygynous bowerbird species meet in parts of New Guinea where their otherwise typically separate altitudinal ranges abut or overlap, and they share the habitat. White-eared Catbirds and Flame Bowerbirds occur mainly in lowland rainforests. The former, a lowland-dwelling species, is replaced in hill forest by the Black-eared Catbird, the two occurring together in some limited areas. The Masked Bowerbird replaces the Flame Bowerbird at higher altitudes of the lower montane forest. The Streaked Bowerbird also lives primarily within the lower montane forest, MacGregor's Bowerbird replacing it at higher elevations of the middle montane forest. Vogelkop and Yellow-fronted Bowerbirds occur primarily in mid-montane forests, as does Archbold's Bowerbird at altitudes above 1750 m. The last-mentioned species occurs mostly above the altitudinal range of MacGregor's Bowerbird, but the two do share habitat in and below Tari Gap, in east-central New Guinea, at least. This higher-lying habitat is often referred to as cloudforest or moss forest, and patches of it are frequently interspersed with grasslands. Archbold's Bowerbird has been observed at 2850–3660 m above sea-level in the Ilaga valley of west-central New Guinea, the highest altitude recorded for any bowerbird.

Bowerbirds are not known to digest seeds, and they therefore serve as highly important seed-dispersers within their habitats, particularly about their courts and bowers, where they spend much time. The selection by bowerbirds of traditional sites for the court or bower and/or for the nest may locally influence habitat choice on a limited scale, and could potentially even bring about localized modification of habitat. Because male bowerbirds defecate large quantities of undamaged seeds around their bower sites, as well as caching entire fruits there for subsequent consumption (see also General Habits), it is conceivable that they indirectly propagate foodplants immediately around more traditional bower locations. As such sites pass from one male generation to the next, a local abundance of food would thus enable males to spend more time close to their bowers. Court-owners and bower-owners at such resource-rich sites would benefit in terms of the potentially maximized visitations by foraging females. Females may, in turn, nest close to traditional courting sites because of the local abundance of food, which they require in order to provision their offspring. This hypothetical scenario could create and enhance ecological "hot spots" within the habitat, males seeking these sites as preferred bower locations.

Flowers are taken by all species. They make up a larger proportion of the diet of subtropical than of tropical forest species, perhaps reflecting the greater variety and availability of fruit in the tropics. In drier habitats, Spotted (Chlamydera maculata) *and Western Bowerbirds* (C. guttata) *eat the flowers of acacia trees. The* ***Tooth-billed Bowerbird****, which eats a typical bowerbird diet of fruits, flowers, leaves and insects during the display season, is a leaf specialist in winter, when it spends long periods among dense canopy foliage, keeping silent and flying little. Its "toothed" bill enables it to tear, manipulate and masticate pieces of leaves and stems before swallowing them.*

[*Scenopoeetes dentirostris*, Australia. Photo: Roland Seitre]

*The **Regent Bowerbird** has a longer, finer bill than most bowerbirds, and is something of a nectar specialist. It also catches arthropods, primarily by gleaning and hawking. Arthropods form a significant part of the diet of adult and young bowerbirds. While bowerbirds obtain some of their insect prey, such as flying termites, by sallying, snatching or hawking, more typically they forage by searching and gleaning on live and dead foliage, tree branches and trunks, epiphytes, flowers, and forest-floor leaf litter. Large insects such as grasshoppers and beetles are carried to the ground, shaken and knocked violently to remove the wings, and torn to pieces.*

[*Sericulus chrysocephalus*, Kempsey, New South Wales, Australia. Photo: David Stowe]

Catbird pairs and the females of polygynous bowerbirds habitually use the same location, and often the same immediate site, in which to build the nest each year. Such traditional nesting possibly reflects local habitat suitability and/or limited availability of suitable sites. In addition to the excreting of intact seeds, the two catbird species in Australia, and possibly all catbird populations, store fruits, particularly figs. Again, this behaviour may result in the propagation of favoured foodplants within their traditional all-purpose territories, and perhaps specifically more so about traditional nesting sites (see also General Habits).

General Habits

For bowerbirds, the establishment of and attendance at the court or bower, as well as courtship, mating, nesting and moult, are in large part governed by climate. This is reflected in the relative availability of resulting food resources, both fruit crops and the abundance of arthropod populations, which are critical to sustaining birds through these energetically demanding aspects of their annual life cycles.

The annual cycles of bowerbirds in New Guinea are little understood, not only because information is limited but also because of the great variation in climatic regimes existing over their geographical and altitudinal ranges. Much more is known about the Australian species, particularly about those living in humid tropical and subtropical rainforest. Here, for the two species of catbird and the Tooth-billed, Golden, Regent and Satin Bowerbirds, the courtship and nesting seasons start as annual temperatures initially rise, typically during August to early September, although males may commence activity at bowers as early as June–July, especially at lower, and thus warmer, altitudes. The peak in courtship and nesting activity is mostly during late September to December, when temperatures and rainfall increase and when fruit, flying insects and forest-floor leaf-litter invertebrates are most abundant. Activities at bowers and nests terminate with the onset of heavy wet-season rains, the nestlings leaving the nests immediately before or during the early wet season. Food resources remain abundant during the wetter months, this period coinciding with that in which the female parents or, in the case of the catbirds, both parents are provisioning fledglings. Annual moult of the adults takes place mainly during December to March, reaching a peak during the wetter months of January to March, after the young have departed from the nests. Towards the end of the moult, immediately prior to the annually drier, cooler and leanest period within these habitats, the body weight and fat levels of bowerbirds increase.

Far less is known about the life history and cycles of the grey bowerbirds, which live in more open habitat, other than the fact that the display and breeding seasons are strongly influenced by seasonal, and far less predictable, rainfall. The peak nesting period for Australian grey bowerbirds typically precedes the annual monsoonal rains, during October to December or January, but this varies from year to year. Initial monsoon rains bring about a greater abundance of insects, mainly grasshoppers (Orthoptera), which primarily stimulate nesting by grey bowerbirds as they represent a large proportion of the diets of these species' nestlings. The availability of fruits of the rock fig may also be important in many areas (see also Food and Feeding). Hatching of the eggs coincides with the peak seasonal availability of larger insects. Typically, grey bowerbirds moult towards the end of the calendar year, following courtship and nesting. Some individuals, however, shed the wing and tail feathers at other times of the year, suggesting the possibility of overlap between their annual breeding and moult cycles, unlike the situation with the rainforest-dwelling species.

Aside from foraging, rainforest bowerbirds visit creeks and water-filled tree holes in order to bathe or drink, whereas grey bowerbirds visit water-holes and cattle troughs in their drier habitats. Males also drink water droplets from forest-floor leaf litter and wet foliage around their bower sites.

Maintenance activities have been recorded for several members of the family. After a brief rainshower, one adult male Golden Bowerbird indulged in foliage-bathing by flying into wet sapling foliage and briefly fluttering and hovering among the leaves. Other maintenance activities include preening, anting and sunning. Preening bowerbirds typically head-scratch indirectly, by raising a leg over the drooped wing on the same side, but Golden Bowerbirds, at least, do so also by the direct method, bringing a leg up directly beneath the wing to the head. Anting, involving the use of live ants (Formicidae) to anoint the feathers, is a relatively rarely observed activity of wild birds, but Tooth-billed, Golden and Satin Bowerbirds, at least, have been recorded as carrying out this type of behaviour.

Sunning is a well-known, widespread, but little-understood aspect of avian behaviour, one which has been observed for only a few bowerbird species. Adult male Black-eared Catbirds and Golden Bowerbirds occasionally adopt a sunning posture, with

the feathers of the breast, rump, head and nape erected, the tail pressed down and the wings drooped, when direct warm sunlight strikes them. One particularly interesting observation involved an aggregation of eight adult male and at least six "female-plumaged" Regent Bowerbirds which sunned themselves upon a semicircular area of 5 m by 1·5 m of open, and directly sunlit, leaf litter and on leafy perches above this. At any one time, up to eight of these individuals were squatting or lying on the litter in typical passerine sunning postures, this activity lasting for up to 15 minutes.

Catbird pairs cache fruits, as do the males of several polygynous bowerbirds, including MacGregor's, Golden and Great Bowerbirds, the stored food destined to be eaten at some future time. Their cache sites are unmodified tree crevices and branch forks, points of contact between epiphytic vines and trees, horizontal branches or large vines, the tops of tree stumps, fallen logs, the crowns of tree-ferns, crevices between fig roots, and similar suitable places. Golden Bowerbirds cache fruits also among forest-floor litter and beneath fallen timber. When first stored, fruits are usually ripe, but they may sometimes be unripe, and they occasionally rot or their seeds germinate (see also Habitat) at the cache site if they are not retrieved by the bird. The storing of fruits may function in maximizing the time that such food-caching males can spend at their bower site. There is no evidence to suggest that cached fruits serve as bower decorations, but some male Golden and MacGregor's Bowerbirds do "store" bower decorations around their bower sites.

Adult bowerbirds are preyed upon by diurnal and nocturnal raptors. As a consequence, they assume an anti-predator posture when they catch sight of a predator nearby. This generally involves nothing more than freezing on the spot, remaining perfectly motionless until the danger has passed.

The flight of these species is strong and purposeful and, over greater open areas, is conspicuously undulating. In normal flight the wings can produce an audible rustling sound, and the males of some species, when flying about their bowers, may produce a loud wing noise. Flights to fruiting trees are typically rapid and undeviating, the bower-owning males flying directly between their bowers and the feeding trees, and parents directly between their nests and the trees. Courtship flights are performed by a few species, the most remarkable being the butterfly-like Flight-hover display of the Golden Bowerbird; some simplistic "flight" displays between adjacent vertical saplings are performed by *Amblyornis* species (see Breeding).

Voice

All three of the socially monogamous, pair-bonding catbird species give loud cat-like wailing and sneezing territorial songs throughout the year, although far more so when breeding. The peak periods of their daily calling are in the early morning and the late afternoon. In addition, the individuals of pairs maintain contact by various sharp, high-pitched "tic", "tick", "tink" or "chink" notes. Vocal mimicry has not been reported for any catbird, either at or away from the nest and, since detailed studies of these species have been undertaken, it is unlikely that they ever do indulge in mimicry. Parent catbirds disturbed at the nest produce harsh scolding notes.

Males of the polygynous species advertise court or bower sites with special songs and other calls, including vocal mimicry of other bird calls and other sounds of their environments. These vocalizations are delivered from habitually used perches, typically immediately above or about the court or bower. Promiscuous adult males advertise the location of their court or bower mostly in the early morning and late afternoon, but by no means exclusively so during peak courting months. The Regent Bowerbird is unusual in that the males advertise bower locations from the forest canopy, and it is possible that other species in the *Sericulus* silky bowerbird group do likewise. Typical songs and calls of the polygynous species consist of variable far-carrying harsh, jarring, churring, chugging, rattling sounds, or deep and hollow whistled notes. Exceptions are the typical advertisement call of male Satin Bowerbirds, which is a clear, pleasant, briefly whistled song, and the distinctive prolonged rattle of male Golden Bowerbirds.

Promiscuous males perform vocal mimicry not only in court or bower advertisement, but also during courtship or upon seeing a potential predator. This may include imitation of the calls of other bird species, including those of predatory birds, and also of other environmental sounds, such as those made by domestic animals and by humans, and even human speech. During court-

Although adapted to drier habitats than other species in the family, grey bowerbirds like the ***Fawn-breasted Bowerbird*** *need to drink regularly. The four grey bowerbirds found in Australia will exploit human environments, including parks, gardens and homesteads, if food and water are available. Bowerbirds are not known to digest seeds, and they serve as important seed dispersers. By defecating large quantities of viable seed, it is possible that males help create a local abundance of suitable food plants around the long-term sites of bowers, which enables them to maximize time at their courts, and may in turn attract females to visit and nest.*

[*Chlamydera cerviniventris*, near Brown River, SE New Guinea. Photo: Brian J. Coates]

The three catbird species form long-standing monogamous pairs within an all-purpose territory. Courtship in the ***Black-eared Catbird*** *involves little more than hopping excitedly about perches by both partners, the male sometimes giving sharp calls. He often holds food in his bill, which he may pass to the female after mating. The dispersion of suitable fruiting trees is the key to the monogamous reproductive system of the catbirds. Figs* (Ficus) *form a significant component of the diet of both adults and nestlings. Fig trees tend to be relatively evenly dispersed throughout catbird habitats, providing predictable fruit crops, and a viable basis for territory-based pair-bonding.*

[*Ailuroedus melanotis maculosus*, Atherton Tableland, Queensland, Australia. Photo: Clifford & Dawn Frith]

ship, the males produce a soft, often continuous subsong of high-quality vocal avian mimicry. There is little doubt that males, if not also females, of all polygynous bowerbird species are competent mimics, and MacGregor's, Streaked, Vogelkop, Archbold's, Golden, Regent and Satin Bowerbirds, as well as all of the *Chlamydera* grey bowerbirds, are confirmed as being such. Moreover, vocal mimicry can be opportunistic, and male bowerbirds will mimic the call of another species in immediate response to hearing it, or even upon merely sighting an individual.

Vocal mimicry is fundamentally an aspect of behaviour acquired by learning and can, therefore, be passed on culturally. The relative age of males would appear to play a significant role in this, as both the repertoire and the quality of vocal avian mimicry improve with age. Among competing Satin Bowerbirds, for example, older males were found to produce longer bouts of higher-quality avian vocal mimicry than younger males, and as a consequence they gained higher mating success. When producing high-quality mimicry during courtship, male Tooth-billed and Satin Bowerbirds repeat a repertoire of the calls of other bird species in a specific order. The males must, therefore, remember both the bird calls and the sequence in which they are to be produced, as must the females, which preferentially select those males performing this mimicry well and in the preferred order. It appears clear, then, that sexual selection by females acts upon this form of vocal avian mimicry by bowerbirds to improve the males' song repertoire and quality.

At the present time, vocal mimicry by female bowerbirds at the nest is reported as typical only of the avenue-builders, and especially of the Satin Bowerbird and the grey bowerbirds. Such mimicry is mostly of predatory birds, evidently as a form of defence, but calls of apparently non-predatory birds have also been noted under such circumstances, as has the imitation mimicry of non-avian sounds. The latter imitations include a cat-like meowing by females of the Spotted, Western and Great Bowerbirds near their nests, cats being, of course, another potential predator.

It is conceivable that the mimicking by female bowerbirds near their nests of the calls of aggressive and predatory birds, and the same behaviour by males near their bowers, may in fact have the function of distracting a potential predator, which hears a call apparently given by one of its own kind. On the other hand, it could function in attracting other birds, which may then, in turn, mob the visiting predator. Another possibility is that, in mimicking calls of potential predators, as they approach, a female provides her nestlings with a species-specific alarm that any surviving offspring can associate with a specific danger, thereby increasing her own fitness by improving the chances of her offspring's survival.

Food and Feeding

Bowerbirds eat a great diversity of plant and animal foods. The seasonal availability of food resources, particularly fruit, is the most important factor influencing distances over which bowerbirds travel from their bowers and nests, their annual cycles, and their mating systems. Fruit forms the major part of the plant diet of these birds, but flowers, including buds, petals, stamens and nectar, and leaves, including buds, shoots, stems and petioles, are also consumed in various quantities, as are seeds and sap. In tropical rainforests, fruits represent 80–90% of the diets of Black-eared Catbirds and Tooth-billed and Golden Bowerbirds. Green Catbirds and Regent and Satin Bowerbirds, dwelling in subtropical rainforests, eat fewer fruits, which make up 65–80% of their diets, while their intake of flowers, leaves and/or animals is larger than that of tropical-rainforest bowerbirds. This difference could reflect the fact that there is a greater diversity of suitable fruits in tropical rainforests than is available in subtropical ones.

Selection of foods, primarily various combinations of fruits, and to a lesser extent the use of differing vertical forest strata and foraging sites, and/or behavioural differences, all result in ecological isolation, or niche differentiation, between sympatric rainforest-dwelling bowerbird species. Bowerbirds select fruits on the basis of their nutritional value, size, texture or colour, or the ease with which they are harvested. They utilize primarily those of the simple drupe or berry structural type, and figs, as opposed to better-protected capsular fruits, for which greater effort and manipulative skill are required, although these are consumed to some extent. Bowerbirds do not use their feet to hold and manipulate foods, and they are therefore unable easily to extract the edible "reward" from the protective husks of capsular fruits. Certainly, bowerbirds typically take arillate seeds from capsules

The brightly coloured ***Masked Bowerbird*** *builds a neat but relatively simple avenue bower, which it decorates with up to six blue or purple fruits, black bracket fungus, snail shells, and yellow to bronze leaves. The plain brown* ***Vogelkop Bowerbird*** *builds two different kinds of maypole bower in different parts of its range. In the Tamrau, Arfak and Wandammen Mountains in New Guinea, the bower is a complex hut-like structure 1–1·5 m tall and 2m in diameter. The roof may be formed of sticks or fern fronds, or more usually epiphytic orchid stems. The base of the sapling "column" is covered with moss that extends down and out to form a frontal mat or lawn. Mats may be decorated with discrete piles of different-coloured items. The Vogelkop Bowerbird lacks the bright yellow-orange crest of its congeners. MacGregor's* (Amblyornis macgregoriae) *and Yellow-fronted Bowerbirds* (A. flavifrons), *with their colourful crests, build relatively simple bowers. According to the "transferral effect" hypothesis, males of less ornate species of otherwise conspicuously crested bowerbird genera have lost the crest as they simultaneously evolved more complex bowers. Presumably these differences arose as a result of sexual selection by females for meaningful, externalized symbols of male fitness, namely the bower and its decorations. However, the populations of the Vogelkop Bowerbird in the Fakfak and Kumawa Mountains build a simple roofless structure similar to that of MacGregor's Bowerbird.*

after dehiscence, when the seeds are more easily accessible. A significant complication when assessing the nutritional content of fruits is the possible presence within them of insect larvae, because these can considerably augment the protein intake of frugivores.

The dispersion of suitable fruiting trees within the habitat is of great significance in understanding the differences between the monogamous reproductive system of the catbirds on the one hand and, on the other, the system of the polygynous bowerbirds. Fig fruits form a significant component of the diet of both adult and nestling catbirds. Fig trees are relatively evenly dispersed throughout catbird habitats in Australia, and present spatially and temporally predictable fruit crops: they provide a viable ecological basis for territory-based pair-bonding, which characterizes social monogamy. Unlike catbirds, however, polygynous bowerbirds feed mainly on highly nutritional drupaceous fruits of numerous plant species, the crops of which ripen over a longer period and are less evenly dispersed than are figs. Thus, the catbird system of a defended and exclusive all-purpose territory could not work for the primarily fruit-eating polygynous bowerbird species because, while a defended area may contain one or more fruiting trees in one month, it may have none in the next. Seasonal abundance of rainforest fruits allows court-owning and bower-owning male bowerbirds emancipation from nesting duties (see Breeding).

Bowerbirds typically forage alone, in pairs, or in small aggregations or true flocks, but Regent and Satin Bowerbirds are exceptional in that they occasionally form flocks of up to one hundred or, in the case of the latter species, up to about 200 individuals (see also Movements). The Ptilonorhynchidae are for the most part arboreal, foraging in the canopy and down to subcanopy foliage, branches, epiphytes and trunks. They do, however, also seek food on the ground, typically in forest leaf litter, especially the catbirds and the Satin Bowerbird.

The members of this family obtain fruits mostly while perching upright, or while leaning forwards or sideways to pluck and swallow the fruit whole and *in situ*. They may take several fruits during a single feeding bout. Some species, especially the Golden Bowerbird, will sally for fruits, snatching them while in flight; this method is used particularly for those on vines or for capsular fruits whose split husks expose the ripe contents. Large ripe fruits, such as those of some figs and climbing pandans (*Freycinetia*), may be torn apart and eaten on the spot. A few larger fruits, or bunches of smaller ones, are plucked and carried in the bill to a branch within the feeding tree, to be eaten there, or are taken away and stored for later consumption (see General Habits).

Australian bowerbirds swallow entire flowers, or their petals, buds, stamens, pollen or nectar, immediately where they seize them. The Regent Bowerbird includes a large proportion of flower product in its diet, taking mostly nectar; its longer, finer bill is better adapted to nectar-eating than those of other bowerbirds. Satin Bowerbirds feed on *Banksia* and *Grevillea* nectar and that of many herbaceous plants. In drier habitats, Spotted and Western Bowerbirds eat the flowers of acacia trees (*Acacia*). With the possible exception of the Golden Bowerbird, all of the Australian species eat some leaf material, as well as succulent leaf buds, stems and/or vine tendrils. Leaves form a major part of the diet of Tooth-billed and Satin Bowerbirds during the winter months, when fewer fruits and arthropods are available. The specialized bill of the Tooth-billed Bowerbird (see Morphological Aspects) enables it to tear, manipulate and masticate pieces of leaves and leaf stems. During the winter, this species remains among dense canopy foliage, keeping silent and flying little, and it is then predominantly leaf-eating, or folivorous. With the return of spring and summer, when fruits again become abundant, Tooth-billed Bowerbirds revert to a mostly frugivorous diet. Similarly, Satin Bowerbirds eat much more foliage during the winter, and "chew" leaf matter before ingesting it, but they have an only slightly notched bill. Black-eared Catbirds and Satin Bowerbirds will occasionally consume tree sap, but seed-eating by bowerbirds is rare, there being just a few records of this for the Green Catbirds and the Regent, Satin, Spotted and Great Bowerbirds.

Arthropods, mostly insects, form a significant part of the diet of adult and young bowerbirds, especially during courtship and nesting periods. Insect groups widely exploited by this avian family include grasshoppers and their relatives (Orthoptera), cicadas (Cicadidae), beetles (Coleoptera), caterpillars, ants (Formicidae), cockroaches (Blattodea), mantids (Mantodea) and stick-insects (Phasmida). When one of these birds captures a larger cicada, it typically carries it in its bill to the ground, where it shakes and knocks off the insect's wings and tears its body into small pieces for eating. Flying termites (Isoptera) are also eaten by ptilono-

*As an alternative to thatched hut-like or tepee-like structures, a maypole bower may consist of a perfectly circular mossy "bowl" with a roughly conical central tower of sticks, up to 3 m tall, like this **MacGregor's Bowerbird** bower. Traditional maypole-bower structures may, with seasonal renovations, persist for more than 20 years. At the beginning of a season, males typically renovate and add to their maypoles of the previous season. The typical bower "style" of a species is partly learnt, and the significant geographical variation in structures, especially as seen among isolated populations of MacGregor's and Vogelkop Bowerbirds, is a reflection of such actively transmitted behaviour.*

[*Amblyornis macgregoriae kombok*,
Tari Gap, New Guinea.

rhynchids, and worms (Annelida), frogs (Anura), skinks (Scincidae), and pieces of birds and their eggs are also included in the diet of some bowerbirds. The members of this family obtain some of their arthropod prey by snatching or sallying, or take them in the air by hawking. More typically, however, they forage for invertebrates by searching and gleaning in such places as live and dead foliage, tree branches and trunks, epiphytic plants, flowers, and forest-floor leaf litter.

The relative proportions of fruits and animals fed to nestlings vary from one ptilonorhynchid species to another. Nestlings of the rainforest species are fed with a greater proportion of fruit, but the nestling diet of the drier-country grey bowerbirds contains slightly less fruit than it does arthropods. Of the animal items fed to nestling bowerbirds, insects are the most important. Females of each polygynous bowerbird species tend to feed the young with a single animal type, such as cicadas, grasshoppers or skinks, as the dominant component of their nestlings' diet. Cicadas and beetles are foods of major importance to adult and nestling forest-dwelling bowerbirds, whereas orthopterans, particularly grasshoppers and locusts (Acrididae), are more important to the grey bowerbirds of drier habitats.

When provisioning their young, parent bowerbirds carry food items along the length of the bill and in the mouth. Unlike the birds-of-paradise, they do not regurgitate them. Both fruits and animals are fed to nestlings of all ages. In the case of predominantly frugivorous parents, the proportion of insects which they feed to their nestlings is greatest in the period just after hatching, and declines thereafter. Once nestlings reach a certain age, however, their dietary needs can probably be provided for by a selection of fruits, some of which are relatively rich in protein and lipid.

During the display and breeding seasons, one to several individuals of a bowerbird species may forage in the canopy of a single fruiting tree, especially a fig tree. Bowerbirds will often feed alongside individuals of other bowerbird species, and other fruit-eating bird species, such as fruit-doves (*Ptilinopus*), but typically they interact little with other foraging birds, although they may occasionally displace them. Aggressive encounters between foraging individuals of a species do occur, but rarely. Regent Bowerbirds are the most aggressive and the most successful in displacing other fruit-eating birds that are attempting to feed in the same tree, including larger species such as Green Catbirds and Satin Bowerbirds, as well as Topknot Pigeons (*Lopholaimus antarcticus*).

Breeding

All three catbird species are socially monogamous, pair-members reproducing together for one or more years within a defended all-purpose territory. Male catbirds do not participate in the tasks of nest-building, incubation of the eggs and the brooding of the nestlings, but they do assist in provisioning the mate and offspring with meals. Catbirds have no court or bower, and their courtship is simplistic. Males hop rapidly back and forth between perches, usually with food in the bill, with no ritualized posturing. They appear not to use their dark mouth pigmentation in courtship displays.

The remaining 17 bowerbird species are polygynous, each promiscuous adult male using advertisement calls and/or colourful plumage to attract females to his court or bower site, where he courts and mates with as many females as possible during each breeding season. Females of these polygynous species undertake the tasks of nest-building, incubation of the eggs, and brooding and provisioning of the offspring entirely alone, unaided by the father. The sophisticated actions of building, decorating, collecting, arranging, thieving, singing, posturing and dancing of promiscuous males at their court or bower are all designed primarily to attract and impress females so that the male may mate with them before they go to nest.

With regard to polygynous species, it is important that the word "bower" be applied only to structures that the birds physically build. The Tooth-billed Bowerbird court is an area of ground that is merely cleared of litter, and does not involve any construction. The remaining 16 polygynous species build a bower, of which there are two basic structural types: maypoles are constructed by members of the genera *Amblyornis*, *Archboldia* and *Prionodura*; and avenues are built by *Ptilonorhynchus*, *Sericulus* and *Chlamydera* species. Courts and bowers are cleared or built and maintained only by male bowerbirds, and they have nothing to do with nests and nesting. A court or bower may be cleared or built at the precise spot upon which that of the previous season

*Male **Macgregor's Bowerbirds** are non-territorial except in defence of the bower. These two males are keeping the maypole between them, in a manner reminiscent of the "hide-and-seek" courtship display of this species. Traditional bower sites are chosen for their advantageous positions, and are well known to females, which may return to a bower where they have been courted. The incumbent male may occupy a site for up to 20 years, presenting a formidable challenge to younger males. Unless the older male dies or disappears, the aspirant will have to confront him in his bower. Males with established bowers may also challenge others to improve their location or status.*

was situated, or it may be located on a different spot but within the same traditional court or bower site. Courts and bowers are not situated randomly within habitats, but are on spots having favoured topography and with immediate environmental features that include one or more of the required characteristics. These could involve appropriate foodplants, saplings, perches, light conditions, foliage cover, and similar criteria. To date, this aspect has received little attention from ornithologists.

The location of a court or a bower is referred to as a "site", the court or bower site of a male representing the focal point upon which almost all sex-related activities of adult and immature males and females are concentrated. Sites may be "traditional" ones, persisting for years and potentially up to many decades, or rudimentary ones, which rarely persist for more than a single season. Unlike the structures of bower-building species, the traditional courts of Tooth-billed Bowerbirds are not so evenly dispersed but, instead, exhibit a tendency to be clumped and thus potentially to form exploded leks. Studies suggest that male Tooth-billed Bowerbirds holding traditional sites at the heart of an aggregation of courts are older and more dominant individuals, with higher mating success than that of their peripheral rivals. The advantages to a male of taking over a longer-term, centrally located, traditional court site would, therefore, involve improved status for him and the possibility that females may return to the site where they were previously successfully courted. The latter holds true also for the traditional bower sites of the bower-builders. For all species studied, traditional bower sites are evenly dispersed through suitable habitat, the fairly regular distances between them being maintained by the social interactions of competitive males. As a result, court and bower sites and, in the case of some maypole-builders, even specific structures are attended by generations of males.

Before acquiring adult plumage, some older immature or subadult males may establish rudimentary sites by clearing an inferior court or by constructing a crude bower, typically located close to a traditional one. The young male, however, attends such a site only irregularly, and abandons it once he is evicted by a locally resident adult male or when he acquires a traditional site of his own. Studies of Tooth-billed, MacGregor's, Archbold's, Golden, Regent, Satin, Spotted and Great Bowerbirds suggest that female-plumaged, immature males undergo an "apprenticeship" of 5–6 years, spent in visiting rudimentary, or practice, courts or bowers of their own making, as well as the bowers of older males, while gaining experience of decorating and thieving, building, bower attendance, displaying and vocalizing, before attempting to establish or take over a traditional site. Once a male has established occupancy of a site, he can ill afford to be deterred from attending and defending such a hard-won asset that is so fundamental to his potential reproductive success, and males do, indeed, exhibit extremely high fidelity to sites.

Male Tooth-billed Bowerbirds clear a forest-floor court and then decorate it with leaves, placed with the paler underside facing upwards. Each court encompasses the trunk of at least one small tree as a "display tree". The maypole-builders accumulate numerous orchid stems or sticks and stack them around a vertical sapling or tree-fern trunk(s), or upon horizontal perches above a bower "mat" made of mosses, rootlets or fern fronds. Piles of bower decorations are placed on this mat. Maypole bowers include diminutive thatched hut-like or tepee-like structures of orchid stems, sticks or mosses and perfectly circular mossy "bowls" with a roughly conical central tower of sticks.

There are three basic maypole types. A simple tower of sticks is built by Golden, MacGregor's and Yellow-fronted Bowerbirds and by the Fakfak and Kumawa Mountains populations of the Vogelkop Bowerbird. The Streaked Bowerbird and the populations of the Vogelkop Bowerbird living in the Tamrau, Arfak and Wandammen Mountains construct a roofed tower of sticks. The third basic type is the dispersed maypole of Archbold's Bowerbird. Golden Bowerbird bowers consist of one or two tall and bulky stick towers, usually terrestrial, but these are uncommonly arboreal, with the bower perch up to 2 m above the ground. That of Archbold's Bowerbird is an amorphous structure that may reach up to 2 m above the ground and occupy a large surface area and volume. Maypole bowers, particularly those of Archbold's and Golden Bowerbirds, are individually more variable in size, design and materials than the bowers of avenue-builders. Traditional maypole-bower structures may, with seasonal renovations, persist for more than 20 years. At the beginning of a season, males typically renovate and add to their maypoles of the previous season.

*The **Streaked Bowerbird** builds and decorates a complex, tepee-shaped maypole bower. The bower has back and side walls, and a semicircular tunnel-like passage around the maypole column, with entrances on either side, facing the front. Decorations used by this and other rainforest bowerbirds include flowers, fruits, fungi, lichens, seedpods, beetle wing-cases and other insect debris, feathers and bones. Precisely where on bowers the decorations are placed is, with some individual variation, characteristic of each genus and species.* Amblyornis *gardener bowerbirds typically decorate their bower mat and maypole-column base. The Streaked Bowerbird also decorates the parapet in front of the mat.*

[*Amblyornis subalaris*, New Guinea. Photo: Clifford & Dawn Frith]

*This **Vogelkop Bowerbird** bower is of the more elaborate hut-like type, for example built by the Arfak mountain population of this species. The bower mat is decorated with fruit, fungi and some discarded human artefacts, sorted into discrete piles according to size and colour. Males strongly favour items of a certain size, shape, texture and colour for their bower decorations. Regardless of location and decoration type, male Vogelkop Bowerbirds have been found to favour blue, black and orange objects. Although the males of some species, such as the Regent Bowerbird* (Sericulus chrysocephalus), *use only one or a few kinds of decoration, most species use many kinds. The relative abundance of decorations enables females to assess the quality, or fitness, of individual males. The colour and quantity of decorations vary from one Vogelkop bower to another, and males steal items from each other, and indeed will also destroy one another's bowers. Recent research suggests that females of some species may select those males that use decorative items that in natural conditions are rare.*

Below: *Amblyornis inornata*, Irian Jaya. Photo: Richard Kirby/ naturepl.com]

An avenue bower typically consists of two walls of sticks or grass stems placed parallel to each other and nearly vertically into a foundation mat of sticks and or grasses laid upon the ground. The bowers of the *Sericulus* silky bowerbirds are small, frail and sparsely decorated avenues, while those of the Satin, Western, Spotted and Great Bowerbirds are increasingly larger, stronger and more decorated, respectively. The basic avenue bower of the Fawn-breasted Bowerbird is enhanced by the fact that it is built upon a raised, and sometimes conspicuously substantial, basal platform of sticks. That of Lauterbach's Bowerbird, beyond being built on a raised basal platform, is further elaborated upon by the addition of two walls at right angles to those of the central avenue, forming more of an open-topped box-like structure.

Avenue bowers of the Satin Bowerbird and the *Chlamydera* grey bowerbirds are refurbished and reused or are replaced at their traditional sites annually. In marked contrast, two-thirds of the bowers of Regent Bowerbirds are maintained for fewer than eleven days. It is thought that this is because, if intruding males do not destroy the bowers of rivals, the bower owners, having become aware of the discovery by rivals, typically destroy or abandon their own bowers. Some avenue-builders have their bower structures influenced by the activities of males of another species. This rare and geographically limited situation is known to have involved pairs of Regent and Satin Bowerbirds, Satin and Spotted Bowerbirds, and Spotted and Great Bowerbirds in Australia and, in New Guinea, Lauterbach's and Fawn-breasted and probably also MacGregor's and Streaked Bowerbird and Masked and Flame Bowerbird pairs in New Guinea.

In the case of those species that decorate an extensive area at one or both ends of an avenue bower, the avenue formed by the two walls of such bowers is very often aligned to a particular compass orientation, usually north–south. This orientation enhances illumination of the bower decorations and male courtship displays, as viewed by females from within the bower avenue.

The typical bower "style" of any particular species is partly learnt by individuals, and the significant geographical variation in structures that has been noted, especially among geographically isolated populations of MacGregor's and Vogelkop Bowerbirds, is a reflection of such culturally transmitted behaviour. Typically, only leaves are used in decorating Tooth-billed Bowerbird courts. Among other things, leaves are used as bower decorations by several maypole-builders and avenue-builders. Other polygynous species decorate their bowers with a broad array of natural and, when available, man-made objects. Decorations used by rainforest bowerbirds include flowers, fruits, fungi, lichens, seedpods, insect frass, insects and their cast old exoskeletons, feathers, bones, and mammal skulls. The grey bowerbirds favour paler decorations, such as bones, stones, shells and glass. Natural experiments at bowers demonstrate that males of different species favour different colours or objects, such as mammal skulls, mammal dung, snail shells, beetle wingcases, orchid flowers, tree resin, parrot (Psittacidae) feathers and so on.

Precisely where on bowers the decorations are placed varies among the species and is, with some individual variation, characteristic of each one. Males show great discrimination in the matter of where and how their decorations should appear. Gardener bowerbirds, constituting the genus *Amblyornis*, typically decorate their bower mat and maypole-column base, some also hanging insect frass from the ends of lower maypole sticks. Items are often placed on the bower mat in discrete piles, while some are put on perches above the bower area. Grey bowerbirds, in the genus *Chlamydera*, lay certain items in discrete piles on particular parts of the bower or immediately around it. Regent Bowerbirds, and perhaps other species in the *Sericulus* silky bowerbird group, put decorations almost exclusively on the floor of the bower avenue, whereas Satin Bowerbirds place them only on the platform outside the avenue entrance.

Males strongly favour items of a certain size, shape, texture, and/or colour for bower decorations. Although the males of some species use only one or few kinds of decorations, as do, for example, Regent Bowerbirds, those of most species use several to numerous kinds. Such decorations can be present in numbers greater than 5000 on a single grey bowerbird bower. The relative abundance of decorations enables females to assess the quality, or fitness, of individual males on the basis of their relative success in conflict with rival males, as rivals steal decorations from one another. Some recent research suggests that females of some species may select those males which use decorative items that are rare in nature. Other recent work revealed that the decorations most favoured by one population of male Satin Bowerbirds

Maypole bowers are individually more variable in size, design and materials than the bowers of avenue-builders. Those of the ***Golden Bowerbird*** *are particularly variable, consisting of one or two tall, bulky stick towers built around a pre-existing perch consisting of a woody vine, sapling, fallen branch or tree root. The perch is used both by the displaying male and the visiting female. The bower may be at ground level or, more rarely, in the trees, with the perch up to 2 m above the ground. Decorations mainly comprise grey-green lichen, but may also include creamy-white flowers and fruit.*

*The **Great Bowerbird** uses snail shells and vertebrate bones among its bower decorations, sometimes bringing them from a considerable distance. One Great Bowerbird used the shells of mudflat-dwelling snails which were not found within 2 km of his bower. In a sample of bowers near Darwin, Australia, the number of decorative items at each bower varied from 6000 to more than 12,000, the majority being white or grey. The combined weight per bower ranged from 6 kg to over 12 kg, with the heaviest individual items weighing 40 g. Great Bowerbirds' avenue bowers are built 1–2 km apart on traditional sites, one of which is known to have been used for more than 70 years. The same structure may be used in consecutive years, or the bower may be rebuilt each season, either under the same bush or under another up to 100 m away. Bowers abandoned after years of use may sit around an active site. The bower is a thick-walled avenue of stout sticks, built upon a substantial platform, with some 700–920 sticks in a single wall. The tops of the inward-curving central inner walls sometimes meet to form a tunnel. Rarely, bowers may have a third or even a fourth wall. Bowerbirds will copy and learn from one another: after one Great Bowerbird began to introduce red objects among his decorations, others began to do so, and red objects are now part of the local Great Bowerbird culture. Other populations of this species actively avoid red objects. In rare instances, Great Bowerbirds have also had their bower structures influenced by males of another species.*

*The male **Fawn-breasted Bowerbird** builds a new bower every season, close to the previous one. The avenue is built on a deep platform of sticks, which extends out beyond each end of the avenue to form elevated apron platforms. One of these apron platforms is usually larger and better formed than the other. The base platform can be up to 170 cm long, 80 cm wide and 60 cm thick. The walls of the avenue are up to 36 cm long and 28 cm high externally, with the central avenue 9 cm wide. One hundred or more bower decorations may be placed in and at the end of the avenue, and hung from the walls. These can include green fruits, normally in small bunches, seed pods, unopened flower buds, and green leaves. This male (below, right) is "painting" the inner avenue wall of his bower, an activity typical of several, possibly all, avenue-building species. The "paint" may be charcoal or vegetable matter mixed with saliva; it dries to a dark powdery deposit. Males can invest considerable time in painting. Its function has not yet been satisfactorily explained, but it might be that freshly applied paint has the effect of assuring females that a bower is actively maintained, and the extent of it may provide females with an indication of the relative attendance of males at their bowers.*

[Above: *Chlamydera cerviniventris*, Portland Roads, N Queensland, Australia. Photo: Clifford & Dawn Frith.

Below: *Chlamydera cerviniventris*, Port Moresby, SE New Guinea. Photos: William S. Peckover]

were darker blue and reflected higher levels of ultraviolet light than less favoured ones; these features increase the visual contrast between decorations and the substrate on which they are placed and/or between the different kinds of decorations.

Not only do the males of some, if not all, of the avenue-building species build and decorate their bowers, but they also apply to the bower walls a "paint" of charcoal and vegetable matter mixed with saliva. In applying this paint, the Satin Bowerbird and some grey bowerbirds will use a piece of vegetable matter as a "brush" or tool; this, in fact, acts as a kind of sponge, wedge or stopper, rather than as a brush. The paint stains the inner avenue walls at about the beak height of the standing bird, and it dries to a dark powdery deposit. That bower-painting is an activity in which males of several avenue-builders invest considerable time raises the question of its function. Several suggestions have been made, but none of these is really a satisfactory one. It seems possible that freshly applied paint has the effect of assuring females that a bower is actively maintained, and the extent of it may provide females with an indication of the relative contemporary attendance levels of males at their bowers.

During the display season, adult males spend a great deal of time at their traditional court/bower site, vocalizing, maintaining the site, which involves building, painting and decorating, chasing away rivals, displaying, with or without another bird present, and courting and mating females. Courtship is instigated by the arrival of a female at the court or bower site, presumably having been attracted by the male's vocalizations. A female's arrival often results in the attending male initially moving away from her, as is so with the grey bowerbirds, or hiding from her view, as in the case of the Tooth-billed and Golden Bowerbirds and the gardener bowerbirds. Whereas male Tooth-billed and Golden Bowerbirds hide behind trees, male gardeners and avenue-builders use parts of their bowers as places behind or within which to hide. The Regent Bowerbird and, possibly, other species of silky bowerbird attract females by means of their colourful plumage and by calling in the canopy, and then lead them to the bower.

Females, while being courted, observe the male passively and silently. Catbirds typically, and other species occasionally, watch in this way from a perch; female Tooth-billed Bowerbirds observe from the court; those of Archbold's Bowerbird and the gardeners from the bower mat; those of the Golden Bowerbird from a bower perch; and females of avenue-builders watch from within the avenue. The males of most species commence courtship displays on the ground, but in the case of some gardener bowerbirds some simplistic "flight" displays between adjacent vertical saplings are sometimes performed first. Males typically court by demonstrating highly ritualized postures and movements accompanied by specific body, head and wing movements and particular calls. They may use decorations as display "props" held in the bill or, as is typical of avenue-builders, tossed towards the female. Latter components of male courtship can appear aggressive, often resulting in a female temporarily or permanently fleeing. Males sometimes perform "courtship" display in the absence of any conspecific, and this may be directed at the bower or its decorations. If a female is unimpressed or frightened by a male's advances, she leaves the bower site, sometimes pursued by the male. If suitably impressed by a male's courtship, she makes her readiness to mate known by solicitation posturing, which typically involves her in crouching, raising the hindquarters and tail, and vibrating the drooped wings. Mating normally takes place on the court or bower. Immediately following copulation, females vigorously flutter their partly opened drooped wings, but it is not known if this has a signal function or a physiological one. Males sometimes aggressively expel females from their court or bower immediately after mating.

Bowers and their accumulated decorations are truly symbolic of each individual male's efforts, and therefore of his relative genetic fitness and experience and, accordingly, his age or survival ability. A bower represents characters of a male bowerbird's sexuality that are external to his body. Upon the arrival of a female at these symbols of relative male attractiveness and fitness, the male dances complex steps in an attempt to attain its all-important goal, a successful mating. It is sexual selection, of male traits by females, that has brought about the amazing and uniquely complex courtship behaviour of male bowerbirds. A reasonable to good amount is known of the courtship of twelve of the 17 polygynous bowerbird species. In contrast, next to nothing is known of that of the Yellow-fronted, Masked and Western Bowerbirds, and nothing at all of courtship of the Adelbert Bowerbird. Limitations of space prohibit detailed descriptions of all of the displays that have been described. The following paragraphs, therefore, provide a broad summary, but, as the main

*The courtship of the **Western Bowerbird** is believed to be similar to that of its congeners. The Spotted Bowerbird* (Chlamydera maculata) *performs both central displays, in which the male stands among the decorations outside the bower with his crest raised, and displays in which he runs around the bower in wide circles. The Western Bowerbird's courtship is known to involve the Nape-presentation Display, in which the male presents his crest to the female. All three* Chlamydera *species with crests perform this display, but the two which lack crests also present their napes. It has been suggested that the latter species lost their crests while simultaneously developing more complex bowers.*

[*Chlamydera guttata*, Alice Springs, Northern Territory, Australia. Photo: Don Hadden]

features tend to be fundamentally similar within a genus, the courtship display of the best-known species of each is detailed.

Tooth-billed Bowerbird courtship commences with a male dropping on to his court and hiding behind his display-tree trunk to continue singing. If an approaching bird is a female, he changes his song to a subsong with vocal avian mimicry. When the female reaches the court, his vocal display suddenly becomes a vigorous visual display. He hops out from behind the tree to reveal a black mouth that strikingly contrasts with his white mandible linings, and he erects a conspicuous white "beard" of throat feathers. His initial side-hops are accompanied by a rapid swing of his closed tail upwards and sideways through an arc, in the same direction as that in which he hops. During the first side-hops the wings are closed or open, or sometimes both, but then the folded wings are rapidly lifted vertically above the side of the bird and the primaries rapidly flicked skywards. Each sideward hop consists of a double movement, or an immediately repeated hop, to the same side, the tail held pointing in that direction. Following side-hops, the male performs the first of a series of vigorous Leap/Wing-flaps, consisting of leaning progressively forwards with bill wide open, until lunge-leaping forwards at his point of imbalance. As he lunges forwards, his wings are fully opened and raised to 45 degrees or more above his back, and then beaten downwards as he leaps forwards and sideways, landing as his wings close. He then performs repeated Leap/Wing-flaps, interspersed by a sideward hop, in a zigzag progression towards the female. During the entire visual display, the male continues his subsong of vocal mimicry, punctuating it with a sharp, harsh, burring snort-like note and with "tuck-tic" notes during Leap/Wing-flaps. After this display to a point immediately in front of the female, he quickly flies to her, either directly or via one or several perches, and copulates. Copulation is aggressive, and during the process the male rapidly flaps his open wings while rocking from side to side and holding or billing the female's nape feathers.

Upon detecting a female near his bower, a male MacGregor's Bowerbird may initially simply raise his crest while rising up on stretched legs to sway his body from side to side, or he may perform an extra-bower display by leaping rapidly between vertical sapling trunks within 1–15 m of his bower. During these back-and-forth leaps, he flaps the wings once or twice and holds the crest erected and fanned. He then flutters or drops on to his bower mat to continue courtship. He hides from the female by moving behind the base of his central maypole, where he stands stiffly, with the beak and head pointing up and the breast pressed towards the mossy column base, with the crest in the normal position, and may begin a subsong of soft whirring or "zishshing" vocalizations, usually audible only from a few metres, that typically includes high-quality vocal mimicry of other birds. While emitting the subsong, he may give repeated simultaneous brief wing-flicks while laterally spreading the tip of his crest, each time accompanied by a sharp little hop; this sudden movement results in a split-second flash of crest colour. This point in the display is sometimes punctuated by a short, brief, forward and upward fluttering flight, rising to some 1–2 m, the male then immediately returning to his take-off point. If the female remains interested, she flies down to the mat, to the side of the maypole opposite that where the male is, and attempts to peer, lean or move to either side of the maypole in order to see him; he attempts to keep out of her sight by moving around the circular mat. This hide-and-seek vocal display continues until, suddenly and rapidly, the male changes his elusive behaviour to a visual display. He fully erects and fans his crest and simultaneously starts to sway extensively from side to side on extended legs, thus giving the female glimpses of his crest alternately on each side of the maypole. Suddenly, he rushes at the female from around the maypole in a rapid semicircular dance of mincing steps, his initial rush sometimes causing her to fly to adjacent foliage. If not, he rushes equally rapidly back and past his starting point, only to rush at her again from the other side of the maypole. This repeated movement is extremely rapid, and the female may initially try to maintain her distance from him by moving away in harmony with his rushes, attempting to keep the maypole between herself and him, or she may remain static throughout the visual display. If a female stands her ground in the face of these rushes, mating may occur.

The advertisement vocalizations of the male Archbold's Bowerbird, given from bower perches above his bower mat, become more frequent and intense and then, when a female is near, softer. By the time a female is on a bower perch, he drops on to his mat to commence courtship. First, he lowers his elongated and sleeked body to prostrate himself on lowered legs and press his underparts into the mat, his crest slightly fanned and his forecrown feathering erect and fanned. In this Prostrate posture,

Some grey bowerbirds make vigorous use of bower decorations during their displays. The peripheral displays of the ***Great Bowerbird*** *involve a strutting walk or run around the bower, during which the bird may pick decorative objects up and fling them down. The central displays, performed at the bower entrances, include an Upright posture, with feathers sleeked and bill open, Forward-stretch and Crest-presentation. The displaying male repeatedly darts rapidly forwards towards the silent female, which crouches motionless within the avenue, and then moves back again, often picking up decorations and aggressively shaking them from his bill.*

[*Chlamydera nuchalis nuchalis*,
Northern Territory, Australia.
Photo: Michael Gore/FLPA]

The avenue bower of ***Lauterbach's Bowerbird*** *is unique in having four walls. At each end of the main avenue, the platforms are elaborated into additional walls that create cross passages at right angles. The two inner walls are the shortest, and are lined with fine grass stems. Male Lauterbach's spend a lot of time "painting" the walls, and decorating the bower with grey and grey-blue river pebbles, large blue fruits, and medium-sized red fruits. When a female comes to the bower, she enters the main avenue and waits, generally without movement, except to turn her head from time to time, although she may pick at the sticks in the walls. The male approaches the entrance she is facing, remaining to one side, and leaning so that his head comes into her field of vision. He turns his head away in the Nape-presentation Display —although he lacks the crest of other members of his genus which perform this display. He often jerks his head sharply up and down. He may interrupt this display to present the female with decorations, such as red fruit, and he may also hold decorations in his bill while displaying. He accompanies his display with soft, "pathetic" calls. Presumably in response to the female's soliciting, he suddenly stops displaying, and runs round to enter the far end of the avenue, and mounts the female. During copulation (lower photo), he flaps his open wings. Courtship may take just a few minutes before copulation, or may last more than half an hour. The male may interrupt courtship to chase away other conspecifics, and the female may remain in the avenue while he does this.*

[*Chlamydera lauterbachi*, Baiyer River Valley, New Guinea. Photos: Clifford & Dawn Frith]

Recent work has revealed that the decorations most favoured by one population of male ***Satin Bowerbirds*** *were darker blue and reflected higher levels of ultraviolet light than less favoured ones. Two hundred or more decorations may be placed on the platform outside one or both avenue entrances. These can include natural objects (upper photo), such as feathers—mostly blue, notably flight-feathers of Crimson Rosellas* (Platycercus elegans) *—as well as flowers, fruits, snail shells, insect parts and pieces of sloughed snakeskin. Bowers closer to human settlements can include man-made items (lower photo), again with a preference for blue objects. In contrast to the decorations of* Chlamydera *bowers, these are not put in discrete piles, but may be sorted according to type. At the start of the display season, the adult male Satin Bowerbird builds a new bower on or adjacent to the spot used in the previous season. A bower can comprise more than 2000 sticks. The bower consists of two outward-curving, parallel walls of sticks, placed upright into a foundation platform of fine sticks and grass. The walls may form an arch, and the inner walls may be painted with ground charcoal, masticated foliage, liverwort, crumbly tree bark or fruits, mixed with saliva.*

he utters a continuous murmuring or bleating subsong while rapidly vibrating his lower mandible, partly exposing his pinkish-yellow mouth. This sound is frequently interspersed with hissing, chugging, spluttering, and notes like the sound of dripping water and lip-smacking, as well as mimicry of other bird calls and of the sound of whirring avian wings and fluttering vegetation. He also makes an occasional rapid and sharp shake of his head from side to side, causing his yellow crest to vibrate and become a blur, sometimes also pushing his bill into the mat as if "nuzzling" it. While prostrating himself, he occasionally raises his head and neck to perform a Shuffle side-hop of two or three movements to one side at the same time as he raises and swings his tail through an arc as he moves towards the female. If the female flies to the mat, the male's initial response is to rush at her in an aggressive way and to Displacement-chase her with loud calls to or just beyond the mat edge. He then prostrates himself again, and may repeat the process several times to entice the female back. With each eviction, the prostrate and softly calling male permits the nervous female to approach him more closely before his next Displacement Chase. When moving from one part of the mat to another, between prostrate displays, the male does so by light bouncing hops as he raises his tail to about 45 degrees and conspicuously swings it through an arc to one side during each hop, before flopping into the Prostrate posture. If a female persists in staying distant from the mat, the horizontally prostrate male appears to "vibrate-shuffle" over and through the thick mat of ferns, performing extremely rapid miniscule bouncing hops or leaps involving little upward movement as he "shuffles" forwards in a Grovel Display; all the time his legs are obscured by the sleeked body pressed into the mat. His head movements as he attempts to locate and follow her are conspicuously jerky, thus enhancing his yellow crest. Once the female is immediately beside the prostrate male, he performs a Head-lift and Shake display involving rapid vibrating of the head as the frontal-crest feathers are erected and projected forwards over the base of his upper mandible, and then repeated lifting of the head and bill from the bower mat. The male progressively increases the tempo of his Head-lift and Shake. At this point, the female will usually peck at his crest feathers once or twice. Suddenly, he utilizes the last of his increasingly rapid head-lifts as a means of raising his entire body and hopping on to the female to mate.

The courtship of the Golden Bowerbird involves five basic display phases: Chase, Bow, Head-nod-and-shake, Flight-hover, and Hiding. In the Bow, the male lowers his bill and head and erects the crown and nape feathering, emphasizing his yellow central crest, while his wings are drooped and occasionally flicked; he pulls his tail forwards beneath his lowered head and sometimes holds it aside. During the Head-nod-and-shake, he nods his downward-pointing head up and down, with head plumage erect, and shakes his head from side to side, thus accentuating his yellow crown and nape; as he nods, he sometimes pecks at his perch. In intense display, the male may perform the Bow and the Head-nod-and-shake consecutively, in either sequence, on the same perch, during which process he sometimes gives a rattle and one or more squeal calls. In the Flight-hover display, the male flies about his bower with slow and deliberate butterfly-like beats of the extensively opened wings, occasionally while holding a decoration in his bill, and from time to time he may rapidly and repeatedly fan his tail to the full extent in brief mid-flight hovers, thereby exposing the yellow outer rectrices. In addition, he will sometimes hover in front of a vertical sapling trunk or its leaves, the bill tip touching or almost touching the stem or leaves, while repeatedly fully fanning and closing his tail. He then flies, butterfly-like, to another sapling to perform the hover display again.

On seeing a female within his bower site, the male Golden Bowerbird does not approach her but, instead, gives some squeals, screeches and vocal mimicry and performs the Head-nod-and-shake and Bow, followed by one or more Flight-hover displays. He then moves up to about 20 m away from his bower to a perch, where he performs the Hiding display accompanied by a soft subsong incorporating high-quality avian vocal and other mim-

Despite the masses of blue decorations he has assembled, the courting male ***Satin Bowerbird*** *generally picks up and uses a relatively dull object, such as this grey-green leaf. With this held in his bill, he may jerk or shake his head aggressively, or drop the leaf and shake his head, as if in distaste. The courtship involves two display elements: the first is an active one, involving vocalized buzzing accompanied by body movements, with rapidly and vigorously repeated opening and closing of the wings, during which the male is mostly hidden by the bower wall; the second is static and involves continuous vocal mimicry, while the male raises and lowers himself on his legs. During either phase, he may raise and fan his tail. If the female solicits by crouching, he enters the avenue at the far end and mounts her.*

[*Ptilonorhynchus violaceus violaceus*, Lamington National Park, Queensland, Australia. Photo: Raoul Slater]

*The **Flame Bowerbird** builds a small, neat avenue with relatively few decorations, which may include blue, purple and brown fruits, bracket fungi, purple and white flowers, snail shells, and yellow-brown leaves within the avenue, and glossy blackish leaves outside it. One instance of courtship has so far been described. On catching sight of a visiting female, the male collected some sticks from nearby and began to dance, trying first to make himself appear as small as possible, and then to look bigger, enhancing the effect by spreading his wings. The dancing seemed to be the signal for the female to inspect the bower, at which point the male's dancing intensified. The birds touched bills while both were at the bower.*

[*Sericulus ardens*, Kiunga, New Guinea. Photo: Otto Plantema]

icry. He hides behind a tree trunk, branch or other suitable structure and peers intently around its edge while softly vocalizing; he often adopts a sleeked, rather serpentine posture, with the body held in a rigid shallow S-shape. Once a female settles on the bower perch, the male stops vocalizing, drops close to the ground, or sometimes on to it to make a brief serpentine run of several metres, and then makes an indirect, rapid, silent flight through the foliage to surprise and aggressively chase the female from his bower with loud calls. The male will repeat this procedure each time a visiting female returns to his bower, when displays other than Hiding can occur at any time and in any sequence. All five display phases are probably performed during successful courtship, perhaps in a typical sequence, but, since no descriptions of matings are available, this requires confirmation.

Most acts of courtship by male Regent Bowerbirds take place after a female arrives at a bower escorted by the bower-owner. Initial arboreal displays may be performed, but these are of low intensity and involve only limited posturing. Courtship at the bower involves three main display phases. During Initial Bower Display, the male stands upright at his bower entrance and emits a low, soft chattering and warbling song while watching the female perched a few metres away. Once she comes to his bower, he moves backwards some 20–50 cm and stands in front of the bower or on a nearby perch, facing her and singing. She comes to sit in the bower avenue or at an entrance to it and looks around her, sometimes pecking at the bower decorations. The male then begins the Central Bower Display, remaining within about 30 cm of a bower entrance, and facing her in upright stance; occasionally he picks up a decoration in his bill while making sideways movements of the head and neck. In this upright posture, he may gape while moving his head to one side. Then, in a slightly lowered posture, he "wing-flicks", by quickly opening and refolding a wing, and in this same slightly lowered posture he presents his nape to her and then lowers his bill; during this Nape-presentation posture his plush yellow nape feathers may be erected. Finally, the male moves his head back while making a series of bobbing movements. He also assumes a forward-bent posture while raising and repeatedly flapping both wings, with his bill open; during this posture, he lowers his head and slightly droops his wings as he runs forward. This Forehead-presentation Advance may be repeated, the male returning to his pre-advance location by running backwards. In the course of these central displays, his irides can suddenly become more conspicuously yellow as the pupils are contracted. The above-described postures can occur in various sequences. In the third and final main display phase, the Peripheral Bower Display, the male runs, hops and flies about, thus flashing his yellow wing markings, within 1 m of his bower; perching briefly, he may perform Wing presentations by repeatedly opening and closing a wing. During peripheral displays he will often be behind the female, which remains seated or crouched in the bower. Throughout the bower displays, and even with his bill closed or while holding a decoration, the male produces a continuous subsong that includes avian mimicry. If the female accepts the male, she crouches in his bower in a forward-tilted posture; he then enters the avenue from behind her and mates. Copulation occasionally occurs on the court directly in front of an avenue entrance.

Courtship by male Satin Bowerbirds involves two typical display phases. The first is a vocalized buzzing accompanied by body movements with repeatedly and rapidly opened wings, and the second a static phase accompanied by vocal mimicry. In a female's presence, the male's courtship follows a ritualized pattern. Giving soft pathetic or pleading-like squeaking and spluttering notes, the male, standing just outside a bower entrance, faces her but is entirely or mostly hidden from her by the end of a bower wall. He may adopt a rounded posture, with the folded wings held just above the back and with the tail down and stiffly vibrating vertically, occasionally opening his bill widely. He faces his bower and repeatedly pecks at or picks up a decoration, his head and bill jerked vertically up and down or shaken vigorously. His body is now held at about 45 degrees to the ground, bill down, tail up and body raised high to give an odd long-legged look as his soft pleading calls continue. Suddenly, his vocalizations change to a continuous mechanical, whirring buzz, while the tail feathers are slightly fanned and separated from one another in the vertical plane to form an inverted V-shape. He then raises his tail to more than 45 degrees and executes a series of twelve or more vigorous upward flicks of the wing farthest from his bower, the wing being usually closed but sometimes half-open; the first flick often involves both wings, and each wing-flick is punctuated by a louder whirring buzz call. The male then strides across and directly in front of his avenue entrance, and thus into full view of the fe-

On first encounter, bowerbirds typically chase off visitors of their own species, whether an adult male, a female-plumaged immature male, or a female. The extent of this "displacement chasing" varies between species. Golden Bowerbirds (Prionodura newtoniana) *aggressively pursue most female-plumaged visitors out of their bower sites. But male* ***Regent Bowerbirds*** *rarely chase visiting rival males, and may, as with the immature male here, display to them. During the various phases of courtship, the male erects and presents the plush yellow feathers on his nape and his forehead. While the female—or in this case, the immature male—crouches in the avenue or one of its entrances, he faces her (or him) in an upright stance, occasionally picking up a decoration, such as a leaf, in his bill, while making sideways movements of his head. Regent Bowerbirds, and possibly other species of silky bowerbird, attract females by means of their colourful plumage, as well as by calling in the canopy, and then lead them to the bower. In contrast to some plain-plumaged species which create elaborate, extensively decorated bowers, the bower of the Regent Bowerbird is simple and sparse. While other avenue bowerbirds reuse or refurbish their bowers, sometimes over several years, two-thirds of Regent Bowerbird bowers are maintained for fewer than eleven days. If intruding males do not destroy the bower, the owner may do so himself if he becomes aware that a rival has discovered it.*

[*Sericulus chrysocephalus*, Lamington National Park, Queensland, Australia. Photo: Clifford & Dawn Frith]

The bower of ***Archbold's Bowerbird*** *is described as a "dispersed maypole". It consists of a cleared area, on which an amorphous mat of fern fronds is gradually built. The mat may in time become more than two metres deep, and several square metres in extent, the largest known covering 29 m². Trailing stems of epiphytic orchids are draped from branches in saplings above the mat. The branches become thickly covered with orchid stems, but favoured perches are left bare, for the male to sing from, and for visiting females to watch the initial stages of his display from. Large mats may be accumulated over several years, the males renovating and adding to them at the beginning of each courtship season. One traditional bower site persisted for more than 15 years, and one adult male attended the same site for more than six seasons. Decorations typically include the occipital plumes, or "flags", of the male King of Saxony Bird-of-paradise* (Pteridophora alberti)*, which are given pride of place in the centre of the mat. These plumes often disappear from bowers between visits by observers, but theft of such decorations by rival males of this species has not been confirmed, although theft is generally common among bowerbirds. Other decorations include snail shells, beetle elytra (wing-cases), fruits, fungi, charcoal and tree resin. Decoration is also provided by the colour of the fern fronds, which are often collected while still green, but which dry to a darker brown, contrasting with the living plants of the surrounding forest. The orchid stems often remain alive for a while after being added, and some may be in flower.*

male, while giving one to three vigorous flicks of a fully opened wing, or sometimes both wings, each accompanied by a louder buzz call. Before, between and after the wing-flicks, he holds his body in a ritualized rounded upright posture, or occasionally in a sleeked horizontal one, usually with a decoration held in the beak and the tail horizontal to the ground or lower. This striding phase takes him to the opposite position at the other bower wall, where he again faces the female and picks at or picks up a decoration while again wing-flicking. He then repeats his striding display across the bower entrance, thus returning to the position at which he started his courtship. Here, he once more faces the bower entrance and lowers his head and beak to pick at or hold a decoration, while holding his tail high above the back, with the rectrices slightly fanned and parted to form a "V"; he may give double wing-flicks, this time flicking the wings out sideways. Simultaneously, he gives a rattle call followed by a continuous vocal display of avian mimicry mixed with odd ticking or tapping notes, and he repeatedly lifts his head and beak, with a decoration in the bill tip. At this point, the male adopts a sleeked bow posture with the tail raised and/or a posture with the plumage ruffled, the back arched and the wings and tail drooped, and he may also turn his lowered beak away to present his nape to the female while holding a decoration, or he may hide behind a bower wall. In this stationary, mimicry-producing phase, the male repeatedly slightly raises and lowers himself on his legs. He will often interrupt these static postures by strutting back and forth, in circular movements, across his court. If the female solicits, by crouching and vibrating her lowered wings and raising her rump, the male strides quickly past the avenue entrance, down the length of his bower, to enter by the far entrance and mate the female from behind, often while still holding a decoration in his beak. One female was observed to be mated at the same bower by the same adult male over two consecutive seasons, while other females may choose either the same male or a different one each year.

Courtship by Spotted Bowerbirds is central and peripheral in nature, depending on where in relation to the bower it is performed. In central displays a male stands among bower decorations on his court immediately adjacent to the bower, and in peripheral displays he postures while running widely around his bower. Peripheral displays more often follow central ones, and in both of them males more or less expand the lilac crest. Four conspicuous central display postures are the Upright, the Raised-wings, the Sideways Crest-presentation and the Forward Crest-presentation, these appearing in any sequence and accompanied by various hissing, crackling and ticking vocalizations. Display movements are erratically jerky and violent, a male frequently leaping upwards to his own height and backwards, to alight some 15 cm farther from his bower. The displaying male repeatedly darts rapidly forwards towards the silent female crouching motionless within his avenue, and then moves back again, often picking up decorations and aggressively shaking them from his beak. Males sometimes perform a Nape-presentation Display, outlined in detail in the following paragraph. In peripheral display, the male Spotted Bowerbird raises the head, stiffens the neck, and opens the beak. The tail is cocked and the wings drooped loosely from the body, much in the manner of a Great Bowerbird displaying in similar circumstances; in doing so, males do not hop but, rather, they strut, walk or run animatedly, the crest fully erect, while hissing and while circling the bower and the female within. During this movement around the bower, the male raises and lowers his head while simultaneously moving his body with jerky and undulating actions, reminiscent of swimming, as his closed wings are drooped and then raised and the tail lowered. The male's crest is erected in the shape of a fan, like that of displaying Western Bowerbirds, but not in the circular shape of the Great Bowerbird. During peripheral display, the male Spotted Bowerbird sometimes holds bower decorations in the beak and also repeatedly picks up and violently throws down these objects. Occasionally, the displaying individual leaps upwards and/or backwards, sometimes simultaneously flicking his wings, to resume the swimming-like running motion. When moving away from the bower, males are less vocal than when moving towards it and they adopt two distinctive postures: the Rooster Pose, in which the head and tail are held high, the wings horizontally away from the body, and the legs moved in a prancing gait; and the Penguin Pose, in which the body is erect, with the neck extended and the head high, the tail down, and the wings tight against the body, while moving with small rapid steps with the legs kept close together. Copulation takes place in or immediately adjacent to the bower avenue. Courtship can last for a few minutes to more than an hour.

Males of all five *Chlamydera* grey bowerbird species, including the Spotted Bowerbird, perform a Nape-presentation Display to females as a latter-stage courtship posture; so, occasionally, do Satin Bowerbirds, and Regent Bowerbirds do so typically but in a more animated way. In the display, the male's nape crest, in the three *Chlamydera* species that have one, is presented to the female while the bill, a potentially threatening feature, is turned away from her. Tellingly, courting adult males of the two crestless species also present the nape to the female in just this way. The

*When the advertisement vocalizations of a male **Archbold's Bowerbird** have brought a female to a bower perch, he drops to the bower mat. In the Prostrate posture, he presses his stretched body into the mat, with his forecrown feathers elongated and his crest partially fanned. He occasionally shakes his head, making his yellow crown feathers vibrate. If the female stays on the perch, he shuffles towards her with tiny hops, his body still prostrate, in the Grovel Display. When the female lands on the mat, he evicts her in a series of aggressive displacement chases, letting her come closer each time she returns.*

[*Archboldia papuensis sanfordi*, Tari Gap, New Guinea. Photo: Clifford & Dawn Frith]

crestless species, therefore, employ a posture evolved specifically to present a colourful crest, a feature that they no longer possess, but in their evolutionary past presumably did. This fits with the insightful "transferral effect" hypothesis of bowerbird student E. T. Gilliard, which implies that males of these species have lost the crest as they simultaneously evolved more complex bowers. This trend is recognized also within the *Amblyornis* species: adult male MacGregor's and Yellow-fronted Bowerbirds sport a large colourful crest and build relatively simple bowers compared with the larger and more complex ones of the much smaller-crested male Streaked Bowerbird and the completely uncrested male Vogelkop Bowerbird. Thus, courts and bowers, or some aspects of them, represent elaborate male display traits. Presumably, this arose as a result of both sexual selection by females for meaningful, externalized symbols of male fitness, namely the bower and its decorations, and natural selection acting to reduce conspicuously bright plumage, which could attract predators and thus make colourful males susceptible to predation.

Female bowerbirds are initially attracted to a bower site and then to the bower therein. It is assumed that they assess the relative level of a male's attendance at his bower site and the quality and quantity of his vocalizations, plumage, bower structure and decorations, displays, and more, before soliciting the individual by which they select to be mated. Female Satin Bowerbirds choose a mate through a complex process, during which they make sequential decisions based on male traits, and females reveal age-specific differences in those male traits assessed by them. One study showed that each female Satin Bowerbird's home range included the bowers of about 5–7 males and that several, up to an average of about three, are sampled by each female; initially, numerous bowers were visited then subsequently fewer, the females returning for mating to the individual male found to be the most attractive.

Because the only contribution that the male will make to successful offspring production is his sperm, the females have to be extremely discerning in their choice of mate. Given the male's limited contribution to the lengthy and costly investment in progeny that the female must make, the female must seek to maximize the quality of genes passed to her offspring by their father. This will, at least, enhance the possibility of her sons being relatively successful in the all-important mating game.

Most active bowerbird nests are located within hearing distance of a male calling at his court or bower. The fact that, in any given area, relatively few, typically older males of polygynous species perform the majority of matings in any breeding season raises the possibility that experienced females could seek to nest near the traditional bower site of a specific male. Females of many polygynous bird species mature and breed at a younger age than males of the respective species, but the age at which female bowerbirds start to breed remains unconfirmed; sparse facts suggest that they may reproduce in their second or third year, as female Satin Bowerbirds do reach sexual maturity at that age. The operational sex ratio of Regent Bowerbirds was estimated to be two adult females to each adult male, which clearly indicates a strong female bias. While this ratio is based on the assumption that only male Regent Bowerbirds in full adult plumage are sexually active, some males in immature to subadult plumage may have fully developed gonads and could be reproductively active.

Bowerbirds, both monogamous and polygynous, often habitually use the same location, and sometimes the very same site, in which to build the nest each year. The traditional use of a location season after season often results in an accumulation of old nests. The time of year when nest-building commences and the length of the nesting season vary with habitat, altitude and weather (see General Habits). In summary, the peak in courtship and nesting activity of most ptilonorhynchids in Australia is during late September to December; for the grey bowerbirds, the peak period typically precedes the monsoonal rains, nesting taking place mainly during October to December or January, although this is subject to annual variation. Mating takes place before or after nest-building and up to a month prior to egg-laying.

Nests are built mostly in forks of trees, saplings, bushes or vine tangles, except for that of the Golden Bowerbird, which, uniquely within the family, is built into a tree crevice. The majority of nest-sites are visually cryptic and often are situated away from convenient arboreal pathways for predators, being isolated from surrounding vegetation. The task of nest-building is undertaken by the female alone.

Catbird nests are large, deep, open bowl-shaped structures consisting of four basic layers. These are, first, a stick foundation, and then a deep nest cup, a layer of decaying wood and/or mud pieces on top of the central leafy bowl, and an inner egg-

*At the beginning of the display season, the male **Tooth-billed Bowerbird** begins to place leaves on an oval or circular site of 1–8 m². The site includes one or more trees for displaying. As the season progresses, he clears the litter from the site, and adds more leaves, with the pale undersides uppermost. The bowers of most bowerbird species are evenly dispersed, but those of Tooth-billed Bowerbirds tend to be clumped together, in what may be exploded leks. Studies suggest that male Tooth-billed Bowerbirds holding traditional sites at the heart of an aggregation of courts are older and more dominant individuals, with higher mating success than their peripheral rivals.*

[*Scenopoeetes dentirostris*, Atherton Tableland, Queensland, Australia. Photo: Peter Marsack/ Lochman Transparencies]

At the commencement of courtship, the male ***Tooth-billed Bowerbird*** *drops from his song-perch onto his court, and hides behind his display-tree trunk, where he continues singing. If the approaching bird is a female, he changes to a quiet subsong involving mimicry of other birds. Golden Bowerbirds* (Prionodura newtoniana) *also hide behind trees when a female arrives, whereas male gardeners and avenue-builders hide behind or within their bowers. When the female Tooth-billed Bowerbird reaches the court, the male's vocal display suddenly becomes a vigorous visual display. He hops out sideways from behind the tree, and gapes to reveal a black mouth that contrasts with his white mandible linings, while simultaneously erecting a conspicuous white "beard" of throat feathers to either side of his gaping mouth. He continues his sideways hops, swinging his tail, and raising and flicking his folded wings. Then he begins a series of Leap/Wing-flaps, lunging forwards, with his wings first fully opened and raised to 45° or more above his back, and then beaten downwards as he leaps forwards and sideways, landing as his wings close. If he is displaying on a perch, the Wing-flap is given without the Leap, which is replaced with vigorous up-and-down flexing of the legs. Throughout the visual display, he continues his subsong, with "tuck-tic" notes during Leap/Wing-flaps. When his display has brought him immediately in front of the female, he flies to her, either directly or via a series of perches. Copulation is aggressive, with the male holding or billing the female's nape while rocking from side-to-side and rapidly flapping his wings. The entire courtship, from the vocal to the visual displays, generally takes under 80 seconds, with the visual display occupying just over a quarter of that time.*

[*Scenopoeetes dentirostris*, Atherton Tableland, Queensland, Australia. Photos: Clifford & Dawn Frith]

*Male **Satin Bowerbirds** take seven years to acquire their full adult plumage. This prolonged period in female-like plumage limits the aggression from adult males, allowing the young birds to visit and learn bower-building and display skills from them. Adult males are tolerant of these visits early and late in the season, but are more aggressive while females are visiting. Immature and subadult Satin Bowerbirds also spend time at communally constructed bowers where they practice bower building and displaying. They also visit occupied bowers in the absence of their owners. As they grow older, they narrow their attention to a few sites, eventually settling on one where they will challenge the incumbent.*

[*Ptilonorhynchus violaceus violaceus*, Brisbane Forest Park, SE Queensland, Australia. Photo: Brian J. Coates]

cup lining. Among bowerbirds, the wood-and-mud component is unique to the catbirds, but its function is unconfirmed. Nests of the *Amblyornis* gardener bowerbirds and of Archbold's and Golden Bowerbirds are substantial, deep, bowl-shaped three-layered structures, having a foundation, a nest cup and a lining. In contrast, those of Tooth-billed, Regent and Satin Bowerbirds and of the *Chlamydera* grey bowerbirds are relatively small, frail, shallow and slightly concave, consisting of only two layers, a loosely built outer saucer-shaped sticky foundation with an egg-cup lining.

Clutches laid by the Ptilonorhynchidae comprise one to three eggs. As both catbird sexes provision their offspring, they might be expected to have larger clutches than those of polygynous bowerbirds, the females of which raise the offspring alone. A marked difference, however, is not apparent. Both the catbirds and the polygynous species have an average clutch size of one egg in New Guinea and almost two in Australia. Bowerbird eggs are typically elliptical ovate, or long oval, in shape.

Eggs of the catbirds, the Tooth-billed, Archbold's and Golden Bowerbirds and the gardener bowerbirds, all of which nest in

*The males of many bowerbird species steal decorations from one another. The abundance of decorations at a bower thus provides females with an indicator of the relative fitness of an individual male, based on his success in conflict with his rivals. The loss of even a few decorations may make the difference between mating failure and success. Theft —and destruction of bowers—tends to take place when the victim is away, as has happened to this **Satin Bowerbird**. The victim may retaliate by stealing his decorations back; but if the raider damages the bower, the victim must first spend time rebuilding, so the raider maximizes the time he can keep the stolen goods.*

[*Ptilonorhynchus violaceus* and *Sericulus chrysocephalus*, Australia. Photo: Roland Seitre]

denser rainforest, are pale and unmarked. Those species of more sparsely foliaged forest and woodland to arid open habitat, namely the Satin Bowerbird, the *Sericulus* silky bowerbirds and the *Chlamydera* grey bowerbirds, lay eggs that are colour-pigmented and vermiculated, streaked or blotched. The white eggs of the Golden Bowerbird are unique within the family, and their lack of colour may be an adaptation to this species' crevice-nesting habit.

Both monogamous and polygynous bowerbirds typically lay the eggs of a clutch on alternate days. Incubation usually, but not always, begins once the clutch is complete, normally commencing, therefore, after the laying of the second egg or, with three-egg clutches, the third egg. The incubation periods of bowerbirds in the wild are known for six species. Those of the monogamous catbirds, at 22–24 days, are similar to those of the polygynous species, at 21–23 days, with the exception of Archbold's Bowerbird, this polygynous species having an incubation period of 26–27 days. With both the monogamous and the polygynous species only the female incubates, and in both groups she devotes about 70% of the diurnal time to the task. The hatching of clutches of more than one egg is nearly synchronous, siblings emerging within 24 hours of each other. Male catbirds provision the mate during the nest-building and egg-laying periods, and, while figs are the principal food that male Green Catbirds feed to the mate, protein-rich insects and insect larvae become more prominent during the egg-laying period.

Information on the nestling periods of ptilonorhynchids in the wild is available for eight species. Again, the periods are broadly similar for the two groups, 20–21 days for the monogamous species and 17–21 days for the polygynous ones. Once more, Archbold's Bowerbird provides an exception, with a period of 30 days. The latter's longer nestling period is presumably an adaptation to the cold and wet high-altitude habitat which it occupies, and where food suitable for nestlings may be scarcer.

The amount of time that a female parent spends in brooding is influenced by brood size. Black-eared Catbirds and Golden Bowerbirds spend more time in keeping single nestlings warm than they do with larger broods, presumably because smaller broods are less demanding in other respects and/or because siblings stay warmer for longer than lone nestlings. The point at which bowerbirds cease brooding their nestlings varies from species to species. Although available information is limited, there appears to be little difference between nestling periods of the catbirds and the Golden Bowerbird, which provision their young predominantly with fruit, and those of the Satin, Spotted and Great Bowerbirds, which feed a greater proportion of animal items to the nestlings.

The rates at which parent Black-eared and Green Catbirds feed the nestlings are similar, at an average of five meals per hour. The average nestling-feeding rates by females of polygynous bowerbirds vary according to species, from three to almost seven meals per hour (see also Food and Feeding). Parent bowerbirds swallow the nestlings' faeces throughout most of the nestling pe-

*In northern Queensland, where the **Great Bowerbird** and the **Spotted Bowerbird** co-occur, hybridization sometimes occurs. Here, a male Great Bowerbird is displaying to a Great/Spotted hybrid (at the far end of the avenue), while a male Spotted Bowerbird looks on. Bower structure has been suggested as a species-isolating mechanism, but some sympatric avenue-building species are known to have influenced each other's structures. Spotted Bowerbird avenues are wider than those of Great Bowerbirds. This may be because courting Spotted Bowerbird males are particularly aggressive, and females may select wider avenues that give room to retreat.*

[*Chlamydera nuchalis orientalis* and *C. maculata*, near Charters Towers, Queensland, Australia. Photo: Clifford & Dawn Frith]

*Females of polygynous species like the **Satin Bowerbird** undertake the tasks of nest-building, incubation, and brooding and provisioning of the offspring entirely alone, unaided by the male. However, most active nests are within hearing distance of a male calling at his bower. Like bowers, nests occupy traditional sites, and are built on or near those of previous years. Each sex may have been influenced by the proximity of the other in their selection of these sites. Satin Bowerbirds build relatively small, frail, shallow nests, consisting of only two layers, an outer structure of twigs with an "egg-cup" lining of leaves.*

[*Ptilonorhynchus violaceus minor*, Paluma, N Queensland, Australia. Photo: Clifford & Dawn Frith]

When provisioning their young, parent bowerbirds carry food items along the length of the bill and in the mouth. Unlike the birds-of-paradise, they do not regurgitate them. Both fruits and animals are fed to nestlings of all ages. In the case of predominantly frugivorous parents, like ***MacGregor's Bowerbird****, the proportion of insects which they feed to their nestlings is greatest in the period just after hatching, and declines thereafter. Bowerbirds lay one to three eggs, although the average clutch size is one egg in New Guinea and almost two in Australia. There is no significant difference between the clutch sizes of the monogamous catbirds, in which both parents help to provision the young, and polygynous species in which the female raises the young alone. MacGregor's Bowerbird lays just one egg. Bowerbird eggs are typically elliptical ovate, or long oval, in shape. The eggs of MacGregor's Bowerbird are plain creamy white, while those of other species that nest in dense rainforest are also pale and unmarked. Those species of more sparsely foliaged forest or arid open habitats, including* Sericulus *silky bowerbirds and* Chlamydera *grey bowerbirds, lay eggs that are coloured and patterned.*

[*Amblyornis macgregoriae kombok*,
Tari Gap, New Guinea.
Photos: Clifford & Dawn Frith]

Females of polygynous bowerbird species tend to feed their young with a single animal type, such as cicadas, grasshoppers or skinks, as the dominant component of the diet. Grasshoppers and locusts are important to the grey bowerbirds of dry and open habitats. Of 359 identified meals that one ***Spotted Bowerbird*** *female brought to her brood, 146 were fruit, and 213 animal, of which 122 were grasshoppers or crickets. Twenty-four of the largest grasshoppers were stripped of their legs, wings and heads. Average nestling-feeding rates by females of polygynous bowerbirds vary according to species, from three to almost seven meals per hour.*

[*Chlamydera maculata*, near Charters Towers, Queensland, Australia. Photo: Clifford & Dawn Frith]

riod. Only when the nestling development is well advanced do the parents carry away faecal sacs and/or seeds, voided into the nest by the young.

Hatchlings characteristically have pink-orange to yellowish-orange skin, a varyingly yellow to orange gape, a white egg tooth, and conspicuous long fluffy down. The bill and leg colours are variable. Nestlings have dense long down in patches on the crown, wings and body, this down being reddish grey-brown on catbirds, greyish-brown on the Tooth-billed Bowerbird and gardener bowerbirds, dark greyish-brown on Archbold's and Golden Bowerbirds, and a much paler grey on Satin and Regent Bowerbirds and the grey bowerbirds. The eyes start to open when the nestling is some 7–9 days old, and are fully open by 9–12 days of age. The flight-feathers of young Black-eared Catbirds and Golden Bowerbirds start to appear at 5–6 days, and those of Archbold's Bowerbirds at 8 days; the primaries burst from their pin sheaths on days 13–14 in the case of the Black-eared Catbird and 11–12 days in the Golden Bowerbird, but not until 14–15 days in Archbold's Bowerbird. On leaving the nest, the youngsters have a tail less than 10% of the average length of that of their parents. They leave the nest when well feathered, in a plumage broadly similar to that of their parents. What little is known about juveniles suggests that there is a period of dependency upon their parent or parents of at least 40–60 days.

Bowerbirds typically nest once in each season, but they can renest following the seasonally early loss of a clutch or brood. Given that nest-building usually takes 1–3 weeks, that incubation and nestling periods each last about three weeks, and that it takes at least 2–3 months to raise a fledgling to independence, few females could have time to raise a second brood in a single season. The proportions of successful nests, eggs and nestlings are far greater for the monogamous catbirds than they are for the polygynous Golden, Regent and Satin Bowerbirds. Catbird pairs produce more fledged offspring than polygynous bowerbirds, their number of fledglings per nesting attempt being twice that of Golden Bowerbirds and three times that of Satin Bowerbirds. It is not surprising to find higher productivity for the large, powerful, and monogamously pair-bonding catbirds compared with the polygynous species, the females of which, unlike those of the catbirds, nest alone, with no assistance from the males. Archbold's Bowerbird has a notably high nesting success rate, which may be due in part to such variables as longer incubation and nestling periods, combined with a high-altitude habitat supporting fewer predators.

While there are many reptile, bird and mammal species that would potentially take the contents of bowerbirds' nests and the attending adults, there are few records of their doing so. Indeed, the cause of egg or nestling loss among the Ptilonorhynchidae usually remains unknown. Catbirds are themselves predators of the nest contents of other birds, including bowerbirds. These and other considerations aside, those bowerbirds whose nesting has been studied are able to maintain a respectably high level of success in terms of the number of offspring produced from eggs laid in climatically typical years. When disturbed by a potential predator, a parent often performs a distraction display; produces vocal mimicry, typically of the calls of predators; adopts a frozen posture; and/or attacks or chases the intruder.

Bowerbirds have a remarkably high survivorship and life expectancy. Individual catbirds are known to have lived for at least 19 years, and males of polygynous bowerbirds for up to 27 years. Adult males demonstrate long-term fidelity, in some cases of up to two decades, to a bower site and even to a specific bower structure.

Movements

All members of this family are essentially resident. Home ranges of Australian catbirds average 1–2 ha, but their all-purpose territory during breeding becomes smaller as the parents focus their foraging closer to the nest-site. Limited evidence suggests that Black-eared Catbirds in some upland areas may move to lower altitudes during the winter months.

Polygynous bowerbird species are non-territorial, except for the defence of the immediate area of the bower or nest-site. Females and immature males maintain relatively large, overlapping home ranges throughout the year, foraging in the same areas as do adult males. Foraging distances vary both from year to

*The nestling period of **Archbold's Bowerbird** is much longer than that of other bowerbird species, at 30 rather than 17–21 days. This is presumably an adaptation to the cold and wet high-altitude habitat that Archbold's occupies, where food suitable for chicks may be scarcer. Of meals brought to the nest by one female, 71% were fruit and 29% animal; of the animal meals, 30% were tree-climbing skinks or parts of them. A lizard's tail is being delivered to the nestling here. The amount of time a female spends in brooding is influenced by brood size, some species spending longer with just a single chick. Despite the longer nestling period, Archbold's stops brooding at around 15 days, which is little different to species whose young leave the nest up to ten days earlier.*

[*Archboldia papuensis sanfordi*, Tari Gap, New Guinea. Photo: Clifford & Dawn Frith]

year and between different times of the year, depending upon relative food availability, which in turn affects home-range size. Greater distances are traversed by males flying to creeks in order to bathe or drink, and shorter ones when stealing a decoration from a neighbouring rival's court or bower, or when chasing a rival from their own site.

Young males in female-like plumage move extensively about their habitat for several years. Subsequently, however, they do so over an increasingly limited area, to visit only several adjacent traditional bower sites before concentrating on one, for ownership of which they may then challenge the occupying adult male. Before or after commencing nest-building each season, female bowerbirds move freely about their habitat from bower to bower, in order to assess the quantity and quality of their structures and decorations, before selecting a mate (see Breeding).

In the winter period, aside from local movements within home ranges, when certain food resources are relatively scarce, some bowerbirds, and perhaps most typically woodland-dwelling Satin Bowerbirds, move to more open habitats and form flocks containing as many as 100–200 individuals. These flocks, generally typical of Satin Bowerbirds but also, to a lesser degree, of Regent Bowerbirds, graze upon shoots and leaves of grasses, herbs, shrubs and trees, including those of eucalypts, and eat cultivated green vegetables and soft fruits. Larger flocks can consist of both adult males and female-plumaged individuals, up to 40 adult males having been observed in one flock, whereas smaller flocks may be mostly single-sex gatherings. Grey bowerbirds also flock in winter, normally in much smaller groups.

Localized movement down to lower altitudes may be made by at least some Tooth-billed, MacGregor's, Golden, Regent and Satin Bowerbirds during the winter months, when food resources are relatively scarce, but little is known about the ages or sexes of the individuals involved.

Relationship with Man

Indigenous peoples of Australia and New Guinea would in all probability have been fascinated, possibly for in excess of 50,000 years, by the building and acquisitive behaviour of male bowerbirds. Some bowerbird skins, or parts thereof, such as crests or capes of the adult males, have been traded within and beyond New Guinea for thousands of years. This would have involved skins of, especially, Masked and Flame Bowerbirds, but also, to a limited extent, of crested adult male gardener bowerbirds. Local people have long adorned themselves with crests of dried skins, of gardener bowerbirds in New Guinea, and of grey bowerbirds in Australia.

Historically, aboriginal Australian and Papuan people have always held male bowerbirds and their works in high regard, respecting these birds for their abilities and industry. Some Australian aboriginal people also respect and fear the male birds as avian custodians of ceremonies involving secret "business", or rites, of their own. It is also believed that some bowerbirds, including at least the Spotted, Western and Great Bowerbirds, may steal bones of humans for their own ceremonial purposes, and so they and their bowers are traditionally left unmolested. Papuan men greatly admire male bowerbirds for their vigour and artistry in accumulating and displaying what they perceive to be the birds' equivalent of wealth, corresponding to the valued items that Papuan men accumulate in order to pay the relatives of intended wives. As a result, there are several stories and myths about MacGregor's Bowerbirds and their bowers, as there doubtless are about other bowerbirds among the peoples of New Guinea and Australia.

The influence of the bower-decorating activities of Great and, to a lesser extent, Spotted Bowerbirds on the Australian landscape recently attracted the attention of a team consisting of one biologist and several archaeologists. They observed that the items accumulated by the birds may include moderately large collections of aboriginal and other human artefacts. While these will reflect certain weight, size and colour restrictions and/or preferences of the bowerbirds themselves, a significant number of artefacts, given that more than 1000 stone pieces have been found on a single bower, may be gathered at more traditional bower sites. It is quite conceivable that the birds may use these over consecutive seasons for decades. Because of the birds' colour preference, it was noted that in dark soil or rock areas, where

Fruit, particularly figs, makes up around 80% of the diet of ***Black-eared Catbird*** *nestlings. The remaining 20% is animal food, over half of this being insects such as beetles, but over 20% may be the heads, legs, intestines and other parts of nestlings or small adult birds, and birds' eggs. Although information is limited, there appears to be little difference between nestling periods of the catbirds (19–20 days), and bowerbird species which feed their chicks a greater proportion of animal items. Male catbirds do not participate in nest-building, incubation of the eggs, or brooding of the nestlings, but they do assist by provisioning the mate and offspring with meals. Brood size averages one in New Guinea, and two in Australia; Black-eared Catbirds spend more time keeping single-chick broods warm, presumably because they spend less time bringing food to the nest for smaller broods, and siblings stay warmer for longer than lone nestlings. The parents spend almost half their time at the nest, sometimes just peering at the nestlings. When disturbed by potential predators they will perform a distraction display, stumbling across the forest floor with fluttering wings. Catbird nests are bulky, deep, bowl-shaped structures consisting of four basic layers: a foundation of large sticks; a deep cup of green and dried leaves; a layer of rotten wood fragments and mud; and an egg-cup lining of small twigs and vine tendrils. Among the bowerbirds, the inclusion of mud and decaying wood is unique to the catbirds, and its function is unknown.*

[*Ailuroedus melanotis maculosus*, Paluma, N Queensland, Australia. Photo: Clifford & Dawn Frith]

The flight-feathers of young ***Golden Bowerbirds*** *start to appear at 5–6 days, and the primaries burst from their pin sheaths at 11–12 days. By 16 days, all feathers are out of pin except those on the throat and head, which remain downy. Over the 17–20 days of their nestling period, the young increase from around 10 g on their first day of life to 55 g, or 75% of mean adult weight, on the eve of departure. Bowerbirds typically nest once in each breeding season, but may try again after the loss of a clutch or brood early in the season. Given that nest-building usually takes 1–3 weeks, that incubation and nestling periods each last about three weeks, and that it takes at least 2–3 months to raise a fledgling to independence, few females could have time to raise a second brood in a single season. Golden Bowerbirds and other polygynous species have far lower nest, egg and nestling success rates than the monogamous catbirds. The overall success rate of Golden Bowerbird nests is probably less than 25%, whereas for Black-eared Catbirds* (Ailuroedus melanotis) *it is upwards of 51%. Catbirds are themselves predators of eggs and nestlings, including those of the Golden and other bowerbirds. For Satin Bowerbirds* (Ptilonorhynchus violaceus)*, egg success is estimated at 15%, and this species may not breed at all in seasons when the populations of cicadas are low. Archbold's Bowerbird* (Archboldia papuensis)*, an exception in this as in several other aspects, has a notably high nesting success rate, with 88% of eggs producing fledglings. This may be due in part to the longer incubation and nestling periods, combined with a high-altitude habitat supporting fewer predators. While many reptile, bird and mammal species are potential nest predators, there are few records, and the cause of egg or nestling loss among the Ptilonorhynchidae usually remains unknown.*

[*Prionodura newtoniana*, Paluma, N Queensland, Australia.
Photo: Clifford & Dawn Frith]

aboriginal artefacts are produced from white or grey stone, the accumulation of them by bowerbirds could be considerable.

Bowerbirds have for long been sought for exhibit in public aviaries, such as within state and national zoological gardens, because the bower behaviour of the males adds significant entertainment and interest value not provided by other birds. The skilful bower-building behaviour of male bowerbirds and the acquisitive manner in which they gather, steal, defend and artistically display bower decorations, and even paint their structures, in order to impress females are character traits to which people can closely relate, as they echo a human-like scenario. The sounds that bowerbirds mimic also make these birds highly endearing to people. It is perhaps the mimicry by Spotted and Great Bowerbirds with which most people would be familiar, because these species associate closely with some town and city suburbs and with homes on outback stations: imitations of the sound of dogs barking, cats meowing, cattle moving through vegetation, mammals walking over ground litter, Emus (*Dromaius novaehollandiae*) crashing through wire fencing, wood-chopping, a stockwhip being used, and even the sound of conversing people have been reported. Some New Guinea bowerbirds are also excellent mimics, including human voices in their repertoire. It is depressing that the males of some ptilonorhynchid species are increasingly likely to be heard mimicking also the sound of chainsaws and of trees falling.

Bowerbirds are perceived by both ornithologists and laypersons as epitomizing the Australian avifauna as much as Emus and kookaburras (*Dacelo*). Indeed, some members of the family feature commonly in the public and commercial sectors of modern life. This widespread fascination continues unabated, with good numbers of books, films, magazine and newspaper articles, postage stamps, and commercial companies and their products featuring facts about and images of these extraordinary birds.

Status and Conservation

Of the Australian bowerbirds none is currently rare or endangered, although habitat destruction and degradation have resulted in range loss for some species, especially the Green Catbird and the Regent, Golden and Spotted Bowerbirds. The last of these is now considered extinct in South Australia and possibly also in Victoria, although it was always limited geographically and in abundance in both states. A recent action plan for avian conservation in Australia excludes the bowerbirds from consideration, other than including them within over a thousand taxa of "Least Concern", and treating the subspecies *carteri* of the Western Bowerbird as a near-threatened taxon because of its highly restricted range and estimated total number of 2000 breeding birds.

Bowerbirds with restricted ranges in New Guinea leave no room for complacency. These include the Yellow-fronted Bowerbird, restricted to the Foja, or Gauttier, Mountains, in the northern part of west-central New Guinea, and the Adelbert Bowerbird, confined to the Adelbert Mountains, in the north-eastern sector of the island. The latter species was until very recently considered globally threatened, the only bowerbird so listed; it was classified as Vulnerable. However, the revised listings for 2009 have reappraised the status of this species with the result that it is now downlisted to Near-threatened. The only other bowerbird currently thought to be potentially close to globally threatened status is Archbold's Bowerbird, which is likewise treated as Near-threatened, within its patchy distribution in the central mountain range of New Guinea.

The Adelbert Bowerbird is generally rather uncommon within its small range, but recent field studies revealed that it can be quite numerous locally. It occupies a relatively narrow elevational zone, mainly at 1200–1450 m. Although the Adelbert mountain range does not have a heavy human population, the altitudinal band in which this bowerbird is found is the same as that within which local agriculture is practised, while villagers rely heavily on hunting for food; fortunately, the people of Salemben village do not hunt this species. Much of the species' range is comparatively inaccessible, and so not immediately vulnerable to logging. In addition, there are extensive areas of mature secondary forest, which seem to be acceptable to this bowerbird. With increasing human population, further deforestation will doubtless occur, although there is hope that this may only be on a small scale. Very few data are available, however, on the current levels and trends of hunting and of forest destruction.

Archbold's Bowerbird, again a poorly known species, is found at a few places in high-lying forests of New Guinea, from the Weyland Mountains eastwards to the Eastern Highlands. Although fairly common locally, it appears generally to be rare. It is believed to have a rather small global population, and this may be declining as a result of habitat loss. The two subspecies of

Young bowerbirds leave the nest when well feathered, in a plumage broadly similar to that of their parents, though tail length is less than 10% of the average for adults. One captive ***Regent Bowerbird*** *fledgling which left the nest at 19 days still had a downy head at 37 days, when it performed flights of up to one metre; at 42 days, contour feathers covered most of its head, its rectrices had reached 8–10 cm, and it was able to fly up to 10 m. The prolonged period of parental care—young birds continue to beg and be fed for two to three months—helps improve juvenile survival. Bowerbirds have a remarkably high survivorship, and life expectancy.*

[*Sericulus chrysocephalus*, Lamington National Park, Queensland, Australia. Photo: Jiri Lochman/ Lochman Transparencies]

No bowerbird species is currently considered to be globally threatened, but the situation of species with restricted ranges in New Guinea, with its human population growing at 3% per year, leaves no room for complacency. These species are generally poorly known, with little or no baseline information from which to assess population trends. The ***Adelbert Bowerbird****, once thought to be in decline because of habitat loss, is now believed to be stable, and so in 2009, the species was downlisted from Vulnerable to Near-threatened on the IUCN Red List. Endemic to the Adelbert Mountains in central-north Papua New Guinea, and occupying a narrow altitudinal band at 1200–1450 m, this species has a range estimated at some 570 km², within which it is suspected to occur at only a handful of locations. The global population is estimated to be fewer than 10,000 individuals, but the Adelbert Bowerbird is relatively numerous within its favoured habitat, which does not appear to be under significant immediate threat, particularly as much of its range remains inaccessible. However, further information on the rate and extent of habitat clearance is needed to confirm its status. Little is known about its mating and breeding biology. The male builds a small avenue of unbranched twigs, like those of other* Sericulus *silky bowerbirds It is typically decorated with a few brown or yellow leaves, and blue fruit of various sizes; most of the decorations are sited within the avenue. The courtship of the male has not been described, although one tame male raised but did not spread the filamentous, silky flame-scarlet feathers of its cape.*

Below: *Sericulus bakeri*, Adelbert Mountains, New Guinea. Photo: Ron Hoff]

Despite the fact that its trend appears to be downwards, the decline in the population of the ***Green Catbird*** *is not as rapid as to approach the threshold for threatened status. Its range, though restricted, still covers over 200,000 km² within the Eastern Australia Endemic Bird Area, and includes many protected areas, particularly the seven separate rainforest areas which together constitute the 2035 km² East Coast Temperate and Subtropical Rainforest Parks World Heritage Site. The species is absent from rainforest fragments under 2·5 ha. The Green Catbird was once considered good eating, and birds are still sometimes killed when they feed on cultivated fruit.*

[*Ailuroedus crassirostris*, Lamington National Park, Queensland, Australia. Photo: Graeme Chapman]

Archbold's Bowerbird have sometimes been treated as separate species (see Systematics). The eastern one, *sanfordi*, appears to have a total range of only about 800 km², and on two mountains within this tiny range it is threatened by logging activities. The western populations, constituting the nominate race, appear to be larger in number and are considered probably secure, at least in the short term.

Fortunately, most bowerbird populations presently appear to be stable. As is the case for most bird species, it is loss and degradation of habitat and predation by exotic animals, particularly feral cats, that potentially threaten some bowerbirds today. Hunting has rarely represented a significant threat, although shooting did play a role in the localized decline of Spotted Bowerbirds. Some Australian bowerbirds are certainly killed by feral cats at water troughs and bores, and at their bowers. The recent spread of feral cats and other exotic predatory vertebrates in New Guinea could represent a real future threat to bowerbirds, especially the more geographically restricted species, in what is the main part of the family's range. It is unlikely that any bowerbird species is presently threatened with extinction, or under threat of significantly serious population decline, unless global warming proves detrimental to upland species. The status of bowerbirds does, however, require far greater vigilance in New Guinea than in Australia.

Several live captive bowerbirds, including all three catbird species and the Fawn-breasted and Flame Bowerbirds, have recently appeared in collections in Europe, North America and the Middle East. Some, if not most, of these individuals were presumably exported illegally, most likely out of West Papua via South-east Asia, but this limited trade is thought at present not to represent a threat to any of the members of the Ptilonorhynchidae. Conserving bowerbirds today should be a matter primarily of ensuring that no significant further loss of habitats occurs.

The two races of ***Archbold's Bowerbird*** *appear widely separated geographically. The eastern race,* sanfordi, *has a total range of around 800 km², with habitat on two mountains threatened by logging. Fire damage has resulted in the abandonment of at least six traditional bower sites below Tari Gap. The nominate race in the west of New Guinea appears to have a larger population, and is considered secure. But the huge Central Papuan Mountains EBA, to which Archbold's Bowerbird is restricted, has been relatively little studied ornithologically. Archbold's may be one of a number of species with apparently disjunct distributions which prove to have more contiguous, larger, populations.*

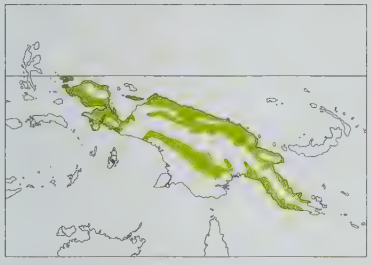
PLATE 19

inches 4
cm 10



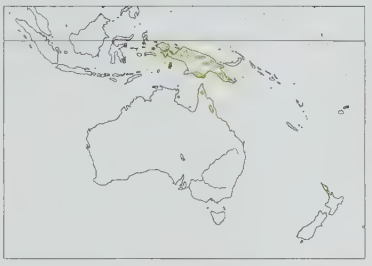
Genus *AILUROEDUS* Cabanis, 1851

1. White-eared Catbird

Ailuroedus buccoides

French: Jardinier à joues blanches **Spanish**: Maullador Cariblanco
German: Weißohr-Laubenvogel
Other common names: White-throated/Barbet-like/Least Catbird

Taxonomy. *Kitta buccoides* Temminck, 1836, Lobo, Triton Bay, New Guinea. Birds from Waigeo included in nominate race, but sometimes separated as *oorti*. Four subspecies recognized.
Subspecies and Distribution.
A. b. buccoides (Temminck, 1836) – W Papuan Is (Waigeo, Batanta, Salawati), and NW New Guinea E to Siriwo R in N and, in S, to Triton Bay.
A. b. geislerorum A. B. Meyer, 1891 – Yapen I (in Geelvink Bay) and N New Guinea from Mamberamo R area E to Collingwood Bay area.
A. b. cinnamomeus Mees, 1964 – S New Guinea from Mimika R E to upper Fly R and L Kutubu area.
A. b. stonii Sharpe, 1876 – SE New Guinea from upper Purari R (including Karimui, Bomai and Soliabeda areas, in Eastern Highlands) E along coast to Amazon Bay.



Descriptive notes. 24·5 cm; male 110–172 g, female 100–152 g. Nominate race has variable mid-brown to olive-brown crown tinged greenish, ear-coverts, side of lower head and throat mostly whitish with some black spotting; upper neck buff, large black feather tips forming broad spotted collar; upperparts, including upperwing-coverts and uppertail, rich parrot-green, flight-feathers brownish-olive with broad paler cream trailing edges, distinctive pale terminal spot on outer web of each secondary; underparts pale cinnamon, sharply contrasting large black spots (particularly on breast); undertail dark brown with green-blue wash (darker than underwing); iris deep blood-red; bill whitish, washed grey-blue; legs blue-grey. Differs from *A. melanotis* in smaller size, unmarked dark brown to tan crown, distinctive white ear-patch, and conspicuous ventral black spotting. Sexes alike in plumage, female on average smaller than male; one captive female was noted to have pure brown iris. Juvenile is like adult, but crown duller, less black, underparts more dilute buff with more greenish wash, iris greyer and bill dusky to blackish; immature like adult, but bill darker. Race *geislerorum* has distinctively paler tan crown than nominate, and white ear-covert feathering extending forwards to include lower lores, underparts variable but tend to be whiter with bolder black spots; *cinnamomeus* is similar to nominate, but brown crown tinged more green, lower lores more white, heavier black spotting on white ear-coverts, cinnamon underparts darker; *stonii* differs from others in having distinctive blackish-brown crown and lores contrasting with pure white ear-coverts, and deep cinnamon underparts with smaller black spots. Voice. Territorial calls by pairs include cat-like nasal meowing, prolonged harsh churring, and low hissing or rasping; partners maintain contact with brief high-pitched metallic sharp "tink" or "chink" notes.
Habitat. Forest, occasionally forest edge; mainly lowland and hill forest, but also monsoon forests in SE. Sea-level to 800, sometimes to 1200 m.
Food and Feeding. Fruits and insects; also small adult birds, and doubtless nestlings. Nestling diet fruits and arthropods. Forages among foliage, mostly of forest substage, also to middle levels. Singly, in pairs and in family parties; sometimes in groups with other fruit-eating birds.
Breeding. Season variable across range, egg-laying recorded in Jan, Apr–Jun and Nov, nestlings in May–Jun; breeding bimodal at some localities. Forms perennial socially monogamous pairs within all-purpose territory. Courtship involves silent vigorous chases through low foliage and on ground, and hopping on to and between sapling trunks and branches. Nest a sturdy bowl of stout twigs with few large leaves, shallow egg-cup depression lined with strong slender stems (unlike nests of congeners, lacks wood pulp and mud), built c. 2–3 m above ground among bases of pandanus tree (*Pandanus*) fronds or in upper fork of slender leafy sapling; in captivity, nest built by female alone. Clutch 1 egg in wild, 1–3 eggs in captivity; in captivity, incubation period 17–24 days and nestling period 17–23 days; only female incubates and broods, but both sexes feed young; one wild juvenile remained with parents for more than 3·5 months after leaving nest.
Movements. Resident.
Status and Conservation. Not globally threatened. Common and widespread throughout most of range; uncommon in Ok Tedi mining area, in C New Guinea. Nine birds/10 ha of lowland rainforest at Brown R, in SE of range.
Bibliography. Banks (1998), Beehler *et al.* (1986), Bell (1982d), Coates (1990), Diamond (1972), Frith & Frith (2001b, 2004), Gilliard (1969), Gilliard & LeCroy (1967a, 1968), Gregory (1996), Hoyle (1975), Marshall (1954), Mayr (1931c), Rand (1942a, 1942b), Richter & Schumann (2008), Ripley (1964), Schodde & Hitchcock (1968), Simson (1907), Wilkinson (2001), Urbach (2008).

2. Black-eared Catbird

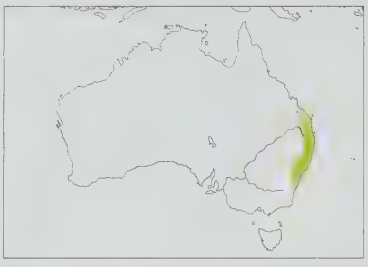
Ailuroedus melanotis

French: Jardinier oreillard **German**: Schwarzohr-Laubenvogel **Spanish**: Maullador Orejudo
Other common names: Black-cheeked/Spotted Catbird

Taxonomy. *Ptilonorhynchus melanotis* G. R. Gray, 1858, Aru Islands.
Probably forms a superspecies with *A. crassirostris*; sometimes considered conspecific, but treatment as separate species supported by morphological and geographical factors, and equivocal protein-allozyme data. Birds of this species in Fakfak Mts, Kumawa Mts and Wandammen Mts (all NW New Guinea) of uncertain racial identity and tentatively included in *arfakianus*, but confirmation required; limits of race *jobiensis* uncertain, and birds in Adelbert Mts could belong to *astigmaticus*; birds in Jimi R area, also of uncertain race, tentatively included in *guttaticollis*. Ten subspecies recognized.
Subspecies and Distribution.
A. m. misoliensis Mayr & Meyer de Schauensee, 1939 – West Papuan Is (Misool).
A. m. arfakianus A. B. Meyer, 1874 – mountains of Vogelkop (Tamrau and Arfak), Onin Peninsula (Fakfak Mts), Bomberai Peninsula (Kumawa Mts) and Wandammen Mts, in NW New Guinea.
A. m. jobiensis Rothschild, 1895 – Bewani Mts, Torricelli Mts, Prince Alexander Mts, middle Idenburg R and Adelbert Mts, in N New Guinea.
A. m. facialis Mayr, 1936 – Nassau Mts and Oranje Mts, in W New Guinea.
A. m. guttaticollis Stresemann, 1922 – Hunstein Range, Sepik R and Jimi R, in NE New Guinea.
A. m. astigmaticus Mayr, 1931 – mountains of Huon Peninsula, in NE New Guinea.
A. m. melanotis (G. R. Gray, 1858) – Aru Is, and lowland Trans-Fly region of S New Guinea.
A. m. melanocephalus E. P. Ramsay, 1883 – mountains of SE New Guinea E from Herzog Mts in N and Mt Karimui (and possibly Kratke Mts) in S.
A. m. joanae Mathews, 1941 – E Cape York Peninsula (Pascoe R and Iron Range areas S to Rocky R, in McIlwraith Range), in N Queensland (NE Australia).
A. m. maculosus E. P. Ramsay, 1875 – wet tropics of N Queensland from Big Tableland S to Seaview Range and Mt Halifax.

Descriptive notes. 29 cm; male 196–285 g and female 196–261g (New Guinea), male 145–205 g and female 140–199 g (Australia). Nominate race has black crown to nape spotted with white to buff (pale feather centres), spots larger and sparser on crown, smaller and denser on nape, and variably washed greenish; remaining facial areas of contrasting black and finely marked white feathering, but conspicuous solid black ear-patch; chin blackish, throat dirty whitish to pale buff, strongly marked by indistinct dark greyish feather tipping; upperparts grass-green to emerald green, upperwing rich parrot-green, white spots on some flight-feather tips; uppertail emerald-green, central feather pair with tiny white tips (or no white), remaining rectrices extensively tipped white; upper breast dirty buff with green wash, heavily scalloped with blackish-brown broad feather edging, remaining underparts buffy with variable greenish wash and variable amounts of dark margins; some undertail-coverts with one or two indistinct broad pale greyish chevron-shaped bars; iris deep blood-red; bill pale grey to creamy white; legs blue-grey. Sexes alike in plumage, female on average smaller than male. Newly fledged juvenile (of race *maculosus*) has downy crown dark chestnut-brown, back and wings like adult, ventral plumage uniformly pale greyish-white with green wash, iris mid bluish-grey (darker, blackish-grey, against pupil), bill pale dirty whitish; immature like adult, but crown and nape (or only nape) marked with finer, narrower, light central feather shafts and buff crown spots, pale throat spots and central feather marking of entire underparts whiter, broad feather edging on underparts more pure green. Races differ mainly in size, plumage coloration and extent of markings, New Guinea birds larger and heavier than Australian ones: *arfakianus* differs from nominate in having extensively much darker (black) spotted throat, dark green chest, paler (white or almost so) large spots on black crown, and larger and clear white patch behind black ear-coverts; *misoliensis* is like previous, but blacker at base of throat; *jobiensis* has spotting on blackish crown more buff (less pure white), obvious white patch behind black ear-coverts, more blackish chin, throat and upper chest but fine buff spotting thereon, and remaining underparts darker; *facialis* is like nominate, but spots on crown and mantle darker, more cinnamon, and throat more buff (less white); *guttaticollis* has spotting of crown to mantle more rufous and less buffy, throat and chin much darker, underparts generally more rufous; *astigmaticus* is longest-tailed race, has blacker crown with fewer, paler and finer spots; *melanocephalus* has blacker-looking crown (buff spots slightly smaller and/or sparser), is blacker on chest and throat, more rufous below; *joanae* is most similar to nominate, but with markings on chest less black; *maculosus* has head, nape and upper back less deep black than nominate, with dark brownish feather edges, pale spots small, underparts paler and greener with broad brown-green feather edges, chest less heavily marked. Voice. Cat-like nasal meowing, wailing territorial song given by pair-members throughout year; also sneeze-like sounds and harsh scold notes; partners maintain contact by sharp high-pitched single or double "tick" or "tic" notes.
Habitat. Lowland and upland tropical rainforest and adjacent tall secondary growth and wet sclerophyll forest, also gardens and orchards; in New Guinea, also mixed (particularly riverine) rainforest to open eucalypt–paperbark (*Eucalyptus–Melaleuca*) forest in S (Merauke R area) and monsoon woodland and scrub in S Trans-Fly. Sea-level to 2250 m (mainly 600–1700 m) in New Guinea; to 1540 m (mainly below 900 m) in Australia.
Food and Feeding. Mostly fruits, predominantly drupes and berries, also some flowers, stems, sap, and animals (mostly arthropods); in Australia (race *maculosus*), also bird eggs and nestlings. Nestling diet mostly fruits, especially figs (*Ficus*), also animals; earthworms (Oligochaeta), insects and pieces of birds recorded for *maculosus* nestlings. Caches fruits in niches for later consumption. Forages mostly by searching, occasionally sallying, in canopy, mainly for fruits; also among understorey and on forest floor for leaf-litter invertebrates, especially when feeding young. Feeds alone, in pairs and in family parties; associated with other fruit-eating birds (including other bowerbird species) in tree canopy.
Breeding. Season Aug–Jan in New Guinea, but little known; Aug–Mar (peak Oct–Dec) in Australia, duration of season c. 4 months. Long-standing monogamous pair within all-purpose territory; pair typically persists for several years within home range, mean size of which 1·6 ha, flies average c. 70 m from nest to forage, little overlap in foraging ranges of adjacent nesting pairs (race *maculosus*). Courtship involves little more than hopping excitedly about perches by both partners, male sometimes giving sharp calls, often while holding in bill food, which he may pass to female after mating. Nest a large, bulky, deep, open bowl with sparse to substantial foundation of larger sticks, deep cup mainly of large green to dried leaves, inner layer of decaying wood pulp and/or mud pieces, and egg-cup lining of fine twiglets and supple vine tendrils; built c. 1–7 m above ground, mostly in sapling or climbing vines; nest-site often reused habitually. Clutch 1–2 eggs (mostly 1) in New Guinea and 1–3 eggs (mostly 2) in Australia, eggs laid on alternate days; incubation by female, period 22–23 days; nestlings brooded by female for up to 15 days, fed by both sexes, nestling period 19–20 days; parents perform display over forest floor to distract predators; one adult-sized juvenile with parents c. 50 m from nest, 49 days after having left it. Overall nest success rate 57% (for 63 nests of race *maculosus*), and average of one fledged young produced per pair per season; will renest following seasonally early loss of clutch or brood. Oldest recorded individual more than 19 years of age.
Movements. Resident. Longest distance travelled by marked individual 2 km. Possible winter dispersal to lower altitudes in Australia.

On following pages: 3. Green Catbird (*Ailuroedus crassirostris*); 4. Tooth-billed Bowerbird (*Scenopoeetes dentirostris*); 5. MacGregor's Bowerbird (*Amblyornis macgregoriae*); 6. Streaked Bowerbird (*Amblyornis subalaris*); 7. Vogelkop Bowerbird (*Amblyornis inornata*); 8. Yellow-fronted Bowerbird (*Amblyornis flavifrons*); 9. Archbold's Bowerbird (*Archboldia papuensis*); 10. Golden Bowerbird (*Prionodura newtoniana*).



Status and Conservation. Not globally threatened. Common and widespread throughout range. Distribution in New Guinea possibly more extensive; once heard throughout mid-montane forests of Ok Tedi area, in C New Guinea, although unrecorded there during four subsequent years.
Bibliography. Bell (1969a), Christidis & Schodde (1992), Coates (1990), Diamond (1972), Ford (1977), Frith, C.B. (1994c), Frith, C.B. & Frith (1990d, 2001b, 2001c, 2001d, 2004), Frith, D.W. & Frith (2000), Gilliard (1969), Gilliard & LeCroy (1967a), Gregory (1996), Higgins *et al.* (2006a), Hoogerwerf (1964), Hunt (1992), MacGillivray (1918), Mack & Wright (1996), Marshall (1954), Mees (1982), Miller (1937), Pratt & Stiles (1983, 1985), Rand (1942a, 1942b), Rowland (2008), Schodde & Mason (1999), Warham (1962).

3. Green Catbird

Ailuroedus crassirostris

French: Jardinier vert **German**: Grünlaubenvogel **Spanish**: Maullador Verde
Other common names: Large-billed Catbird

Taxonomy. *Lanius crassirostris* Paykull, 1815, "Nova Hollandia" = Sydney, New South Wales, Australia.
Probably forms a superspecies with *A. melanotis*; sometimes considered conspecific, but treatment as separate species supported by morphological and geographical factors, and equivocal protein-allozyme data. Monotypic.
Distribution. Coastal E Australia from SE Queensland (Dawes Range area) S to SE New South Wales (to area due E of about Canberra).

Descriptive notes. 31 cm; male 167–289 g, female 169–211 g. Plumage above is mostly green, blackish feather tipping giving variably smudged finely spotted appearance to crown, ear-coverts, malar area and chin, and fine line of white feathers, finely flecked blackish, encircling eye; nape, mantle and side of neck finely and sparsely streaked whitish, streaks becoming broader and forming conspicuous white patch on lower neck (above carpal joint of closed wing), outer webs of primary coverts, tertials and secondaries broadly tipped whitish (conspicuous spotted appearance); chin and throat dirty whitish with blackish feather bases and greenish tips (heavily mottled appearance); breast paler, more yellowish-green, than upperparts, becoming more dilute on lower parts to straw-yellow central abdomen; feathers of lower throat finely streaked to spotted white centrally, marks becoming increasingly broad and elongate on breast (spotted appearance) and below (streaked appearance); undertail-coverts with very dilute green wash, and basal ones with narrow greenish subterminal and terminal bar; iris deep blood-red; bill pearly whitish, variably washed greenish; legs variably pale. Sexes alike, female on average smaller than male. Newly fledged juvenile has russet down on crown, upperparts like adult but duller, underparts much less green and darker, dirty whitish with very faint green wash on central belly and abdomen; immature has finer, narrower, pale nape markings, reddish-brown iris, greyer bill. Voice. Territorial song of pair variable cat-like wailings; also sneeze-like sounds; partners maintain contact with sharp high-pitched "tick" or "tic".
Habitat. Subtropical rainforest and associated edges, eucalypt (*Eucalyptus*) forest and woodland, gardens and orchards; favours watercourses, especially for nesting. Sea-level to c. 1000 m.
Food and Feeding. Mostly fruits, especially figs (*Ficus*), some flowers, leaves, succulent stems; animals, mostly arthropods, but also tree-frogs and nestling birds. Nestling diet mostly fruits, especially figs; some animal items, including beetles (Coleoptera), cicadas (Cicadidae), millipedes (Diplopoda), pieces of birds. Caches fruits for later consumption. Forages mostly by searching, occasionally making sallies, predominantly in canopy for fruits, but occasionally on ground for invertebrates. Robs smaller passerines of their prey. Feeds alone, in pairs and with other fruit-eating birds, including other bowerbird species.
Breeding. Breeds mid-Sept to Feb/Mar, peak Oct–Dec, duration of season c. 4 months. Monogamous pair within all-purpose territory; nesting territory 0·6 ha, parents ranging average of c. 38 m from nest, at other times foraging mostly confined to 1·2-ha home range. Courtship involves intense chasing by partners in and about tree canopies; male feeds mate throughout year. Nest a large, bulky, open cup consisting of foundation of sticks and twigs, discrete deep, compact and substantial bowl of large dried leaves and few vine stems, inner layer of decaying wood and sometimes earthy epiphytic fern matter, with finer twiglet and vine tendril egg-cup lining; built c. 2–18 m above ground in fork of densely foliaged small to large tree, in vine tangle or atop epiphytic ferns; nest-site often reused habitually. Clutch 1–3 eggs, mostly 2, laid on alternate days; incubation by female, fed on nest by male, period 23–24 days; nestlings brooded by female, brooding declines after day 13 but continues at low intensity until fledging, young fed by both sexes, nestling period c. 21 days; parents display on forest floor to distract predators; one juvenile remained partially dependent on parents for more than 72 days, two others independent c. 80 days after fledging. Overall nest success 65% (25 nests), each pair averaging 1·1 fledged young per season; pairs renests following loss of clutch or brood, particularly if early in season. Oldest marked individuals lived for at least 13 years.
Movements. Resident. Longest distance travelled by marked individual 9 km.
Status and Conservation. Not globally threatened. Restricted-range species: present in Eastern Australia EBA. Fairly common and widespread throughout range where extensive habitat remains; rare or absent in isolated rainforest patches less than 2·5 ha in extent.
Bibliography. Baker *et al.* (1999), Blakers *et al.* (1984), Chaffer (1931b), Church (1997), Donaghey (1981, 1996), Frith (1980), Frith & Frith (1979, 2001b, 2004), Gannon (1936), Gwynne (1937), Higgins *et al.* (2006a), Howe (1986), Innis & McEvoy (1992), Jackson (1921), Lea & Gray (1936), Lenz (1999), Male & Roberts (2002), Marshall (1930, 1935, 1954), McGill & Lane (1955), Rowland (2008), Schodde & Mason (1999), Woodall (1994, 1997).

Genus *SCENOPOEETES* Coues, 1891

4. Tooth-billed Bowerbird

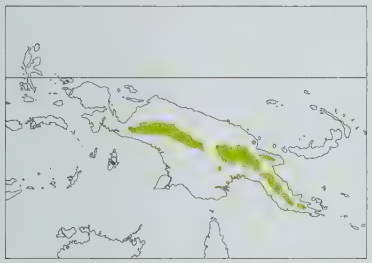
Scenopoeetes dentirostris

French: Jardinier à bec denté **German**: Zahnlaubenvogel **Spanish**: Pergolero Dentado
Other common names: (The) Stagemaker, Stagemaker Bowerbird, Toothbill/Tooth-billed Catbird

Taxonomy. *Scenopoeus dentirostris* E. P. Ramsay, 1876, Bellenden Ker Range, 3000–4000 feet [c. 915–1220 m], north Queensland, Australia.
Sometimes placed in genus *Ailuroedus*. Birds from Johnstone R described as a geographical race, *minor*, but differences from those in rest of range considered trivial. Treated as monotypic.
Distribution. Wet tropics of NE Queensland (from Big Tableland S to Mt Elliot), in NE Australia.

Descriptive notes. 27 cm; male 132–199 g, female 157–182 g. Drably plumaged cryptic brownish bowerbird with bill adapted for leaf-eating (folivory); specialized notches and cusps (or "teeth") on cutting edges of lower mandible fitting into reciprocal indentations in closed upper mandible. Male has head and entire upperparts brown-olive, with fine eyering of rust-coloured feathers; ear-coverts finely streaked dilute cinnamon (paler feather centres); leading edges of flight-feathers and wing-coverts paler, more cinnamon-brown, bases and proximal inner webs of primaries horn-coloured, remainder of primaries and entire secondaries pale brownish-olive; throat dirty buff, variably smudged and streaked with pale cinnamon-grey horn, underparts dirty whitish, heavily streaked brownish-olive, undertail-coverts barred fuscous; iris dark deep brown, almost blackish; bill blackish, paler mandible tips and cutting edges, mouth interior blackish to black; legs variably mid-grey. Sexes alike, female may be on average slightly heavier than male, and mouth yellowish to pinkish-flesh. Newly fledged juvenile is slightly downy grey on head, has breast and throat buff with grey markings, mantle dark olive-grey, upperwing-coverts olive-brown, edged rufous, primaries grey, outer webs edged brown, iris grey, bill grey with darker tip, mouth pale orange, legs light grey; immature male mouth colour as for adult female, rectrices more pointed terminally, and conspicuously paler ochreous leading edges of flight-feathers and upperwing-coverts; male takes at least 4 years to gain black mouth, subadult male mouth partly blackish to black. Voice. Male gives loud advertisement vocalizations (single squeal, screech and "chuck" notes, continuous babble and mimicry) from perches above display court; excellent mimic, at least 40 other bird species, fruit-bats (Pteropodidae), frogs, crickets (Orthoptera) and cicadas (Cicadidae) imitated. Quieter courtship subsong given together with vocal mimicry of avian and other sounds. Silent in austral winter.
Habitat. Upland rainforests, typically at 600–900 m, occasionally higher, to 1600 m; in winter months also lower, 350 m and sometimes to sea-level. Traditional court sites mostly on hilltops and contiguous slopes or ridges, less densely on steep slopes, flatter areas dissected by creeks, typically in undisturbed rainforest but also in adjacent disturbed rainforest and in acacia (*Acacia*) regrowth forest.
Food and Feeding. During display season eats mainly fruits, with some flowers, stems, leaves and animals (mostly arthropods); in winter months mostly leaves and succulent stems. Nestling diet fruits and insects, particularly beetles (Coleoptera). Forages by searching in canopy for fruits; also sallies and hawks termites (Isoptera) and cicadas. Uses mandibles to manipulate leaf pieces skilfully into compact wads, before mandibulating, or "chewing", them and then ingesting food. Feeds alone or with other fruit-eating birds, including other bowerbird species.
Breeding. Season Sept–Jan, peak of egg-laying Nov–Dec; display season starts Aug–Sept (earlier if fruits abundant), peak Oct–Dec (when male attendance on average more than 60% of daylight hours), wet-season rain (Jan–Mar) ends court attendance, but some brief post-moult activity Feb–Apr. Polygynous, promiscuous male seasonally clears and decorates terrestrial court; female builds and attends nest alone. Traditional court sites clumped and may form exploded lek, average inter-court distance 50–68 m, fidelity to single court site by individual adult male 20 years or more; court up to c. 2 × 4 m, encompassing base of at least one display tree trunk and decorated with up to c. 180 fresh leaves (placed paler underside uppermost), recleared each season; leaf theft by rival males common; average home range of four adjacent court-attending males 9·5 ha (mean overlap between them 50%), males travelled average of c. 60 m from court to forage and to steal or harvest leaves, and up to c. 400 m to creeks to drink or bathe. Courtship by male involves hiding behind display trunk and giving subsong of mimicry (Vocal display), followed by vigorously animated posturing and vocalization (Visual display) as male rushes across court to female; if she holds her ground in face of this advance, male mates upon reaching her. Nest sparse with stick (sometimes orchid stem) foundation, egg-cup lining of finer twigs, built c. 8–27 m above ground in densely foliaged vine tangle; two active nests were c. 50 m from active traditional court sites. Clutch 1–2 eggs, mostly 2; no information on incubation and nestling periods; female performs display to distract predators; a juvenile still being fed by parent in Apr. One male lived for at least 19 years and another for 20 years after capture, former discernibly immature in appearance for at least 4 years and adult for 15 more, latter was adult when marked and thus lived to more than 24 years old; average annual survival rate and life expectancy over 19 consecutive seasons for 24 males in Paluma Range 90% and 9·4 years, respectively.
Movements. Presumed mainly resident; during winter months some individuals, possibly immatures, descend to as low as sea-level.
Status and Conservation. Not globally threatened. Restricted-range species: present in Queensland Wet Tropics EBA. Common throughout small range; surviving habitat fully protected. In Paluma Range, traditional court sites relatively densely clumped in optimal habitats, where c. 2 courts/ha and inter-court distance 60 m, but more dispersed on less favoured topography, where less than 1 court/ha and courts more than 100 m apart. Selective logging results in reduction, by one third, of numbers of courts attended by males.

Barker & Vestjens (1990), Crome & Moore (1989), Frith & Frith (1979, 1985a, 1993e, 1994b, 1995a, 1999a, 2001b, 2001d, 2004), Frith & McGuire (1996), Frith, Frith & Moore (1994), Grant & Laurance (1991), Higgins *et al.* (2006a), Jackson (1909, 1910), Lavery & Grimes (1974), Marshall (1951b, 1954), Moore (1991), North (1909), Phillips (2002), Rowland (2008), Schodde & Mason (1999), Vinson & Freeman (2006), Warham (1962).



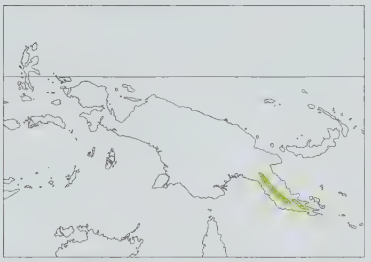
Genus *AMBLYORNIS* Elliot, 1872

5. MacGregor's Bowerbird

Amblyornis macgregoriae

French: Jardinier de MacGregor **Spanish**: Pergolero de MacGregor
German: Goldhaubengärtner
Other common names: Crested/Gardener/Mocha-breasted Bowerbird, Crested/MacGregor's Gardenerbird; Huon Bowerbird (*germana*)

Taxonomy. *Amblyornis macgregoriae* De Vis, 1890, Musgrave Range, 7000–9000 ft [c. 2130–2740 m], south-east New Guinea.
Has hybridized with *A. subalaris*. Race *germana*, bowers of at least some of which differ from those typical of species, possibly represents a separate species. Seven subspecies recognized.
Subspecies and Distribution.
A. m. mayri E. J. O. Hartert, 1930 – W & C New Guinea (Weyland Mts E to W Hindenburg Mts).
A. m. kombok Schodde & McKean, 1973 – E New Guinea probably from at least Strickland R (possibly from Hindenberg Range) E to Mt Hagen, Kubor Range, Bismarck Range and Kratke Range.
A. m. lecroyae C. B. Frith & D. W. Frith, 1997 – Mt Bosavi, in EC New Guinea.
A. m. amati T. K. Pratt, 1982 – Adelbert Mts, in NE New Guinea.
A. m. germana Rothschild, 1910 – mountains of Huon Peninsula, in NE New Guinea.
A. m. macgregoriae De Vis, 1890 – SE New Guinea from W Kukukuku and Herzog Range E to W Owen Stanley Range.
A. m. nubicola Schodde & McKean, 1973 – E Owen Stanley Range (Mt Dayman and Mt Simpson massifs, and probably E from Mt Suckling), in extreme SE New Guinea.



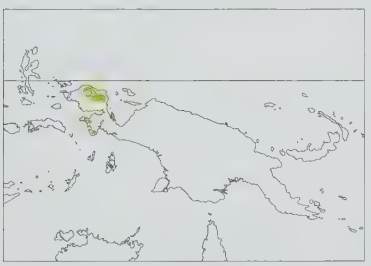
Descriptive notes. 26 cm; male 100–145 g (immature male 110–139 g), female 104–140 g. Male nominate race is dark brownish-olive above, a little paler on face and neck, slightly greyer on lores, with slight orange-reddish wash on crown and darker on mantle and tail; extensive broad, filamentous, elongated, erectile and spreadable crest glossy deep-orange (showing white highlights in some lights), some feathers tipped brown, and brown feathering overlying orange crest base and its lateral edges; variable umber below, darkest on side of breast and outer lower flanks, paler on chin, throat and lower parts; undertail browner, central shafts yellowish; iris dark brown; bill blackish, paler and bluish base; legs dark bluish-grey. Female is similar to male but lacks crest, and has upperparts slightly paler and washed umber, giving more orange appearance. Juvenile undescribed; immature like female, but slightly warmer brownish below and with more distinct dark breast; subadult male like adult female, but with initial signs of crest. Races differ mainly in size and in crest length, but also some plumage variation: *mayri* is largest, with longest crest; *kombok* is similar in size and proportions to nominate, but crest rather densely feathered, throat and upper breast pale brownish-olive, lower breast, abdomen and undertail-coverts bright light buffy brown; *lecroyae* is small and short-tailed, differing from previous in being smaller and darker, and more strongly suffused with orange on head and upperparts; *amati* is smallest race (but only two adult male specimens), with short wing (like *germana*) and tail (like preceding race), has chin to upper breast dark olive-brown, only slightly paler than side of head and forehead; *germana* is like nominate, but on average lighter and fractionally smaller in wing and crest; *nubicola* has entire undersurface uniformly dull coffee-brown, and crest rather densely feathered. Voice. Male at bower site gives loud advertisement vocalizations, including harsh tearing sounds, growls, thudding and tapping sounds, and ventriloquial hollow to clear whistles, as well as avian and other vocal mimicry (including of human-made sounds). Male courtship subsong includes high-quality avian mimicry; flight of adult male about bower produces whirring, which it also mimics vocally.
Habitat. Primary tall mixed montane and southern beech (*Nothofagus*) rainforest, and rarely moss forest or cloudforest; 1000–3000 m, mainly 1600–2300 m. Traditional bower sites regularly and linearly spaced along forested ridges with appropriate slope and width, closure of canopy, and density of saplings adjacent to bower sites. Tree species important to diet are common along ridges and slopes where bowers present.
Food and Feeding. Mostly fruits, also some flowers and animals (mostly arthropods). Nestling diet fruits and arthropods, including cicadas (Cicadidae) and ants (Formicidae). Forages mostly in canopy.
Breeding. Season Sept–Feb; eggs Oct–Jan on Mt Missim (E New Guinea), and a well-incubated egg in early Jul on Mt Hagen; display season extends for up to 9–10 months (May–Feb), peak early Oct, when male bower attendance on average more than 50% of daylight time. Polygynous, promiscuous male seasonally decorating terrestrial bower of simple maypole type; female builds and attends nest alone. Non-territorial except for defence of bower site; median distance adult male travels from bower c. 88 m, but up to 800 m in order to steal decorations; home range c. 150–200 m in diameter and generally elliptical about bower site. Bower consists of conical tower of sticks up to 3 m tall around a sapling or tree-fern trunk, placed atop thick circular, saucer-shaped mossy platform (c. 1 m in diameter) raised at its circumference into elevated rim up to c. 75 cm above inner mat (in Huon Peninsula, race *germana* bowers have broader lower tower section and circular bower mat, on base of which are fibres like those of tree-fern, instead of moss); one Mt Missim bower used for more than 20 consecutive years; on Mt Missim bowers c. 180 m apart; bower decorations include fruits, charcoal, berries and fungi, also many other items, including human-made ones; insect frass and vegetable matter placed on lower central column sticks; bower destruction and theft of decorations occurs. Courtship involves an extra-bower display, male leaping rapidly between vertical sapling trunks, a "hide-and-seek" on bower mat with subsong (Vocal display), wing-flicking and crest-flashing, followed by sudden rush at female in rapid semicircular dance of mincing steps with crest intermittently erected and fanned (Visual display). Nest a sparse stick foundation, with leafy cup, and egg-cup lined with supple twiglets and rootlets, placed 2–3 m above ground in pandanus (*Pandanus*) tree crown, sapling, or tree-fern crown; mean distance of six active nests from nearest active bower 116 m (Mt Missim). Clutch 1 egg; incubation in excess of 17 days; no information on nestling period.
Movements. Resident. Immatures and females may descend to lower elevations in winter months. Females and immature males maintain relatively large, overlapping home ranges throughout year, foraging in same areas as adult males.
Status and Conservation. Not globally threatened. Common and widespread throughout range. Mt Bosavi race (*lecroyae*) known from just nine specimens. In Oct 1999, portable saw-mill logging, and associated cutting of saplings, caused abandonment of at least four traditional bower sites in Southern Highlands (E New Guinea). Crests of adult males formerly used in Papuan headdresses and also in trade; this practice and trade possibly still occur, at least locally.
Bibliography. Bell (1972a), Coates (1990, 2001), David & Gosselin (2002b), Diamond (1972), Diczbalis (1968), Frith (1970a), Frith & Frith (1992a, 1997e, 1998a, 2001b, 2004), Gilliard (1969), Greenway (1935), Hopkins (1992), Kocher-Schmid (1993), Mackay & Cheeseman (1990), Marshall (1954), Mayr & Gilliard (1954), Mayr & Rand (1937), McCarthy (2006), Pratt & Stiles (1983, 1985), Pruett-Jones, M.A. & Pruett-Jones (1982, 1983), Pruett-Jones, S.G. & Pruett-Jones (1985), Rand (1942b), Schodde & McKean (1973a).

6. Streaked Bowerbird

Amblyornis subalaris

French: Jardinier à huppe orange **German**: Rothaubengärtner **Spanish**: Pergolero Estriado
Other common names: Gardener Bowerbird, Striped (Gardener-)Bowerbird, Orange-crested Bowerbird, Eastern (Gardener-)Bowerbird, Eastern Gardenerbird

Taxonomy. *Amblyornis subalaris* Sharpe, 1884, Astrolabe Mountains, south-east New Guinea.
Has hybridized with *A. macgregoriae*. Monotypic.
Distribution. Mountains of SE New Guinea, from upper Angabunga R E to Mt Suckling, Mt Simpson and Mt Moiba areas.



Descriptive notes. 24 cm; male 96–107 g, female 95–122 g. Male has entire face and upperparts warm olive-brown, lores and feathers on each side of crest darker and richer; extensive erectile and laterally spreadable crest rich orange, tips of feathers darker and redder to a deep brown; flight-feather shafts amber; paler below, central portion of chin, throat and upper chest feathers palest, almost tawny-olive, creating indistinct streaking; undertail-coverts slightly darker; underside of tail olive-brown with whitish feather shafts; iris dark brown; bill mostly bluish-grey, blackish basally and along culmen; legs blue-grey. Female is similar to male but crestless; older female may have one to several elongated narrow crown feathers (coloured as on either sex), reminiscent of adult male crest. Juvenile undescribed; immature male like adult female; subadult male has crest smaller and possibly with more brown feathering. Voice. Insufficient information; repertoire evidently similar to that of *A. macregoriae*, but detailed study required.
Habitat. Primary forest and taller secondary forest with *Lithocarpus* and *Castanopsis* oaks in lower montane zone, at 650–1300 m, occasionally to 1500 m. Traditional bower sites on upper steep slopes of ridges c. 5–30 m below a forested ridge crest with secondary growth.
Food and Feeding. Almost unknown, but presumably fruits and insects; frequents forest substage to canopy.
Breeding. Few data on season, a few eggs collected in Dec–Jan; display season Sept–Dec. Polygynous, promiscuous male seasonally decorates complex maypole bower; female builds and attends nest alone. Non-territorial except for defence of bower sites; inter-bower distance c. 50–75 m. Bower a hut-like, teepee-shaped structure based upon central maypole (column of sticks or tree-fern fibres built around thin sapling) with roughly dome-shaped roof of sticks with back and side walls, and an opening at front providing access to semicircular tunnel-like passageway entered on each side of central maypole; bower to c. 80 cm high, 120 cm wide and 100 cm in diameter; bower decorations include small fruits of various colours, flowers and leaves, confined to central column base, and larger items including also beetle (Coleoptera) elytra, tree resin and pieces of fungi on outer mat and top of stick parapet before it, often placed in discrete piles; average male attendance more than 40% of daylight hours; bower destruction and theft of decorations occur. Courtship not fully described, but apparently similar to that of *A. macregoriae*. One nest was a large bowl-shaped structure with long brown dead leaves and few sticks, lined with twigs. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in Central Papuan Mountains EBA. Widespread and locally common throughout range. Crest of adult males used by Papuans for head-dresses and also in trade.
Bibliography. Coates (1990), Frith (1970a), Frith & Frith (1998a, 2001b, 2004), Gilliard (1969), Harrison & Frith (1970), Marshall (1954), McCarthy (2006), Opit (1975), Schodde & McKean (1973a), Simson (1907), Weiske (1902).

7. Vogelkop Bowerbird

Amblyornis inornata

French: Jardinier brun **German**: Hüttengärtner **Spanish**: Pergolero Pardo
Other common names: Crestless/Plain/Brown (Gardener-)Bowerbird, (Vogelkop) Gardener Bowerbird, Brown Gardener/Gardenerbird, Crestless Gardener

Taxonomy. *Ptilorhynchus inornatus* Schlegel, 1871, Hatam, Arfak Mountains, north-west New Guinea.
Taxonomic status of birds in Fakfak Mts uncertain; compared with those in Arfak Mts, they are slightly darker above and brownish-yellow below, but with grossly different bowers, although genetic material reveals little differentiation; study required. Monotypic.
Distribution. Mountains of Vogelkop (Tamrau, Arfak), Onin Peninsula (Fakfak), Bomberai Peninsula (Kumawa) and Wandammen Mts, in NW New Guinea.

Descriptive notes. 25 cm; male 105–155 g, female 105–146 g. Has deep warm brown crown, paler on sides of head and hindneck, becoming more brownish-olive on rest of upperparts; chin indistinctly scalloped by greyish feather edging; upperparts dark brownish-olive, tinged cinnamon-brown; flight-feathers pale and dilute brownish-olive, broad buff basal trailing edges to all but outer two primaries, inner edges of primaries ochreous, as axillaries (contrasting with dull outer edges in Kumawa Mts, less contrasting in Arfak and Tamrau Mts, least so in Wandammen Mts); tail feathers brownish-olive with pale greyish inner margins; buff to pale cinnamon below, darker, more olive-brown, on sides, undertail-coverts buff; iris dark brown; bill blackish, base of lower mandible paler, slightly bluish; legs deep bluish. Sexes alike in plumage, female on average fractionally smaller than male and with legs darker and less blue. Juvenile undescribed; immature male like adult female; subadult male like adult male. Voice. Male at bower sites gives loud advertisement vocalizations, including wavering whistles, chugging, wheezing, spitting and ratchetting sounds, a sharp click, a "kah kah" repeated at intervals, and a series of "keu keu keu keu" notes; also mimicry of other birds and of human-made sounds; male also has courtship subsong with mimicry.
Habitat. Rainforest with canopy 25–30 m tall and with emergents of *Agathis labillardieri* and *Araucaria cunninghamii*; at 1000–2075 m, mainly 1200–2000 m. Traditional bower sites on ridge spines and flanks with sloping ground; absent from extensive areas of bare karst.
Food and Feeding. Little known. Diet of fruits and insects.

Breeding. Two nests each with single egg in early Oct; display season Jul–Feb, months of peak activity varying across range. Polygynous, promiscuous male seasonally decorating complex or simple maypole bower; female builds and attends nest alone. Non-territorial except for defence of bower sites. Two distinctive maypole bower types, both based around central column of sticks or other material placed around sapling trunk, one type (in mountains of Tamrau, Arfak and Wandammen) a complex hut-like structure, similar to that of *A. subalaris*, with roof of epiphytic orchid stems but sometimes of sticks or fern fronds, column base covered with moss that extends down and out to form frontal mat or lawn, bower to 1·5 m (mostly c. 1 m) tall and 2 m in diameter, other type (in Fakfak Mts and Kumawa Mts) a simple roofless structure built around saplings, similar to that of *A. macgregoriae*, with tower to 2 m tall and basal circular mat to 2 m in diameter; bower mat decorated with discrete piles of colourful fruits and flowers, insect exoskeletons, pieces of charcoal, fungi, and other items, colour and quantity varying greatly from one site to another; bower destruction and theft of decorations occurs. In courtship, male responds to arrival of female by rushing into rear of bower to crouch and hide while producing a subsong, then standing stiff and erect and occasionally running out from concealment to bower entrance, head cocked to one side for a few moments, then dashing back inside again; male sings throughout. Two nests found, both built into forking branches of sparsely foliaged sapling, respectively 1 m and 2·5 m above ground; one nest was an untidy structure of sticks with a leaf lining, like that of *A. macregoriae* but with fewer sticks in base. Clutch at least 1 egg; no information on incubation and nestling periods.
Movements. Resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in West Papuan Highlands EBA. Widespread and common throughout range. People near Hatam, in Arfak Mts, avoid destroying bowers of this species.
Bibliography. Astley (1913), Bailey (1996), Beccari (1878), Coates (1990), David & Gosselin (2002b), Diamond (1986b, 1987a, 1988), Frith & Frith (2001b, 2004), Gibbs (1994), Gilliard (1969), Gilliard & LeCroy (1970), Marshall (1954), Mayr & Meyer de Schauensee (1939), Uy (2002), Uy & Borgia (2000).

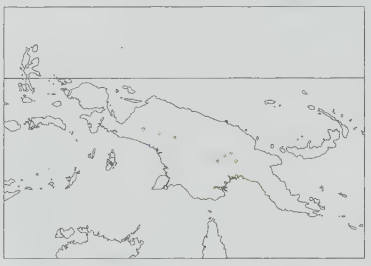
8. **Yellow-fronted Bowerbird**

Amblyornis flavifrons

French: Jardinier à front d'or **German**: Gelbscheitelgärtner **Spanish**: Pergolero Frentigualdo
Other common names: Golden-fronted Bowerbird, Yellow-fronted Gardenerbird, Golden-fronted/Gold-maned Gardener

Taxonomy. *Amblyornis flavifrons* Rothschild, 1895, "Dutch New Guinea" = western New Guinea. Monotypic.
Distribution. Foja Mts, in N New Guinea.

Descriptive notes. 24 cm. Male has forecrown and conspicuously extensive broad erectile and laterally spreadable crest from beak to mantle brilliant glossy deep yellow, a few top feathers with brown tips; mantle and back dark rufous-brown, upperwing and uppertail brown-olive; side of face, lores, chin, throat and upper chest similar to back, but paler and less reddish; breast and abdomen, undertail-coverts and underwing-coverts rich buff, variably washed with deep cinnamon; iris dark brown; bill blackish; legs bluish-grey. Female (no specimens) resembles male, but without crest. Juvenile undescribed; immature male probably like female; subadult male acquires orange-yellow under-feathers of crest before the more yellow superficial ones. Voice. Male at bower gives loud advertisement vocalizations, including short high nasal screeches, rasps, clucks, wheezes, croaks, crackling, whip-like sounds, and vocal mimicry of birds and human-made sounds. During courtship, a male gave weak high-pitched 2-note whistle; subsong unrecorded.
Habitat. Montane moss forest dominated by *Araucaria*, southern beech (*Nothofagus*), *Podocarpus*, and *Lithocarpus* oaks; 940–2000 m, mainly 1100–1800 m. Traditional bower sites on ridge crests c. 0·5 km apart.
Food and Feeding. Fruits recorded as eaten. Frequents middle storey and lower canopy at 6–20 m, also forest floor.
Breeding. Little known. Presumed polygynous. Non-territorial except for defence of bower sites. Male builds simple maypole bower, tower to c. 1 m high and basal circular mat c. 1 m in diameter; bower decorations include discrete piles of blue, green and yellow fruits, each on a distinct part of bower mat. During one observed display to a presumed female, an adult male held a blue fruit in bill and directed it at female as she moved about bower site; he frequently spread crest laterally, raised and lowered it vertically, and shook his head rapidly from side to side, causing crest to quiver. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in North Papuan Mountains EBA. Has very small global range, within which total population estimated at a few thousand at most.
Bibliography. Beehler *et al.* (2007), Coates (1990), Diamond (1982b, 1982c), Frith & Frith (2001b, 2004), Gilliard (1969), Rothschild (1895).



Genus *ARCHBOLDIA* Rand, 1940

9. **Archbold's Bowerbird**

Archboldia papuensis

French: Jardinier d'Archbold **German**: Archboldlaubenvogel **Spanish**: Pergolero de Archbold
Other common names: Black/Gold-crested Black Bowerbird; Sanford's (Golden-crested)/Tomba Bowerbird (*sanfordi*)

Taxonomy. *Archboldia papuensis* Rand, 1940, Bele River, 2200 m, 18 km north of Lake Habbema, Snow Mountains, western New Guinea.
Races long thought to constitute two separate species, on alleged grounds that *sanfordi* was crested and built a "mat" bower and male nominate was uncrested and possibly built an avenue bower; this belief now known to be mistaken, as males of both races have crest and build maypole bower. Two subspecies recognized.
Subspecies and Distribution.
A. p. papuensis Rand, 1940 – mountains of WC New Guinea (Wissel Lakes, in Weyland Mts area; Nassau Range and Oranje Mts; Bele R and L Habbema region).
A. p. sanfordi Mayr & Gilliard, 1950 – mountains of EC New Guinea (Mt Hagen, Mt Giluwe, Tari Gap, and S Karius Range).

Descriptive notes. Male 37 cm, 170–195 g; female 35 cm, 163–185 g. Male nominate race is dark sooty grey to jet-black, with extensive prominent black-streaked orange-yellow crest from forehead to nape and tapering to a point posteriorly; some tapering yellow crest feathers may be umber immediately adjacent to terminal black tip; flight-feathers dark grey-brown, tinged olive or blackish; upperwing blackish, primary coverts sooty brown or jet-black, sometimes with traces of cinnamon; iris dark brown; bill black; legs blue-grey. Female is smaller, particularly in wing and tail lengths, than male; lacks crest, plumage not so black as male's, primary coverts conspicuous cinnamon to yellowish (appearing to form patch on leading edge of wing) and this sometimes lightly to heavily spotted/smudged blackish. Newly fledged juvenile has downy crown, blackish bill, purple-grey legs and dark brown-grey iris; immature male like female, but blacker and lacking paler chin/forecrown; subadult male like adult male, but only few crest feathers intruding into black crown. Race *sanfordi* is slightly larger and longer-tailed than nominate, bill proportionately smaller, plumage blacker (especially in immature and subadult stages). Voice. Male at bower gives loud advertisement vocalizations with ventriloquial quality, including whistles, buzzing, snapping, tearing, and harsh grating or churring sounds; also vocal mimicry of numerous sympatric bird species (at least ten noted) and inanimate sounds within habitat. Subsong during display including bleating calls and mimicry of bird calls, of whirring bird wings and of fluttering vegetation.
Habitat. Frost-prone high montane mossy beech (*Nothofagus*) forest with coniferous (*Podocarpus*) tree species in canopy and pandanus (*Pandanus*) and umbrella trees (*Schefflera*) and scrambling bamboo on gentle topography; at 1750–3660 m, mainly 2300–2900 m. In lower subalpine habitat in Ilaga valley (E range of nominate race) found at 2850–3660 m, this being highest altitude for any bowerbird. Traditional bower sites evenly dispersed within forest patches interspersed with grassland.
Food and Feeding. Virtually no information on adult diet. Nestling diet predominantly fruits, also some animals; latter mostly tree-climbing skinks (Scincidae), as well as insects and pieces of nestlings of other birds. No information on foraging habits.
Breeding. Season Sept–Feb, with eggs Nov–Dec; display season Sept–Dec, but Mt Hagen bowers attended as early as Jul. Polygynous, promiscuous male seasonally decorating arboreal maypole bower; female builds and attends nest alone. Non-territorial, except for defence of bower by male; for 16 traditional bower sites over 1000 ha at Tari Gap (E New Guinea), mean nearest-neighbour distance 370 m. One traditional bower site persisted for more than 15 years and one adult male attended same site for more than six seasons. Bower consists of cleared area (largest 6 × 5 m) on which a mat of fern fronds is accumulated; perches above mat draped with stems of epiphytic orchids, sometimes in flower (these represent bower material, i.e. not decorations), up to 2·6 m above bower mat; average male bower attendance more than 50 % of daylight hours (Tari Gap); decorations include large snail shells, beetle (Coleoptera) wingcases, fruits, fungus, tree resin, and charcoal, placed on mat in discrete collections, also occipital nuptial plumes of adult male King of Saxony Bird-of-paradise (*Pteridophora alberti*). Courtship by male involves two display elements, Prostrate posture and Grovel Display, and he performs various other postures on bower mat while giving subsong; also Displacement-chases female from bower mat until she succumbs to his advances. Nest an untidy large deep, bulky bowl with stick foundation, deep substantial cup of large dried leaves (with uppermost ones still fresh and green), egg-cup lining of curved twiglets, built 3–7 m above ground in leafy crown of sapling within or adjacent to small gap in forest (no canopy directly above); average distance of seven active nests from nearest active bower 250 m; female may nest in same area, sometimes in same tree, for years in succession. Clutch 1 egg; incubation 26–27 days; average nestling period 30 days. Overall success rate for eight nests at Tari Gap 88%; mean number of fledged offspring per female 0·88 per season. Oldest marked adult male lived for at least 6 years.
Movements. Resident.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Central Papuan Mountains EBA. Reasonably common locally; generally rare throughout patchy range. Global population thought to be rather small, and possibly declining as a result of habitat loss. Nominate race in W appears to have larger population and considered probably secure, at least in short term; E race, *sanfordi*, has total range of only c. 800 km², and habitat on two mountains within its range is threatened by logging activities. Habitat disturbance and destruction resulting from increasing human population, and associated logging and habitat degradation, represent potential threats. Fire damage following a severe drought 20 months previously, coupled with human activity, resulted in abandonment of at least six traditional bower sites below Tari Gap.

Genus *PRIONODURA* De Vis, 1883

10. **Golden Bowerbird**

Prionodura newtoniana

French: Jardinier de Newton **German**: Säulengärtner **Spanish**: Pergolero Dorado
Other common names: Newton's (Golden) Bowerbird, Queensland Gardener, Newton's (Gardener-)Bowerbird

Taxonomy. *Prionodura newtoniana* De Vis, 1883, Tully River Scrubs, north Queensland, Australia.
Monotypic.
Distribution. Uplands of wet tropics of NE Queensland (from Thornton Range and Mt Windsor Tableland S to Seaview–Paluma Range), in NE Australia.

Descriptive notes. Male 25 cm, 62–86 g; female 23 cm, 62–96 g. Smallest bowerbird. Male has head, chin and upperparts olive-green, richly suffused with glossy deep golden-yellow (thus appearing rich deep brownish-yellow), small central crown crest and extensive nape patch pure glossy deep yellow (glossy plumage reflecting white highlights in some lights); upperwing more olive with yellow wash; central pair of rectrices and extensive dark tips of adjacent two pairs olive-brown, contrasting with dilute deep yellow of other rectrices; throat and entire underparts and undertail dilute orange-yellow, glossy and variable in intensity on chest, abdomen and belly; iris pale buff, darker at outer edge; bill blackish-brown, paler tip and base; legs blue-grey with olive wash. Female is heavier than male, has considerably shorter tail; plumage radically different, brownish-olive above and much paler, glaucous, below, with paler chin and throat and darker, slightly brownish, side of breast and flanks; iris and bill darker than male's. Newly fledged juvenile has downy crown, plumage similar to female, but darker, less grey, below, less yellow in flight-feathers, iris dark brown, bill and legs blue-grey; immature male like female; some immatures moult directly from female-like to adult male plumage in single moult, others wear discernible subadult plumage (some yellow feathers in otherwise female-like plumage) during season before gaining full adult plumage; one male was immature-plumaged for at least six years before acquiring adult plumage. Voice. Male bower-advertisement song a pulsating rattle note, typically lasting for 1–2 seconds, repeated several times, geographically variable; peak calling Sept–Dec. Other calls at bower site, or elsewhere, include squeals, screeches, scold-rasps, or wolf-whistle notes or a medley of them; also high-quality mimicry of calls of other bird species (more than 20 recorded) and of mechanical sounds. Mimicry sometimes opportunistic; courtship display with soft subsong incorporating high-quality avian and other mimicry.
Habitat. Upland rainforests at 350–1530 m, mainly 700–990 m. Traditional bower sites on flatter terrain and along ridge slopes, gentle slopes, ridges immediately around hill crests, and below steeper slopes where terrain levels off; canopy coverage usually of more than 70%; none on hill tops or in disturbed forest.
Food and Feeding. Mostly fruits, particularly from vines, also flowers, buds, also arthropods. Nestling diet mostly fruits, with some insects, mostly cicadas (Cicadidae), proportion of fruit increasing with age of nestling. Fledglings eat fruits and insects. Males cache fruits, particularly bunches of wild pepper (*Piper*) in Paluma Range, in niches around bower sites to be retrieved for later consumption; one nesting female observed to retrieve a cached fruit. Forages by searching and sallying; occasionally hawks cicadas. Usually feeds alone, but 3–4 (often immature) individuals may do so in same fruiting canopy, sometimes with other bird species, including other bowerbirds.
Breeding. Season Sept–Feb, egg-laying peak Nov–Dec, nestlings Dec–Jan, season lasting c. 4 months; display season Jul/Aug–Jan, ceasing with onset of wet-season rains, also some post-moult bower activity (often by immature males) Mar to early May. Polygynous, promiscuous male decorating large simple maypole bower; female builds and attends nest alone. Foraging male travels mean distance of 143 m from bower site to collect and/or steal decorations from rivals, estimated mean home range of eight adult males 7 ha; from up to five years before gaining ownership of traditional bower, immature visits many bower sites, at average of 391 m from the one eventually occupied, distance diminishing to average 186 m in year before acquiring full occupancy. Traditional bower sites attended for at least 20 years; for 12 traditional bower sites over 50 ha in Paluma Range, mean nearest-neighbour distance 150 m. Traditional bower a single tower or twin towers of sticks, up to c. 2–3 m tall and built around, and supported by, saplings, vines or tree, sticks becoming fused together by fungi (some bower structures survive for more than 20 years), has pre-existing horizontal perch consisting of woody vine, living sapling, fallen dead branch or tree root; small arboreal and/or terrestrial subsidiary stick structures may be built around main bower; during peak season males spend average of 50% of daylight time at bower site; individual male attends same bower site for up to 16 years (average 7 years); bower decorations mainly grey-green lichen and sprigs of creamy-white fruit with attached black seed (of a *Melicope* species), and other creamy-white flowers, placed on platform(s) of tightly aligned sticks formed where tower sticks abut bower perch; theft of decorations occurs. Five basic display elements, Chase, Bow and Head-nod-and-shake on bower perch or nearby ones, Flight-hover around bower (last three displays performed in any sequence and accompanied by brief vocal rattles and squeals), and Hiding (behind tree trunk or bough, accompanied by subsong); once a female settles on bower perch, male may suddenly stop vocalizing and aggressively Displacement-chase her from bower with loud calls. Nest takes up to 25 days to construct, a deep, bulky, open cup with stick foundation, discrete substantial bowl-shaped structure of dead leaves and leaf skeletons, with egg-cup lining of fine supple and springy tendrils, built up to 5 m above ground within "roofed" vertical crevice in tree trunk or crevice-like situation; average distance of 37 active nests from an active bower site 97 m; nest-site may be reused in one or more subsequent seasons. Clutch 1–3 eggs, mostly 2, laid on alternate days; incubation 21–23 days; brooding ceases when nestlings 14–15 days old (irrespective of brood size), nestling period 17–20 days; female performs display to distract predators. Overall success of 29 nests 28%; average of one fledged young produced per female per season. Recorded longevity for male in excess of 23 years, one female at least 14 years; average annual survival rate and expectation of further life over 19 consecutive seasons for 48 males 91% and 10·9 years, respectively (Paluma Range).
Movements. Resident. In Paluma Range, a marked adult female resighted 140 m from original point of capture c. 14 years later. During winter months some individuals in female-like plumage move to lower altitudes.
Status and Conservation. Not globally threatened. Restricted-range species: present in Queensland Wet Tropics EBA. Reasonably common throughout small limited remaining range. Habitat in range fully protected. One adult male remained in attendance of bower while immediate habitat was logged; when bower was destroyed, he built another 8 m from original (15 m from a much-used logging track), and persisted with new bower throughout logging activity and into subsequent years.

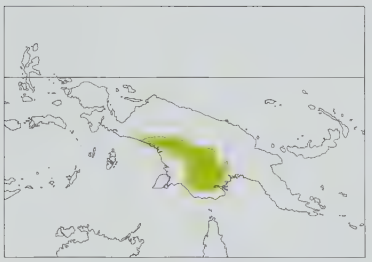
Genus *SERICULUS* Swainson, 1825

11. Masked Bowerbird

Sericulus aureus

French: Jardinier du Prince d'Orange **German**: Goldlaubenvogel **Spanish**: Pergolero Áureo
Other common names: Black-faced (Golden) Bowerbird, New Guinea Golden Bowerbird, Northern Flame Bowerbird, Golden Regentbird

Taxonomy. *Coracias aurea* Linnaeus, 1758, "Asia"; error = Vogelkop, north-west New Guinea.
May form a superspecies with *S. ardens*, *S. bakeri* and *S. chrysocephalus*; often treated as conspecific with first of those, with which it hybridizes in area of marginal range overlap on Wataikwa R (SW New Guinea). Monotypic.
Distribution. NW & N New Guinea, from mountains of Vogelkop, Wandammen Mts, Weyland Mts, Oranje Mts, and C ranges and N coastal ranges (Torricelli Mts, Prince Alexander Mts) E to near Sepik R.



Descriptive notes. 24·5 cm; male 175–180 g, female 165–175 g. Male has head, nape, mantle and side of neck highly glossy brilliant deep orange with pure white highlights, contrasting black facial mask, chin and throat; elongate filamental deep orange upper neck plumage (may fall to either side of neck) and mantle become increasingly suffused with orange, and mid-back, rump and most uppertail-coverts entirely deep yellow; upperwing mostly brilliant deep yellow, area of black spotting just above carpal joint extending to alula and primaries, alula feathers with variable amount of brownish-black on leading edges and terminal part of inner webs; outer primaries blackish-brown, very small area of paler deep yellow at bases, latter becoming progressively larger across primaries; secondaries deep yellow, tipped blackish-brown, darker tipping becoming progressively smaller towards body; uppertail dark blackish-brown, outer rectrices with small, fine deep yellow tips; underparts deep yellow, slightly paler than upperparts, more pale and washed out on undertail-coverts; undertail like uppertail but brown more than blackish, thighs black; iris pale lemon-yellow; bill pale bluish-grey, extensive black tip; legs greyish. Female is less heavy than male, has slightly longer tail; plumage radically different, more olive-brown above and orange-yellow below, and with chin, throat and upper breast washed olive-brown, dark edging on chest feathers (forming obvious scalloping), iris dark brown. Juvenile undescribed; immature male like female, rectrices more pointed than those of subadult/adult male; subadult male also similar to female, but with variable amount of adult male plumage (one or two feathers, to almost all) intruding. Voice. Few records; occasional faint "ksh" notes, harshly rasped note, and odd buzzing during courtship.
Habitat. Hill and middle montane forests at 850–1400 m, occasionally down to 500 m; a few bowers located along ridgetops.
Food and Feeding. Diet little known; fruits, including figs (*Ficus*), also insects. Forages from 12 m above ground to treetops. Forages alone or in small groups, possibly in groups more during winter months; observed in fruiting canopy with *Amblyornis inornata*, and other avian frugivores, without interaction; individual in female-like plumage fed in canopy within a mixed-species flock.
Breeding. Bowers in Vogelkop (Tamrau Mts and Arfak Mts) active Aug–Nov. Polygynous, promiscuous male seasonally building and decorating terrestrial avenue bower. Avenue bower similar to that of *S. chrysocephalus*, but few described; one in Tamrau Mts 18 cm along central avenue and 26 cm from ground to tallest of wall sticks; bower decorations few, up to six, including blue and purple fruits, black bracket fungus, snail shells, and yellow to bronze leaves; unconfirmed if decoration fruits observed to have disappeared were stolen by rivals or eaten by visiting *Ailuroedus melanotis*; "painting" of inside of bower walls recorded. Courtship little known; some postures similar to those of *S. chrysocephalus* and *Chlamydera* species. No other information.
Movements. Presumed resident.
Status and Conservation. Not assessed. Usually treated as conspecific with *A. ardens*. Probably not globally threatened. Little-known species. In W of range, not uncommon in forests of Vogelkop and on N slopes of Snow Mts near Mt Wilhelmina. Dried skins seen at Goroka (extreme E of range) indicated a geographically extensive plume trade until recently.
Bibliography. Coates (1990), Diamond (1969, 1985), Frith & Frith (2001b, 2004), Gilliard (1969), Gilliard & LeCroy (1970), Hartert (1930), Iredale (1950), Marshall (1954), McCarthy (2006), Salvadori (1876).

12. Flame Bowerbird

Sericulus ardens

French: Jardinier ardent **German**: Flammenlaubenvogel **Spanish**: Pergolero Flamígero
Other common names: Golden Bowerbird(!), Golden Regent Bowerbird, Yellow-throated Golden Bird

Taxonomy. *Xanthomelus ardens* D'Albertis and Salvadori, 1879, upper Fly River, 430 m, New Guinea.
May form a superspecies with *S. aureus*, *S. bakeri* and *S. chrysocephalus*; often treated as conspecific with first of those, with which it hybridizes in area of marginal range overlap on Wataikwa R (SW New Guinea). Monotypic.
Distribution. S New Guinea from Wataikwa R–Mimika R and upper Noord R–Endrich R E to upper Fly R, Strickland R and Nomad R, and to near Ludesa Mission (Mt Bosavi); also in Tarara–Morehead area and inland from Merauke (between Kumbe and Merauke R).
Descriptive notes. 25·5 cm; two captive males 120 g and 140 g, five females 127–168 g. Generally like *S. aureus*, but slightly smaller, shorter-tailed, and lacking black facial mask, and with bill finer,

paler and slightly longer. Male has crown, nape and mantle rich and dark glossy flame-scarlet, gloss reflecting white highlights; chin and throat deep yellow; elongate deep orange upper neck plumage (may fall to either side of neck) and mantle become increasingly suffused with orange, and mid-back to uppertail-coverts deep yellow; upperwing mostly brilliant deep yellow, small area of black spotting just above carpal joint (forming black patch); uppertail black, fine yellow edging on some or all rectrices, very faint yellow tips (can be lacking); underparts deep yellow, paler than upperparts, undertail-coverts more pale and washed out; iris bright yellow; bill pale grey; legs blackish. Female is similar in size to male, except for longer tail; plumage radically different, olive-brown above, redder about head, orange-yellow below, chin to upper breast washed olive-brown, slightly darker feather edging on chest feathers (forming only faint scalloping), iris dark brown. Newly fledged juvenile has crown down silvery grey, bare face, bill base and throat bright flesh-pink, underpart plumage soft downy white with faintest yellow wash, thereafter like female but paler, bright yellow underpart feathering intruding into softer, white plumage on each side of central sternum, iris dark grey-brown; immature male similar to adult female; subadult male like adult female, but with few to almost all feathers of adult male plumage intruding into female-like plumage. Voice. Few records; harsh rasping and hissing notes, and oft-repeated churring "shh" or faint "ksh" note.
Habitat. Lowland and foothill rainforest and tall secondary forest, including patches in flat savanna (mainly beneath *Melaleuca* in Trans-Fly). A few bowers were on gently sloping ground in foothill forest, swamp-forest, and tall secondary forest with sparse undergrowth and slender trees, sometimes adjacent to a treefall.
Food and Feeding. Diet little known; fruits and insects. Forages singly, sometimes in twos or threes, and occasionally in company with other avian frugivores.
Breeding. Display season in E of range mostly May–Jul at Nomad R and Aug–Nov near Strickland R. Polygynous, promiscuous male seasonally building and decorating avenue bower. Bower neatly constructed with thicker, shorter sticks in outside bases of walls and finer longer ones within, average dimensions of three bowers 23 cm long, 16 cm wide and 19 cm high externally, avenue 17 cm long and 8 cm wide, and compass orientations at 355°, 55° and 30°; decorations (up to about ten) include blue, purple and brown fruits, purple and white flowers, snail shells, and yellow-brown leaves within avenue, blackish glossy leaves outside it; decoration theft unrecorded, but bower destruction may occur (one bird destroyed a bower, but unknown if it was owner or a rival male); "paint" applied to inside avenue walls. Courtship recently observed at Kiunga (in NE of range): on catching sight of visiting female, male collected some sticks from nearby and began to dance, during which he tried first to make himself appear as small as possible, and then to look bigger by "pumping" himself up (enhancing the effect by spreading his wings); dancing seemed to be signal for female to inspect bower and, when she did, male's dancing intensified; male and female touched bills while both were at the bower. No information on nest and other aspects in the wild; in captivity, clutch 1 egg, incubation period 21–22 days, nestling period 21–23 days (partly artificial incubation period 21 days and nestling period 22 days), juvenile feeding independently 50–56 days after hatching.
Movements. Presumed resident.
Status and Conservation. Not assessed. Usually treated as conspecific with *A. aureus*. Probably not globally threatened. Little-known species. Not uncommon in Wataikwa R area in W of range and in Fly R region in EC part. People of Fly R wore dried skins of adult males, with skins traded to coast and Daru I; a dried skin obtained at Mt Hagen (outside range of this species). Skins of adult males occasionally decorate vehicle rear-view mirrors in Kiunga area; contemporary and future forestry activity of concern in this area.
Bibliography. Bell (1970a), Coates (1990), Diamond (1969, 1985), Frith & Frith (2001b, 2004), Gilliard (1969), Gregory (1997), Jensen & Hammer (2003), Marshall (1954), McCarthy (2006), Plantema & van der Spek (2007).

13. Adelbert Bowerbird

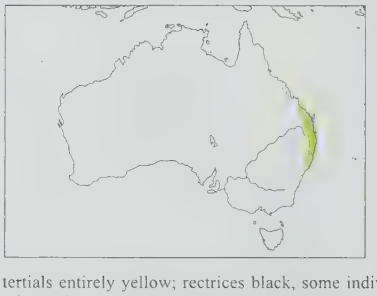
Sericulus bakeri

French: Jardinier de Baker **Spanish**: Pergolero de los Adelbert
German: Rotscheitel-Laubenvogel
Other common names: Adelbert Regent/New Guinea Regent Bowerbird, Baker's/Beck's/Madang/Macloud Bowerbird, Madang Golden Bird, Fire-maned Bowerbird

Taxonomy. *Xanthomelus bakeri* Chapin, 1929, Madang, Astrolabe Bay = Adelbert Mountains, c. 915 m, above Maratambu Village, north-east New Guinea.
May form a superspecies with *S. aureus*, *S. ardens* and *S. chrysocephalus*. Monotypic.
Distribution. Adelbert Mts, NE New Guinea.

Descriptive notes. 27 cm; male 178–183 g, female 164–184 g. Male has rich deep glossy flame-scarlet crown finely spotted and smudged black, nape and extensive glossy filamentous silky cape (arising from lower nape) flame-scarlet at base to mostly deep orange, with gloss reflecting white highlights; upperwing and tail black, deep yellow bases of primaries and secondaries forming conspicuously extensive yellow wing patch; rest of plumage glossy jet-black, this colour extending in narrow band over eye and lower lores to base of upper mandible; iris pale yellowish; bill blue-grey, extensive black tip; legs blackish. Female is similar in size to male, except for longer tail; plumage differs radically, generally brownish-olive above, a little paler about head than elsewhere, and dirty whitish below, variably washed dilute buff and finely barred or scalloped on chin and throat, broadly barred with variable brownish-olive

On following pages: 14. Regent Bowerbird (*Sericulus chrysocephalus*); 15. Satin Bowerbird (*Ptilonorhynchus violaceus*); 16. Lauterbach's Bowerbird (*Chlamydera lauterbachi*); 17. Fawn-breasted Bowerbird (*Chlamydera cerviniventris*); 18. Spotted Bowerbird (*Chlamydera maculata*); 19. Western Bowerbird (*Chlamydera guttata*); 20. Great Bowerbird (*Chlamydera nuchalis*).



to brownish-grey on underparts; iris and bill dark brown. Juvenile undescribed; immature male similar to adult female; subadult male variable, like adult female but with few feathers of adult male plumage intruding to almost wholly like adult male. Voice. Few records of sharp hissing, rasping and ratchety notes; adult male near his bower gave short churrs and mimicked call of Magnificent Riflebird (*Ptiloris magnificus*) and Magnificent Bird-of-paradise (*Cicinnurus magnificus*). Nest-building female gave quite loud "k-zzz k-zzz" or "tk-sss tk-sss" from above nest-site and nearby trees, and repeated a piping note several times.
Habitat. Hill forest, also secondary growth at rainforest edges; 1200–1450 m, occasionally down to 900 m. One bower on gentle ridge slope c. 60 m below its crest in slightly disturbed primary hill forest, broken canopy permitting more light to bower than typical elsewhere in habitat; second bower also lacked low foliage canopy above it.
Food and Feeding. Fruits, including figs (*Ficus*) and berries, also arthropods, including ants (Formicidae). Forages from middle storey up to canopy; visits fruiting trees in native gardens. Encountered singly, in twos, or in small groups containing many more individuals in female-like plumage than adult males.
Breeding. One nest in Feb, and female with enlarged ovary in Feb; one adult male called at his bower in Sept. Presumably polygynous, promiscuous male seasonally building and decorating avenue bower; female builds and attends nest alone. Small avenue bower like that of congeners, average dimensions of five bowers 28 cm long, 26 cm wide and 33 cm high externally, the avenue 14 cm long and 7 cm wide, and mean compass orientation 251°; bower decorations (up to c. 50) include blue and purple fruits and a yellowish-brown leaf. Courtship undescribed. One nest built in crown of small epiphytic fern on semi-dead tree near a track. No other information.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Adelbert and Huon Ranges EBA. Until very recently (2009) listed as Vulnerable. Generally rather uncommon but locally fairly common; possibly sparser at lower end of altitudinal range, but confirmation required. Total extent of range estimated at 570 km², and global population at fewer than 10,000 individuals. Although Adelbert Mts not heavily populated by humans, elevational band in which this species occurs is zone within which local agriculture practised, and for food villagers rely greatly on hunting; in at least some places, however, this species not hunted. Relatively little primary forest remains in region, but extensive areas of mature secondary forest, evidently acceptable to this bowerbird, are available. Much of species' range is comparatively inaccessible, and so less vulnerable to logging. Some further deforestation likely in view of increasing human population, although small-scale clearance for garden agriculture need not pose a major problem.
Bibliography. Anon. (1975, 2009), Bell (1970a), Bender (2000), Butchart & Stattersfield (2004), Chapin (1929), Coates (1990), Frith & Frith (2001b, 2004), Gilliard (1969), Mackay (1989), Marshall (1954), Stattersfield & Capper (2000).

14. **Regent Bowerbird**

Sericulus chrysocephalus

French: Jardinier prince-régent **German**: Gelbnacken-Laubenvogel **Spanish**: Pergolero Regente
Other common names: Australian Regent Bowerbird, (Australian) Regentbird, Golden Regent(bird)

Taxonomy. *Meliphaga chrysocephala* Lewin, 1808, Patterson's River [= Hunter River], New South Wales, Australia.
May form a superspecies with *S. aureus*, *S. ardens* and *S. bakeri*. Two documented cases of hybridization with *Ptilonorhynchus violaceus*. Birds from Blackall Range (SE Queensland) proposed as race *rothschildi* on basis of supposedly richer orange crown of male, but studies indicate no constant geographical difference in this character. Monotypic.
Distribution. Coastal zone of CE Australia from E Queensland (Connors and Clarke Ranges, on Eungella Plateau) S, with distributional gap about Fitzroy R valley inland of Rockhampton, to E New South Wales (to area immediately N of Sydney).

Descriptive notes. 24·5 cm; male 76–110 g, female 91–138 g. Male has forehead, crown, nape and upper mantle brilliant deep yellow, often washed darker flame-scarlet on forecrown; forehead and crown feathers short, dense, plush-like; remaining upperparts and entire underside jet-black, including narrow arching line over eye; two outermost primaries and all upperwing-coverts matt black, remainder of primaries largely golden-yellow with broad to narrow black tips and leading edges, secondaries (lacking black leading edges) with black tipping becoming smaller towards innermost feathers, latter and most tertials entirely yellow; rectrices black, some individuals with fine central yellow terminal tips, others with yellow on outer edges of inner webs of some rectrices; iris bright yellow; bill orange-yellow; legs blackish-brown. Female is on average larger than male in weight and body, but not in bill length; plumage differs radically, variable dull dirty off-white to drab grey on head, which finely streaked, mottled and smudged and with contrasting dull sooty-black crown patch, upperparts variably olive-brown, mantle spotted off-white, dirty off-white to creamish below, broad central line of dull sooty-black feathers down throat, underparts broadly barred blackish-brown; old females may have darker forehead, and may show some plumage characters of adult male; iris dark brown, bill blackish. Newly fledged juvenile has well-developed wing feathers and down persisting on crown, nape and mantle, this then replaced by soft and loosely textured plumage resembling immature of both sexes, one-month-old juvenile has striking crown and nape pattern, dark brown iris, blackish bill, light grey legs; immature male like female, acquires adult plumage, iris and bill coloration gradually (mostly during fourth and fifth years); subadult male (by sixth year) variable, like immature male with few feathers of adult plumage intruding to like adult male with few feathers of immature plumage remaining, and with almost completely yellow eye and orange bill, full adult plumage gained in seventh year; female in first post-juvenile plumage more densely/heavily scalloped and barred ventrally than adult, black crown bordered around nape with narrow line of dark grey, retains typical brown plumage and dark bare parts and iris to third year, but by end of fourth year iris may be yellow with brown mottling. Voice. Away from bowers the least vocal member of family; in courtship gives typical harsh grating notes and continuous subsong of avian mimicry.
Habitat. Subtropical rainforest, associated sclerophyll woodland, and more open habitats, including cultivated country and urban gardens; sea-level to 900 m, altitudinal limits varying across range. Traditional bower sites dispersed through appropriate ridgetop habitat; tend to be within rainforest on flat or less sloping ground, with immediate liana-thicket cover providing concealment and protection.
Food and Feeding. Mostly fruits, also flowers (buds, petals, nectar), seeds, leaves, and arthropods (mostly insects); most leaf-eating during Jul–Oct non-breeding season. Nestling diet fruits and insects; insects include cicadas (Cicadidae), caterpillars, katydids (Tettigoniidae) and beetles (Coleoptera), cicadas representing significant dietary component. Forages mostly in upper levels of trees. Catches arthropods primarily by gleaning and hawking. Often forages alongside other bowerbirds and other fruit-eating bird species, actively displaces other species from fruiting trees; females dominate males at feeding trees; sometimes forms mixed-species foraging flocks with *Ptilonorhynchus violaceus* and Pied Currawongs (*Strepera graculina*).
Breeding. Season Sept–Feb, peak in egg-laying Nov–Dec, fledging late Feb to early Mar, nesting cycle c. 3–4 months; display season Sept–Jan on Sarabah Range, earlier at some other localities. Polygynous, promiscuous male building and decorating small avenue bower; female builds and attends nest alone. Non-territorial, except for defence of bower site by male, which may attend same site for at least three seasons; for 24 traditional bower sites in Sarabah Range (Queensland), mean nearest-neighbour distance 195 m. Bower a sparse, frail avenue of sticks (sticks touching each other often become fused by whitish fungus), mean dimensions of 33 bowers (Sarabah Range) 23 cm long and 20 cm wide externally, avenue 8 cm wide and 18 cm high, average deviation of 44 avenues from N–S compass orientation 38°; male spends only c. 3% of daylight time at bower site; bower decorations (up to c. 30) include green leaves, pale flowers and petals, seeds, fruits, snail shells, cicada nymph ectoskeletons, and human-made blue items; "painting" of bower and theft of decorations occur; bower structure often short-lived (ten days or less), as regularly destroyed by rival males, or by owner when a rival known to have found it, new bower takes c. 3–4 hours to build (beneath different thicket within same site). Male attracts females in upper forest canopy by means of his bright plumage (rather than, as with other bowerbirds, vocalizations), then leads females to bower site; male courtship consists of three display elements, Initial Bower Display at avenue entrance to bower, Peripheral Bower Display around bower, and Central Bower Display within bower avenue; display postures include wing-flicking, gaping, Nape-presentation postures, and male also charges at female and makes brief vertical "flights", all presenting/enhancing plumage coloration. Nest a frail shallow saucer of loosely placed sticks, egg-cup lining of finer twigs and occasionally a few leaves, cryptically sited 2–31 m above ground in dense foliage of clump of vines, mistletoes (Loranthaceae) or other plant; mean distance of four active nests from nearest active bower was 266 m (closest 20 m). Clutch 1–3 eggs, mostly 2, in captivity laid on alternate days; in captivity, replacement clutch laid in new nest after failure; incubation c. 17–21 days, nestling period 17 days. Overall success of seven nests in Sarabah Range 43 %. Female may first breed in third year, more often in fourth year. Maximum recorded longevity of male at least 23 years.
Movements. Resident. Localized movement to lower altitudes may occur during winter months; individuals in female-like plumage said to make such movements 3–4 weeks earlier than adult males. Of 22 marked individuals recaptured, longest distance travelled was 4 km.
Status and Conservation. Not globally threatened. Restricted-range species: present in Eastern Australia EBA. Locally common or moderately common in larger forest "islands"; uncommon in small remnants. Numbers have diminished in several areas as a result of habitat loss and degradation. Once common about Sydney, but S limit of range now Gosford/Hawksbury R area of New South Wales. Break in distribution in N of range from near Casino to Woolgoolga, with small isolated populations at Iluka and Washpool; absent from Guy Fawkes R valley, where former presence may have linked populations; absence from Comboyne Plateau and Hunter Valley (New South Wales) probably result from clearing of rainforest. Adult males were once hunted for mounting as household novelties, and common in cabinets of mixed birds. Most populations appear fairly stable today.

Genus *PTILONORHYNCHUS* Kuhl, 1820

15. **Satin Bowerbird**

Ptilonorhynchus violaceus

French: Jardinier satiné **German**: Seidenlaubenvogel **Spanish**: Pergolero Satinado
Other common names: Satin-bird

Taxonomy. *Pyrrhocorax violaceus* Vieillot, 1816, "Nouvelle Hollande" [= Sydney, New South Wales], Australia.
Two documented records of hybridization with *Sericulus chrysocephalus*. Two subspecies recognized.
Subspecies and Distribution.
P. v. minor A. J. Campbell, 1912 – wet tropics of NE Queensland (from Mt Amos, just S of Cooktown, S to Seaview–Paluma Range), in E Australia.
P. v. violaceus (Vieillot, 1816) – SE Queensland (Dawes Range, just S of Fitzroy R at Rockhampton) S in coastal zone (less than 250 km broad at widest point) to S Victoria (Otway Range, immediately W of Melbourne).

Descriptive notes. 32·5 cm; male 173–290 g, female 170–258 g. Male nominate race is entirely glossy indigo-blue, showing violet highlights to black in some lights; glossy tips and edges of tertials and upperwing-coverts contrast against exposed duller blackish bases (in some lights); primaries blackish; uppertail blackish, tips and outer edges of each feather with strong indigo-blue gloss; lower belly and thighs less glossy, a little more blackish, than rest of underparts, undertail-coverts blackish with strong glossy edges; iris vivid purple, deep blue at outer edge; bill whitish, or pale yellowish-green with blue wash at base; legs vari-

ably pale-coloured. Female is on average lighter in weight than male and has longer tail; plumage radically different, variable ashy grey-green upperbody relieved by cinnamon-brown wings and uppertail, green below, whitish striations to streaks on chin, throat and upper breast becoming paler downwards, fading to off-whitish, scalloped and barred with greenish; iris deep blue, bill blackish, legs usually rather pale, flesh-coloured to grey. Juvenile has crown softly textured brownish-olive, washed greenish, upperparts brown, off-white below, feathers of chest edged dark grey-brown and those of remainder with broad chevrons and fine edges of same colour, giving scalloped appearance; immature male like female for first three years, but with markedly more pointed rectrices, in fourth to fifth years generally becomes discernibly like adult male through acquisition of increasingly green breast and throat (intermediate-plumaged immature), with increasing age ear-coverts become darker and browner and broad band on upper chest (from directly beneath throat) becomes more yellowish and with chevrons finer, darker (to almost blackish) and denser (latter diminish with subsequent moults, to leave this area more solidly green with almost whitish central feather shafts), dark bill starts to show paler areas; subadult male in sixth year with irregular and variable amounts of blue-black feathering often mottled by patches of green contour feathers, and some dark flight-feathers; female gains adult plumage with first post-juvenile moult. Race *minor* is smaller than nominate, and in female-type plumage has dull bluish-grey cast above. Voice. Bower-advertisement song of adult male a clearly whistled "quoo-eeeew"; also loud harsh churring notes and other vocalizations, including mimicry (avian and human-made sounds); odd mechanical buzzing, and a subsong with avian mimicry during courtship. Nesting female mimics calls of potential predators; flocks vocally conspicuous in non-breeding season.

Habitat. Rainforest, with strong preference for edges, also woodland, adjacent tall sclerophyll woodlands with sapling understorey; winter flocks also in open habitats (parks, fruit orchards, and gardens). Traditional bower sites evenly dispersed through suitable rainforest and woodland.

Food and Feeding. Mostly fruits, but some flowers (petals, stamens and nectar), leaves, seeds, and animals (mostly insects). Nestling diet 95% insects, particularly scarab beetles (Scarabaeidae) and cicadas (Cicadidae), few small fruits; fledglings fed on insects and fruits. Forages at all levels. Fruits mostly plucked in canopy 18 m or more above ground; takes animal items by gleaning and sallying, rarely hawking. Forages alone or with other members of family and other frugivorous bird species; adult males dominate younger birds at food sources. During display season male forages closer to bower, within 50 m, and feeds more on insects; female forages mostly within 100 m of nest. During winter months in flocks of up to 200 individuals, which fly to pastures to graze on grassy shoots, succulent white clover leaves, herbaceous plants; also visit gardens and orchards to eat green vegetables, soft fruits, and nectar. Several individuals of race *minor* foraged in figs, eucalypts (*Eucalyptus*) and paperbark trees (*Melaleuca*) in late May at Julatten (c. 7 km from rainforest); at same site, subadult male seen to fight with and dominate up to three *Chlamydera nuchalis*.

Breeding. Season late Aug/Sept–Jan, egg-laying peak Nov–Dec, young leave nest by late Feb, cycle lasts c. 3·5 months; display season starts May–Jul, peak bower attendance Aug–Oct (when adult male spends c. 70% of daylight within 50 m of bower), activity declining late Nov to Dec. Polygynous, promiscuous male building and decorating avenue bower; female builds and attends nest alone, range of each female encompassing about five bower sites and female visiting at least three males. Bower site can be in continuous use for more than 30 years, one occupied by same male for at least 15 years. Non-territorial, except for defence of bower site by male; mean nearest-neighbour distance for 24 traditional bower sites along rainforest edge 284 m and for 43 in woodland 311 m (Beaury State Forest, in New South Wales), and for 34 sites in rainforested area with much regrowth and adjacent cleared and disturbed areas average 183 m (Bunya Mts, in Queensland). At start of display season, adult male builds new bower on or adjacent to spot used in previous season, bower of two outwardly curving parallel walls of sticks placed upright into foundation platform of fine sticks and grass straws on ground, walls may form arch as uppermost twigs meet and intermesh above avenue, area of platform sticks laid upon ground court extends beyond avenue (bowers with third wall, thus forming two avenues, occasionally occur), bower can comprise more than 2000 sticks; mean dimensions of 36 bowers 31 cm wide and 23 cm high externally, avenue 26 cm long and 14 cm wide, and area of sticks laid upon ground (each platform) extending beyond avenue entrance 45 cm (Beaury State Forest); bowers of race *minor* smaller and typically have avenue floor (sometimes also one or both platforms) lined with fresh green moss; avenue mostly orientated along or close to N–S axis; decorations (up to 200 or more) placed on platform outside one or both avenue entrances, include mostly blue feathers, notably flight-feathers of Crimson Rosellas (*Platycercus elegans*), flowers, fruits, and cicada and spider ectoskeletons, skulls, brownish snail shells, sloughed snakeskin pieces, and much more (including both natural and human-made items); "paint" applied to inner bower walls with ground charcoal, masticated foliage, liverwort, crumbly tree bark, fruits mixed with saliva; theft of decorations and bower destruction common. Adult male displays alone to females in ritualized progression of movements and postures (displays also to immature or subadult males, or when alone, but in less ritualized way); courtship involves two display elements, the first an active one involving vocalized buzzing accompanied by body movements with rapidly and vigorously repeated opening and closing of wings while picking at/up decoration (male mostly hidden from female's line of sight) interspersed with struts/strides across and directly in front of avenue entrance (i.e. in view of female), second one static and involving male in continuous vocal mimicry and raising and lowering himself on flexing legs; also presents nape to female while holding decoration in bill; if female solicits, by crouching and vibrating lowered wings and raising rump, male enters far avenue entrance to mount her from behind. Nest takes 1–2 weeks to build, a shallow saucer of sticks and twigs with egg-cup lining of green and dry leaves, built mostly 2–40 m (average 15 m) above ground in tree or bush; mean distance from nearest active bower of 14 active nests in rainforest 122 m and of eleven nests in woodland 313 m (Beaury State Forest), corresponding figure for nests in rainforested area with much regrowth and adjacent cleared and disturbed areas 85 m (Bunya Mts); nesting site may be repeatedly reused by same female. Clutch 1–3 eggs, mostly 2, probably laid on alternate days; replacement laid if first clutch lost, but second successful brood recorded only once (when insect food atypically abundant); incubation 21–22 days; brooding by female declines after day 13 of nestling life, but continues at low intensity until nestlings fledge (irrespective of brood size), nestling period 17–21 days; female allocates much time to anti-predator behaviour, aggressively chasing away conspecifics and potential predators, adopts frozen posture until danger passes, performs "broken-wing" distraction display while mimicking calls of potential predators; one female fed brood of two at 59 days after they left the nest. Overall success of five nests 25%, each female producing average of 0·35 fledged young per season (Beaury State Forest). Longevity of both sexes at least 20–30 years.

Movements. Mainly resident. Some individuals, particularly those in woodlands, move into more open habitats during winter months to form flocks; during non-breeding period adult males travel more than 1 km from bower site, when males have extensively overlapping foraging ranges. Some localized seasonal movements to lower altitudes during winter. Two individuals found, at different locations, 68 km from where initially marked.

Status and Conservation. Not globally threatened. Common to reasonably abundant in remaining habitat. Much habitat already lost to human exploitation, and some populations in decline. Otway Range population now cut off from main one W of Melbourne; break in distribution of nominate race at Hunter Valley probably due to clearance of rainforest, and Iluka population isolated. Few data on adult male home ranges, but those of six immature males had estimated average of 13·7 ha (Bunya Mts); home range of breeding female in typical years c. 13–14 ha (Bunya Mts), and roughly twice this size in particularly dry seasons. Occurred locally until early 1950s in Australian Capital Territory, where recent increases noted in suburban gardens and parks (developed since mid-1970s), initially only birds in female-like plumage involved during colder winter months, but subsequently summer visitors, adult males and bower-building and bower attendance recorded, most bower activity in winter (when more birds present); first recorded successful breeding there Nov–Dec 2000.

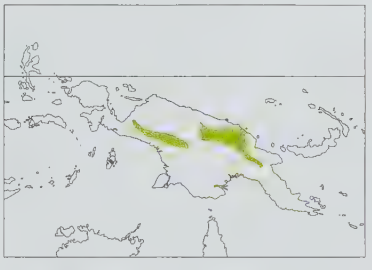
Genus *CHLAMYDERA* Gould, 1837



16. Lauterbach's Bowerbird

Chlamydera lauterbachi

French: Jardinier de Lauterbach **Spanish**: Pergolero de Lauterbach
German: Dreigang-Laubenvogel
Other common names: Yellow-breasted/Yellow-bellied Bowerbird; Uniform Bowerbird (*uniformis*)

Taxonomy. *Chlamydodera lauterbachi* Reichenow, 1897, Jagei River, upper Ramu, eastern New Guinea.
Two subspecies recognized.

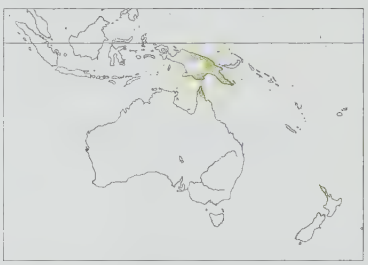
Subspecies and Distribution.
C. l. uniformis Rothschild, 1931 – C New Guinea from Siriwo R (E of Geelvink Bay) E to upper Ramu R and to Okapa–Aiyura area of Eastern Highlands.
C. l. lauterbachi Reichenow, 1897 – Aiome area of upper Ramu R, possibly also near Bogadjim (in Finisterre Mts), in NE New Guinea.

Descriptive notes. 27 cm; male 128–135 g, female 112–120 g. Male nominate race has yellowish olive-green head, obvious silky-rose crown with coppery sheen; feathering of face side and neck conspicuously streaked (pale shaft and adjacent web); upperparts brownish-olive with slender pale feather shafts and pale buff-yellow to olive feather edging (scalloped appearance), uppertail-coverts slightly more yellowish; upperwing-coverts and flight-feathers dusky brown-olive with pale outer edging and much off-whitish to yellowish broad tipping, and larger spotting on tips of flight-feathers; uppertail feathers similar to flight-feathers, but outer edges of outer rectrices more yellow towards base; chin to upper breast greyish to pale yellow, feathers strongly edged dusky grey-brown or olive; remaining underparts yellow, with indistinct pale brown-grey barring on side of breast to flanks; iris dark brown; bill black; legs brownish to greyish. Female is similar to male but duller, with less yellow-olive on crown, slightly paler upperparts, more buff-yellow below, also lighter in weight and slightly shorter-winged. Newly fledged juvenile is like adult, but more streaked above, chin to breast, flanks and abdomen soft downy off-white with grey mottling, pale yellow wash on central abdomen; immature male like adult female; subadult male has few to nearly all reddish feathers intruding into crown. Race *uniformis* (only two specimens) differs from nominate only in having crown yellowish olive-green, not coppery. Voice. Bower-advertisement song and calls of adult male sharp "chilp chilp chilp" and rasping, grating, churring, rattling and hissing sounds; mimics environmental sounds, but avian mimicry recorded only for captives. In courtship gives soft pathetic notes and churring calls.

Habitat. Lowland and middle montane secondary growth, remnant forest patches and forest edges, overgrown gardens and associated or adjacent bushy grasslands, pit-pit (*Miscanthus floridulus*), canegrass-swamps, coffee plantations, and casuarina (*Casuarina*) stands; sea-level to 1800 m. Traditional bower sites amid dense vegetation under large bushy trees just within edge of forest or forest patches, and immediately adjacent to kunai (*Imperata*) or pit-pit grassland with dispersed shrubs and trees.

Food and Feeding. Little known. Fruits and insects, including caterpillars and beetles (Coleoptera); one young was fed with insects. Typically occurs singly or in small parties.

Breeding. Breeds in all months except May, eggs in Apr and Jun–Jan; display season Apr–Jan. Polygynous, promiscuous male building and decorating elaborate avenue bower; female builds and attends nest alone. Non-territorial, except for defence of bower sites by male; bowers c. 0·5–1 km apart, on level ground, atop small rise, beneath bushes, and in marshy areas (where substantial stick bower base may serve as an island). One bower site used for more than ten years. Avenue bower unique in having four walls built upon substantial stick and cane base, main walls angled outwards (rather than vertical or arched over avenue), at each end of avenue platforms extensively developed into additional walls that form cross-passages at right angles to central avenue; consists of up to 3000 sticks, lined with 1000 or more strands of brownish grass, mean dimensions of bower 64 cm long, 67 cm wide and 43 cm high, of main avenue 23 cm long and 10 cm wide, mean size of exposed stick platform at each end of avenue 84 cm long and 17 cm deep, no favoured orientation of central avenue apparent (Baiyer valley, in E of range); bower decorations (up to 1000 or more) mostly grey to blue-grey river-washed pebbles and large spherical blue quandong fruits (*Elaeocarpus*) placed against/into sticks of inner end walls and in central avenue, smaller red decorations placed on bower floor, charcoal used if stones rare; "painting" of bower and bower destruction occur. Courtship involves several display elements, including Nape-presentation (despite unadorned nape), with or without a decoration



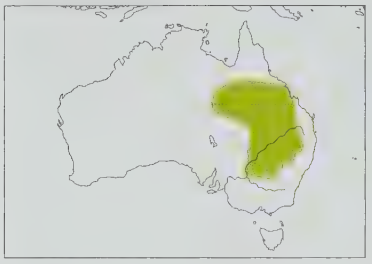
(typically a red fruit) held in bill, with simultaneous soft vocalizations; an Upright posture with sharp wing-flicks, accompanied by loud hissing as bill widely opened towards female to expose orange mouth; sharp jerking of head up and down and flicking of tongue in and out; reminiscent of behaviour of congeners and *Sericulus chrysocephalus*. Nest a neat, compact shallow cup of fine twigs, vine tendrils, dried grasses and bark upon sparse foundation of dry sticks, built 1–4 m above ground, mostly in tree, bush, sapling or grass; mean distance of four active nests from nearest active bower 204 m (Baiyer valley). Clutch 1 egg; no information on incubation and nestling periods.
Movements. Resident.
Status and Conservation. Not globally threatened. Can be locally fairly common and conspicuous, yet scarce elsewhere. Common to abundant in mid-mountain valleys of Wahgi R and Baiyer R, but uncommon on Sepik R; common in savanna and woodland of the drier Ramu valley. Distribution patchy in grasslands in mountains (Weyland Mts, Snow Mts and Star Mts) and in Central and Eastern Highlands, including Mt Hagen suburbs. Single records for Bewani Mts, in North Coastal Range, and in lower Jimi valley.
Bibliography. Bell (1967), Chaffer (1949), Coates (1990), Diamond (1972), Diczbalis (1974), Forshaw & Cooper (1977), Frith & Frith (1989, 2001b, 2004), Gilliard (1969), Gilliard & LeCroy (1966, 1968), Gyldenstolpe (1955a), Marshall (1954), Mayr & Gilliard (1954).

17. Fawn-breasted Bowerbird

Chlamydera cerviniventris

French: Jardinier à poitrine fauve **Spanish**: Pergolero Pechipardo
German: Braunbauch-Laubenvogel
Other common names: Buff-breasted Bowerbird

Taxonomy. *Chlamydera cerviniventris* Gould, 1850, Cape York, north Queensland, Australia.
Both sexes of Australian population heavier than New Guinea ones, but differences considered insufficient to warrant naming of geographical races. Monotypic.
Distribution. NW & E New Guinea (Ransiki and Kebar valleys, in E Vogelkop; and coasts from Jayapura in N and, in S, from Merauke E, including isolates in Jimi valley and Aiyura valley, to SE mountains); and N Queensland (from N tip of Cape York Peninsula S on in E coastal zone to Massy Creek area, E of Coen), in extreme NE Australia.



Descriptive notes. 29 cm; male 145–182 g, female 117–170 g. Plumage is brownish-olive above, slightly paler and greyer on crown, with pale dirty off-white to buff shaft streaks and spotting on feather centres and tips, latter more buff on rump and uppertail-coverts; forehead, lores, side of face and neck irregularly marked with off-whitish streaking and feather tipping; flight-feathers and tail like upperparts, primaries, secondaries and tertials with pale buff leading edges, rectrices with similarly pale outer edging and broad tips; chin, throat and chest pale buff, feathers broadly edged dusky grey-brown to produce streaking, especially across chest; remaining underparts clean pale cinnamon; underside of flight-feathers pale brownish-grey; in worn plumage, lacks larger pale tips on back and wing-covert feathers; iris dark brown; bill blackish; legs greyish-brown to blackish. Sexes alike in plumage, male slightly heavier than female. Juvenile undescribed; immature first-year plumage distinguished from adult by rounder outer web of first primary, more crown spotting, and more fulvous colour of back spotting; subadult like adult. Voice. Bower-advertisement song and other calls of male varied harsh churring, sputtering and rattling with repeated loud, harsh, drawn-out rasping or hissing notes and slurred hollow whistles; has ventriloquial qualities and includes avian and other mimicry. Soft but harsh vocalizations uttered, including mimicry of other birds, during courtship.
Habitat. In New Guinea found in lowland to hill forest patches and in eucalypt–paperbark (*Eucalyptus–Melaleuca*) woodland in savanna and other light woodland and scrub in extensive savanna and grassland, or forest and mangrove edges abutting it; also larger grassy areas within forest, and in parks, gardens and teak (*Tectona*) plantations; sea-level to 500 m, locally to 1700 m. In Australia occupies mangroves and *Melaleuca* bordering them, as well as open and closed forest (where it meets *C. nuchalis*); sea-level to 100 m. Traditional bower sites beneath low bushes in open savanna or woodland, just inside edge of gallery forest or mangroves, or within tall secondary growth.
Food and Feeding. Little known. Diet fruits and insects. Nestlings fed with fruits and insects, including caterpillars and beetles (Coleoptera). Forages mostly in trees and shrubs. Observed to sally-hover to snatch fruit. Solitary, in twos and in small groups.
Breeding. Breeds in all months in New Guinea, peak months varying regionally, and in Sept–Dec, laying mostly Nov, in Australia; display season 8–9 months of each year, mainly Jun–Dec. Polygynous, promiscuous male building and decorating avenue bower; female builds and attends nest alone. Non-territorial, except for defence of bower site by male; average distance between bowers 500 m. Male builds new bower every season within same site, often in same undergrowth, close to previous one; bower avenue built atop substantially deep, long base of sticks that extends beyond each avenue entrance to form elevated platforms (one usually larger and better formed than the other), varies in size and dimensions, base up to 170 cm long, 80 cm wide and 60 cm thick, avenue atop this up to 36 cm long and 28 cm high externally, with central avenue 9 cm wide, avenue compass orientation variable; bower decorations (up to 100 or more) include green fruits, usually in small bunches, seed pods, unopened flower buds, and green leaves; male "paints" bower, and bower destruction occurs. Courtship not well known, but postures include Nape-presentation, in part similar to that of *C. lauterbachi* and other congeners; bunch of fruits sometimes held in bill; soft but harsh vocalizations, including avian vocal mimicry. Nest a fairly large foundation of sticks, vine tendrils, sometimes with strips of bark, lined with finer twiglets, a few curly vine tendrils and/or sometimes dry grass stems, built up to 10 m above ground in large tree, bush or shrub, or in mangrove; mean distance of six active nests from nearest active bower 143 m; site may be reused habitually over years. Clutch 1 egg; no information on incubation period; one nestling in nest 21 days before leaving it.
Movements. Resident.
Status and Conservation. Not globally threatened. Patchily common; otherwise scarce to absent. Some upland New Guinea localities possibly colonized following habitat modification brought about by agriculture; e.g. local populations in Jimi valley (c. 145 km inland), and Aiyura valley both at 1700 m. Isolated populations in Ransiki and Kebar valleys (E Vogelkop) poorly known. Fairly common in small range in NE Australia.
Bibliography. Bailey (1992), Bell (1969b, 1982d), Coates (1990), Frith (1987b), Frith & Frith (1989, 1993d, 2001b, 2004), Gilliard (1959b, 1969), Gilliard & LeCroy (1968), Harrison & Frith (1970), Hartert (1930), Hicks (1988), Higgins *et al.* (2006a), Hoogerwerf (1964, 1971), MacGillivray (1918), Mackay & Mackay (1974), Marshall (1954), Mayr & Rand (1937), Mees (1982), Menzies (1976), Peckover (1969, 1970), Peckover & Filewood (1976), Rand (1942a), Rowland (2008), Schodde & Mason (1999), Silva (1970).

18. Spotted Bowerbird

Chlamydera maculata

French: Jardinier maculé **Spanish**: Pergolero Moteado Oriental
German: Fleckenlaubenvogel

Taxonomy. *Calodera maculata* Gould, 1837, "New Holland" = Liverpool Plains, New South Wales, Australia.
Probably forms a superspecies with *C. guttata*, and in the past considered conspecific. Hybridization with *C. nuchalis* recorded SE of Charters Towers (E Queensland). Monotypic.
Distribution. Interior of Queensland S of 20° S (except extreme W & SW) and interior of W & C New South Wales (except extreme W border country) S to extreme NW Victoria, in E Australia.

Descriptive notes. 29 cm; male 125–150 g, female 124–162 g. Has variable warm buff head striated and streaked with warm greyish, forecrown feathers having blackish margins, a few elongate central crown feathers finely tipped silvery white; erectile filamentous pink nuchal crest (with pink-orange highlights), directly below which a discrete patch (or "halter") of plain brown; upperparts, including upperwing-coverts and tail, variably blackish-brown with extensive terminal and/or subterminal amber to clay-coloured feather spotting, which becomes paler (to buff or dirty white) on tertials, secondaries, some primaries and rectrices; fine outer edges of flight-feathers pale buff, remainder being paler blackish-brown than upperparts; chin, throat, ear-coverts and breast tawny-olive to buff, finely streaked and (mostly) barred with dusky warm greyish; rest of underparts pale buff to cream-coloured, scalloped and barred drab greyish, a dilute pale yellowish wash over lower belly and undertail, more obvious barring on flanks, thighs and undertail-coverts; iris dark brown; bill blackish; legs olive-brown. Sexes alike, but female crest varies from non-existent through to complete. Juvenile has heavy pale central feather streaks on nape; immature male mostly like adult female, but larger pale tips on primaries, more pointed rectrices, and crest (when present) smaller than adult's; subadult crest remains smaller than that of adult. Voice. Bower-advertisement song, courtship and other calls of male loud and harsh churrings, also vocal avian mimicry (and imitation of human-made sounds). Mimicry of calls of predatory birds given by male at bower and by distressed female at nest in presence of people or other potential predators; foraging birds may mimic. Courtship accompanied by various hissing, crackling and ticking vocalizations.
Habitat. Brigalow (*Acacia*) and eucalypt (*Eucalyptus*) woodlands, with preference for riverine woodland; sea-level to c. 500 m. Traditional bowers sites preferably beneath darker, larger, thorny bushes producing edible fruits; associates with homesteads in interior, where males build bowers in shade of buildings and exotic plants and forage on soft fruits and green vegetables.
Food and Feeding. Primarily fruits, flowers and seeds; also arthropods, including grasshoppers and relatives (Orthoptera), beetles (Coleoptera), ants (Formicidae), spiders (Araneae). Large quantities of fruits and insects (mostly orthopterans) fed to nestlings; large grasshoppers stripped of wings, legs and often also head, before being fed to nestling. Forages mostly in trees and shrubs, occasionally on ground. Forages singly and in small groups, sometimes associating with other birds, e.g. honeyeaters (Meliphagidae); in non-breeding period, forms flocks of 10–30 individuals, and exceptionally of more than 50 birds. Visits gardens, where it feeds on soft fruits and green vegetables.
Breeding. Season prolonged over range, Jul–Mar, peak of egg-laying Oct–Feb; display season Apr–Jan, peak Jul–Nov. Polygynous, promiscuous male building and decorating avenue bower; female builds and attends nest alone. Non-territorial except for defence of bower sites; average inter-bower distance 1–2 km; bower-owning males have larger crest than that of other individuals, and greater crest area proved best predictor of an individual male's status (but crest size did not correlate with mating success among bower-owners). Traditional bower sites can persist for 10–20 years, and individual adult males may remain at a site for 5–6 years or more; two bowers were each built at same site for at least 16 years; bowers rebuilt each season under same bush, on same spot or immediately nearby, or under adjacent bush, and sites of former bowers indicated by accumulations of pebbles or bones remaining long after bower structure disappeared (at one site remains of eight former bowers within 50 m of active one). Bower large, with wide avenue, outside basal walls of sticks and remainder of grass stems, mean dimensions of twelve bowers 48 cm wide and 34 cm high externally, avenue 59 cm long and 20 cm wide, platform extension beyond avenue on average 118 cm (Bullamon Plains, in Queensland), avenues orientated mostly E–W, but variation across range; adult male spends more than 50% of daylight time at bower site; bower decorations (up to c. 2000) vary geographically; include snail shells, bleached bones, water-worn pebbles and many other items, including human-made ones; "painting" of bower by male recorded, and theft of decoration and bower destruction recorded. Courtship involves central and peripheral displays, in former the male standing among decorations adjacent to bower and in latter male posturing while running around bower in wide circles, both involving raising/expanding of lilac crest; four conspicuous central display postures described, Upright, Raised-wings, Sideways Crest-presentation and Forward Crest-presentation, given in any order and accompanied by various vocalizations; two other postures, Rooster Pose and Penguin Pose, performed by a male as he moves away from bower. Nest a bulky, loose foundation of dead twigs and sticks, and egg-cup of fine twiglets, sometimes with dried grass stalks, most built 3–12 m above ground in tree or bush; mean distance of 47 active nests from nearest active bower 400 m; habitual reuse of nest-site or nesting tree over consecutive years not unusual. Clutch 1–3 eggs, mostly 2, possibly laid on alternate days; no information on incubation period; brooding ceases when nestlings 14–15 days old (irrespective of brood size), nestling period at one nest 21 days. Longevity to at least 11–13 years.
Movements. Resident.
Status and Conservation. Not globally threatened. Locally fairly common to scarce. Formerly extended W along Murray R system just into South Australia (where range was always small), but considered now extinct there. Declining in S New South Wales and Victoria; probably nearly extinct in latter state. Reasons for declines thought to include illegal shooting and poisoning, predation by cats and red foxes (*Vulpes vulpes*), and widespread clearance and/or modification and fragmentation of habitat. Members of large flocks attacking fruits and vegetable gardens may be killed, resulting in local declines.

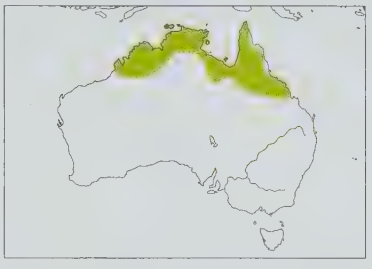
19. Western Bowerbird

Chlamydera guttata

French: Jardinier tacheté **German**: Tropfenlaubenvogel **Spanish**: Pergolero Moteado Occidental
Other common names: Spotted Bowerbird(!), Yellow-spotted/Large-spotted/Pale-spotted Bowerbird, Guttated Bowerbird

Taxonomy. *Chlamydera guttata* Gould, 1862, "North-West Australia" = probably upper Fortescue River, Western Australia.
Probably forms a superspecies with *C. maculata*, and in the past considered conspecific. Two subspecies recognized.
Subspecies and Distribution.
C. g. carteri Mathews, 1920 – North West Cape, in Western Australia.
C. g. guttata Gould, 1862 – Western Australia from Eighty Mile Beach S, immediately E of North West Cape, through Pilbara into C interior of state; and from Rawlinson Range E into S Northern Territory (E to c. 200–300 km N & E of Alice Springs), and S to NW South Australia (to c. 100 km S of border).



Descriptive notes. 28 cm; male 128–142 g, female 122–148 g. Male nominate race has rufous-buff head and neck with extensive black feather margins and exposed bases, much of crown with glossy silvery-white sheen and feather tipping; large erectile filamentous nuchal crest variably pale to bright pink; upperparts, including upperwing and tail, variably blackish-brown to blackish, paler on wing and tail, with bold terminal and/or subterminal clay-coloured rounded feather spotting, spots paler buff or dirty white on tertials, secondaries, and some primaries and rectrices; fine outer edges of remiges and rectrices pale buff; chin, throat, ear-coverts and upper breast blackish-brown to blackish with bold terminal and/or subterminal clay-coloured spotting, spots becoming browner close to wing; remaining underparts dirty and variably buff, darker on breast and yellower on central belly; side of breast and flanks grading from paler central colour to increasingly rich wash of clay colour; undertail-coverts pale and dilute clay colour, broadly barred olive-brown; iris dark brown; bill blackish; legs olive-brown. Differs from similar *C. maculata* mainly in much darker general appearance, brighter and yellower central region of underparts, stronger silvery sheen on crown. Female is similar to male in plumage, but lacks crest (or acquires smaller one with age), and tail on average slightly longer. Juvenile undescribed; immature male lacks crest, has dorsal spotting creamier and tail on average slightly longer than adult male; subadult male has smaller crest than adult and tail on average slightly longer. Race *carteri* is smaller than nominate, particularly in wing, has shorter nuchal crest, and plumage richer and more russet in colour. Voice. Little known. Male's bower-advertisement song consists of repeated loud and harsh churring calls, probably also with mimicry; mimicry utilized also at other times, e.g. when potential predator present. Repertoire said to be similar to that of *C. maculata*, but few documented descriptions.
Habitat. Riverine woodland, scrub thickets in rocky ranges and gorges, and "break-away areas" with available water; sea-level to 500 m. Visits gardens around human habitations.
Food and Feeding. Fruits, particularly rock figs (*Ficus platypoda*), flowers, buds, nectar, seeds; also animal items, mostly insects. Forages mostly in trees and shrubs; sometimes on ground. Usually solitary, in twos or in small groups of up to about six individuals; occasionally larger flocks of up to c. 15.
Breeding. Season prolonged, Jul–Mar, egg-laying in Jul–Dec, on North West Cape (race *carteri*) breeding in Aug–Sept and nestlings/fledglings Sept–Oct; display season most of year, peak Aug–Dec. Polygynous, promiscuous male building and decorating avenue bower; female builds and attends nest alone. Non-territorial, except for defence of bower site by male; traditional bower sites c. 2 km apart, modified according to availability of suitable bushes under which to build. New bower built at site of previous one(s), several disused bowers often within 1 m of active one, or relocated close by; bower large, with wide avenue, external basal walls of sticks and remainder of grass stems, similar to that of *C. maculata*; mean dimensions of four bowers in Western Australia (between Hamersley Range and Barlee Range) 36 cm long and 16 cm wide externally, avenue 23 cm high, platform extending 48 cm beyond end of bower walls, apparently no particular preference regarding avenue orientation; bower decorations (to 1600 or more) include bone fragments, snail shells, pebbles, green fruits and other items (including human-made ones); "painting" of bower recorded, and bower destruction and theft of decorations probably occur. Courtship little known, but postures include Nape-presentation similar to that of *C. maculata* and *Sericulus chrysocephalus*. Nest a shallow bowl foundation of dead twigs and dry vine tendrils, shallow egg-cup lining of finer twigs, tendrils, casuarina (*Casuarina*) needles, acacia (*Acacia*) phyllodes, and/or dried grass stems, typically 2–6 m above ground in low tree or bush; average distance of two nests from nearest active bower 354 m. Clutch 1–2 eggs, mostly 2; no information on incubation and nestling periods.
Movements. Resident. Some local wandering in response to fruit availability and rainfall.
Status and Conservation. Not globally threatened. Generally uncommon. North West Cape population (race *carteri*), recently estimated to be stable at c. 2000 breeding birds, occupying c. 500 km²; in Australia, listed as "near-threatened". Sometimes adversely influenced by drought conditions; a population around a clay pan deserted it, and an incomplete nest, as water evaporated. Many individuals were, and doubtless still are, killed because of their habit of taking garden fruits and vegetables.

20. Great Bowerbird

Chlamydera nuchalis

French: Jardinier à nuque rose **German**: Graulaubenvogel **Spanish**: Pergolero Grande
Other common names: Great Grey Bowerbird, Lilac-naped Bowerbird

Taxonomy. *Ptilonorhynchus nuchalis* Jardine and Selby, 1830, Port Darwin district, Northern Territory, Australia.
Hybridization with *C. maculata* recorded SE of Charters Towers (E Queensland). Proposed races *oweni* (described from Point Torment, in N Western Australia) and *yorki* (from Utingu, in extreme N Queensland) synonymized with, respectively, nominate and *orientalis*. Two subspecies recognized.
Subspecies and Distribution.
C. n. nuchalis (Jardine & Selby, 1830) – N Western Australia (Kimberley Division) E, including numerous offshore islands, to N Northern Territory and extreme NW Queensland.
C. n. orientalis Gould, 1879 – Queensland (except extreme NW) S in W to c. 20° S and in E to Clermont and Connors Range (generally absent from humid coast in Cardwell–Tully region and E watershed of wet tropics).

Descriptive notes. 35 cm; male 180–265 g, female 153–215 g. Male nominate race is entirely brownish-grey, slightly darker and greyer on chin, throat, upper chest and upperparts; crown more grey, darker and browner on lores, variably finely spotted with both a darker colour and a silvery colour; erectile filamentous pinkish-mauve nuchal crest; mantle, upperwing, uppertail-coverts and tail feathers basally and centrally variably dark brown, with conspicuous large whitish tips, extensive pale tips on some uppertail-coverts may have several darker bars across them; undertail-coverts paler brownish-grey, each feather with 3–5 bars of darker brownish-grey; iris dark brown; bill blackish; legs olive-brown. Female is similar to male in plumage, but lacks crest (or has only small one), is also smaller (notably in wing length) and less heavy. Juvenile has mantle, back and rump conspicuously spotted with pale buff (as on adult *C. maculata*); immature male lacks crest, has dusky throat, and heavily barred and mottled brown-grey breast; subadult male like adult but with crest incomplete, sometimes traces of flank barring remaining. Race *orientalis* is smaller and darker than nominate, more brownish upperpart markings contrasting more with whitish feather tips, underparts typically paler and more likely to be strongly barred on flanks. Voice. Male's advertisement song, courtship calls and other calls include loud harsh notes, explosive hissing, churring, cackling and chattering, also vocal avian and other mimicry (including human-made sounds); given from regularly used perches atop trees 6–8 m tall, on average 30–200 m from bower (closer during peak display). Mimicry of calls of predatory birds given by male at bower and by female at nest in presence of people or other potential predators; calls of other birds may be opportunistically and temporarily imitated.
Habitat. Eucalypt (*Eucalyptus*) forest and woodland, particularly riverine forest and thicket within it, mangroves, edges of rainforest and of monsoon forest, also suburbs and gardens; usually close to water. Sea-level to c. 600 m. Bowers built beneath bushes with shading canopy, typically close to edge of riverine or other protective vegetation adjacent to open habitat; also in parks and gardens, on footpaths, and even within or (if overhung by foliage) on top of buildings.
Food and Feeding. Fruits, flowers, nectar, green vegetables, animals (mostly insects), seeds, and food scraps; figs (*Ficus*) a major component of fruit diet. Nestlings fed more with animals, mostly large grasshoppers (Acrididae), than with fruits. Bower-owning males cache fruits about bower site for later consumption. Forages mostly in trees, especially fruiting figs, and in shrubs, also on ground. Mainly singly or in twos, sometimes in small groups of 3–6 individuals; in non-breeding period occasionally 20–30 gather in fruiting trees.
Breeding. Recorded in all months except Apr and Jun across range, peak of egg-laying Oct–Nov and nestling presence Oct–Mar; display season May/Jun–Dec/early Jan (from early Feb at some localities), peak activity Jul–Nov. Polygynous, promiscuous male building and decorating avenue bower; females builds and attends nest alone. Non-territorial, except for defence of bower site by male; traditional bower sites c. 1–2 km apart. One bower site used for more than 70 years; bowers rebuilt each season or same structure used over consecutive years; erected under same bush as previous one(s) or beneath another nearby (up to c. 100 m distant) but within same site; several old structures may remain around a bower site for five decades or more. Bower a long, substantial, thick-walled avenue of stout sticks (700–920 sticks in a single bower wall), tops of inwardly curving central inner walls sometimes meeting to form tunnel, platform upon which avenue built substantial; a few bowers may have a third or fourth wall; in Queensland, mean dimensions of 54 bowers 61 cm long, 51 cm wide and 37 cm high externally, avenue 14 cm wide (Townsville), of ten others 51 cm wide and 37 cm long externally, avenue 59 cm long and 15 cm wide (McCleod R); avenue alignment typically N–S or close to that, but some geographical variation; adult male spends more than 50% of daylight time at bower site; bower decorations (as many as 12,000), placed on platform at each avenue entrance, include white or grey land-snail shells and mammal bones, green fruits, leaves, some red or reddish items, and many other items (including human-made ones); "painting" of bower recorded, theft of decorations and bower destruction recorded. Courtship involves peripheral displays (strutting walk or run around bower) and central postures (Upright, Forward-stretch, Crest-presentation) performed at bower entrances; similar to that of *C. maculata*. Nest a loosely built, shallow to deep saucer with foundation of slender sticks and twigs, egg-cup lining of finer twigs and few leaves, built c. 2–9 m above ground mostly in tree, bush or sapling; average distance of six nests from nearest active bower 64 m; habitual reuse of nest-site or nesting tree not unusual. Clutch 1–2 eggs, mostly 1; incubation period at one nest 21 days; brooding ceases when nestlings 14–15 days old (irrespective of brood size), nestling period at one nest 20–21 days; female mimics calls of predators if potential predator approaches, if disturbed may also perform distraction display and/or chase conspecifics from nest area; fledged young fed by parent Feb–Apr, and female foraging on fruits with identical-looking dependent young in Mar.
Movements. Resident.
Status and Conservation. Not globally threatened. Locally common to fairly common. Appears possibly to have declined in S Atherton Tableland area of N Queensland since c.1940. Can cause damage in areas of commercially grown crops; birds attacking soft fruits and green vegetable crops, particularly when in winter flocks, are not uncommonly killed by people.

Baker *et al.* (1999), Barker & Vestjens (1990), Barnard (1914), Blakers *et al.* (1984), Borgia (1995), Breeden & Wright (1989), Frith, C.B. & Frith (1990e, 1995b, 1999b, 2001b, 2004), Frith, C.B., Frith & McCullough (1995), Frith, C.B., Frith & Weineke (1994, 1996), Frith, H.J. & Hitchcock (1974), Gilliard (1969), Higgins *et al.* (2006a), Hopkins (1953, 1974), Marshall (1952a, 1954), Mayr & Jennings (1952), McCarthy (2006), McKenzie *et al.* (1995), North (1902), Rowland (2008), Schodde & Mason (1999), Sedgwick (1946), Shingleton (2005), Thorogood (1941), Veselovský (1978, 1979), Warham (1957, 1962), White (1922), Whitlock (1925).

Class AVES

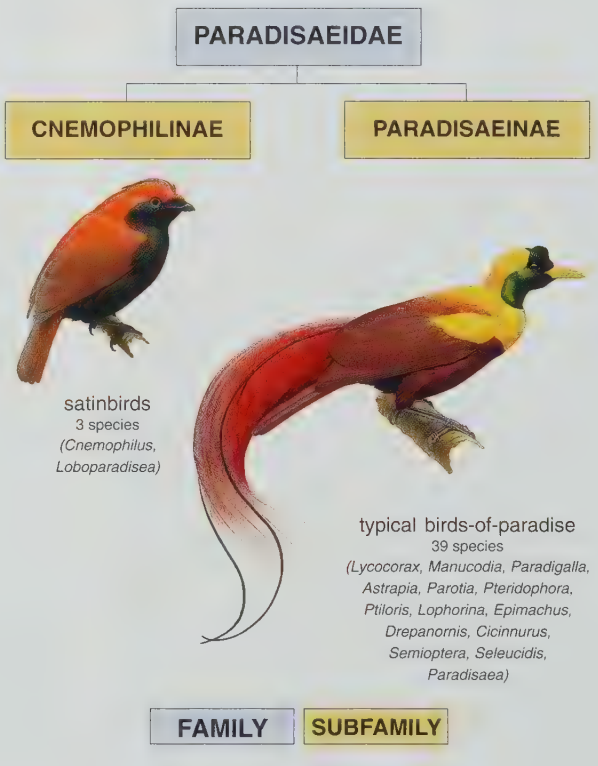
Order PASSERIFORMES

Suborder OSCINES

Family PARADISAEIDAE (BIRDS-OF-PARADISE)

- Small to large passerines with stout powerful bill of diverse size and shape, several with long or exceedingly long tail; males typically ornately plumaged.
- 15–44 cm (up to 110 cm, with tail streamers).

- Moluccas, New Guinea and satellites, and north-eastern Australia.
- Rainforest and other dense vegetation, a few also in more open habitats.
- 16 genera, 42 species, 90 taxa.
- 3 species threatened; none extinct since 1600.



Systematics

For a long time, ornithologists treated the bird-of-paradise family, Paradisaeidae, as closest to the bowerbirds (Ptilonorhynchidae), even after avian anatomists published contrary views. Indeed, some combined the bowerbirds and the birds-of-paradise into a single family, Paradisaeidae. Just as increasing biological evidence for a major dichotomy between the two was acknowledged, results of several biomolecular studies supported the discrete status of Paradisaeidae, which was found to be not only distinct from the bowerbirds but also relatively distant from them. Contemporary research involving hypothetical "molecular clock" calibrations suggests that the separation of the birds-of-paradise and their immediate relatives from the bowerbirds occurred some 28 million years ago, although the validity of such calibrations remains to be seen.

Today, the prevailing view is that the majority, about 85%, of passerine species living in Australia and New Guinea have a southern, Gondwanan, origin. This major group, termed the "parvorder Corvida", comprises three major lineages: these are the superfamilies Menuroidea, Meliphagoidea and Corvoidea. The first of these, Menuroidea, includes the bowerbirds, and the last, Corvoidea, incorporates the birds-of-paradise. As a result of analytical studies based on avian DNA–DNA hybridization, the findings of which were summarized in 1990, Paradisaeidae was seen as the sister-group to the radiation comprising the wood-swallows (Artamidae), the butcherbirds (Cracticidae), the Old World orioles (Oriolidae) and the cuckoo-shrikes (Campephagidae); at the next highest level, the crows and their allies (Corvidae) form the sister-group to this lineage comprised by the paradisaeids, orioles and butcherbirds. A subsequent phylogeny of the passerines, based on two single-copy nuclear-gene sequences, placed Paradisaeidae close to the apex of "core Corvoidea" and among the Australian mudnesters (Struthideidae), monarchines (Monarchidae) and true corvids; in this phylogeny, the birds-of-paradise are far removed from the cnemophilines, which, together with the berrypeckers and longbills (Melanocharitidae) and New Zealand wattlebirds (Callaeidae), form a sister-group to the core Corvoidea.

In addition to the bowerbirds, a number of species or groups, including the Silktail (*Lamprolia victoriae*) of Fiji, the New Zealand wattlebirds, and the Lesser Melampitta (*Melampitta lugubris*) of highland New Guinea, have been mooted to be members of the bird-of-paradise family. Both the Silktail and the wattlebirds are now known to be unrelated to birds-of-paradise, the former currently being placed with the monarch-flycatchers in the Monarchidae, and the latter, as mentioned above, being accorded their own family, Callaeidae. The Lesser Melampitta is presently included with the jewel-babblers and allies in the family Eupetidae, but the results of recent biomolecular studies place it with the Australian monarchines and the corcoracid mudnesters, thus putting it close to Paradisaeidae but not as part of this family.

In the current arrangement, the family Paradisaeidae comprises 42 species in 16 genera. These are distributed primarily in New Guinea and its satellite islands, which have 38 species. Two of these, the Trumpet Manucode (*Manucodia keraudrenii*) and the Magnificent Riflebird (*Ptiloris magnificus*), extend also to extreme north-east Australia, and the two other members of *Ptiloris* are confined to the latter country, being found in the north-eastern to mid-eastern coastal region. The remaining two mem-

Subdivision of the Paradisaeidae

[Figure: Chris Rose]

Two subfamilies may be recognized in Paradisaeidae as constituted herein. The three "wide-gaped" species in the genera Cnemophilus *and* Loboparadisea *make up the subfamily Cnemophilinae, and the "typical" birds-of-paradise, the Paradisaeinae.* ***Loria's Bird-of-paradise****, the Crested Bird-of-paradise* (C. macgregorii) *and the Yellow-breasted Bird-of-paradise* (Loboparadisea sericea) *are conspicuously weak-billed, with weak legs and feet, which they do not use to manipulate food. Some recent taxonomists have accorded them their own family, Cnemophilidae, typically referred to as the "satinbirds".*

[*Cnemophilus loriae*, Ubaigubi, EC New Guinea. Photo: William S. Peckover]

bers of the family, in the monotypic genera *Semioptera* and *Lycocorax*, are restricted to the northern part of the Moluccas. The five species of manucode and the Paradise Crow (*Lycocorax pyrrhopterus*) reproduce as socially monogamous pairs, whereas the remaining 36 species in the family are polygynous, the promiscuous males attracting females to traditional solitary courts, display perches or communal leks, where they court and mate with them (see Breeding).

Since about the middle of the twentieth century, ornithologists had established a remarkable stability with regard to the definition of species limits within the birds-of-paradise. Recently, however, the phylogenetic species concept was applied to the group, resulting in a dramatic increase in the number of constituent species recognized, to about 90. For numerous reasons, the elucidation of which is beyond the scope of the present work, this taxonomic treatment has not received wide acceptance.

Two subfamilies have been recognized in recent decades. The three "wide-gaped" species in the genera *Cnemophilus* and *Loboparadisea* constitute the subfamily Cnemophilinae, and the remaining 14 genera, the "typical" or "true" birds-of-paradise, are united in Paradisaeinae. Unlike the condition in the latter, the skulls of the Cnemophilinae lack nasal ossification, the lacrymal is absent, and the head of the orbital processes of the quadrate is expanded; in addition, the three species are conspicuously weak-billed and weak-footed (see Morphological Aspects). Nevertheless, a number of characters shared by the two subfamilies appeared to support the hypothesis that they merited placement together in the Paradisaeidae, their cranial and mandibular osteology indicating to some authorities that the cnemophilines are a basal sister-group to the main paradisaeine lineage. Increasingly contradicting this perception, however, were a number of observations about the cnemophiline species. First, their small, weak feet appear never to be used as a means of holding items against a perch; secondly, it looks as if the weak bill and the strikingly wide gape are adaptations to an obligate or near-obligate frugivorous diet, in addition to which they build a globular domed nest structure with a side entrance hole, and they have a distinctive juvenile plumage. These are all traits not shared by typical birds-of-paradise. Moreover, recent biomolecular studies indicate that the three wide-gaped species form a quite distinctive group, and that this forms a clade with the New Guinea berrypeckers and longbills and the New Zealand wattlebirds, far removed from the true birds-of-paradise and towards the lower, or basal, oscines, and thus closer to the bowerbirds, with which

Pointing to its affinity with the Cnemophilus *species, the* ***Yellow-breasted Bird-of-paradise*** *is sometimes known as the Yellow-breasted Cnemophilus. A number of characters shared with the Paradisaeinae support the hypothesis that the cnemophilines belong in Paradisaeidae. However, recent biomolecular studies indicate that they are a quite distinctive group, forming a clade with the New Guinea berrypeckers and longbills (Melanocharitidae), and the New Zealand wattlebirds (Callaeidae). Far removed from the true birds-of-paradise, they appear closer to the bowerbirds (Ptilonorhynchidae).*

[*Loboparadisea sericea*, Crater Mountain, EC New Guinea. Photo: William S. Peckover]

the cnemophilines exhibit similarities in some skull characters, than to the "true" birds-of-paradise. Although the cnemophilines are still covered in the present family, there is serious doubt as to whether they really should be seen as members of Paradisaeidae. Indeed, some recent taxonomic lists have accorded them a family of their own, Cnemophilidae, the satinbirds. A 2008 molecular phylogenetic study even found "reasonable support for a Passerida affinity of Callaeatidae [sic] and Cnemophilidae, contrary to previous molecular studies".

The relationships of MacGregor's Honeyeater (*Macgregoria pulchra*) within the Paradisaeidae remained much debated until the publication, in 2000 and later, of a number of biomolecular studies. This was because, as many authorities had reported, this species appeared to exhibit some characteristics of both the Cnemophilinae and the Paradisaeinae. The last significant systematic attempt at a phylogeny of the Paradisaeidae placed the monotypic genus *Macgregoria* basally within the Paradisaeinae, as did several immediately preceding studies. The reason for the long unsettled position of *Macgregoria* is that its morphology, its zoogeography and the little that is known of its biology proved to be completely misleading; biomolecular analyses have now established that this bird is, in fact, a giant, patchily distributed, high-altitude, specialist honeyeater (Meliphagidae). It is noteworthy, in hindsight, that in 1962 the bird was described as "very active, darting into the bushes in honeyeater fashion".

Anatomically, the birds-of-paradise are broadly typical of the oscine passerines, and are generally crow-like, as is reflected in their average size, shape, strength, demeanour, powerful appendages, and vocalizations. Features typical of the paradisaeine skull include a small or non-existent lacrymal and, consequently, a large ectethmoid plate solidly fused with the frontal bone and a short orbital process of the quadrate with an expanded distal tip. The family is morphologically and behaviourally extremely diverse, but the following combination of characters, not all of which are shown by the three cnemophilines, helps to define them. The hatchlings lack down and have dark to black skin, and the chicks are fed by regurgitation. The adult male plumage includes strong iridescence, and the species display a range of extremely bright plumages not otherwise found among the corvoid assemblage; plumage maturation of males is greatly delayed. The body is compact and powerful, the bill is diverse but stout and strong, and the feet are large and powerful, like those of a crow, the feet being employed for holding and manipulating food items. Open-bill probing is one of the feeding methods used by these birds, which move mostly by hopping but also have the ability to walk. They

Within the typical birds-of-paradise, the subfamily Paradisaeinae, are two well-defined lineages. One comprises the manucodes in the genus Manucodia *along with the* ***Paradise Crow*** *in the monotypic genus* Lycocorax. *Together these genera may constitute a valid subfamily: unlike most of the other Paradisaeidae, all are socially monogamous, and sexually monomorphic, both sexes being basically all black, with degrees of blue and/or green iridescence. They are mostly quite large for paradisaeids, and are generally longer-winged than one would expect in relation to their mass.*

[*Lycocorax pyrrhopterus*, Halmahera, Moluccas. Photo: Tim Laman]

have a distinctive flap-and-glide undulating flight, in addition to which the wings of adult males in many genera produce a characteristic sound during flapping flight. The birds-of-paradise construct nests not from sticks, but, instead, use supple long stems of epiphytic orchids and vines; they lay attractively coloured eggs typically decorated with darker broad elongate brush-like strokes. They are predominantly polygynous, the promiscuous males persistently vocal at traditional display leks, courts or perches, and the females take sole responsibility for the rearing of the chicks.

Almost every publication reviewing the Paradisaeidae has presented a listing, or a phylogeny, of the family, with assessment of the differences, ranging from gross to subtle, in the perceived relationships among the genera. A study in the mid-1990s provided a first partial phylogeny of the birds-of-paradise based on base-pair sequences of mitochondrial DNA, but the researchers in this case lacked material of the Cnemophilinae and of the genera *Paradigalla*, *Astrapia*, *Pteridophora* and *Semioptera*. The findings of this study placed the manucodes, then the genus *Parotia* and then the sicklebills (*Epimachus* and *Drepanornis*) basally within the Paradisaeinae; separated the sicklebills into two lineages; treated *Paradisaea* as a lineage basal to a clade including *Cicinnurus*, *Seleucidis* and *Ptiloris*; and treated *Ptiloris* and *Lophorina* as sister lineages.

Within the typical birds-of-paradise, the subfamily Paradisaeinae, are two well-defined lineages. One of these comprises the manucodes in the genus *Manucodia* along with the Paradise Crow in *Lycocorax*, and the other contains the 26 species known as "plumed paradisaeine birds"; the latter are discussed below. Lineages of less certain affinity are *Paradigalla* and *Astrapia*; the former appears basal, whereas *Astrapia* is considered the sister-group to the plumed birds and in terms of its morphology is arguably a member of them. The lineage with the manucodes and Paradise Crow is distinctive, possibly constituting a valid subfamily, and is well defined by a range of characters but especially by plumage and tracheal morphology. Recent biomolecular studies indicate that the manucodes and the plumed paradisaeine lineages may have diverged about 20–18 million to as recently as about 7 million years ago. The geographical distributions of these two lineages are the same in that they extend from the Moluccas southeastwards to the humid forests of eastern Australia.

The two paradigallas form a lineage of obscure affinities, particularly as they remain little known. Their nesting habits are like those of typical paradisaeine birds-of-paradise, but the black plumage of both sexes and the egg morphology link them to basal taxa such as *Manucodia*. In terms of habit, plumage, and body and bill morphology, however, *Paradigalla* appears closest to *Astrapia*. The predominantly black plumage of the two sexes, both of which also are long-tailed, links *Astrapia* to the basal Paradisaeinae taxa, but the male's ornate erectile head and mantle feathering, the ventral barring of females, and the egg morphology ally this genus to the plumed lineage. The 26 plumed species appear to have resulted from a single radiation. They can be divided into four clades, well defined by morphology: these are the "flagbirds" (*Pteridophora*, *Parotia*), the riflebirds (*Ptiloris*, *Lophorina*), the sicklebills (*Epimachus*, *Drepanornis*), and the "sickletails" (*Cicinnurus*) together with the typical plumed species (*Semioptera*, *Seleucidis*, *Paradisaea*). Males of the two flagbird genera have velvety black dorsal plumage, erectile occipital plumes, a small iridescent throat patch, and distinctive courtship displays. Male riflebirds, suggested as having diverged

With its crown feathering distinctively curled, in addition to its distinctive neck feathers, the ***Crinkle-collared Manucode*** *may form a superspecies with the largest of the paradisaeids, the Curl-crested Manucode* (Manucodia comrii). *The altitudinally limited distribution of different forest habitats dictates the distributions of the various species. The Crinkle-collared Manucode is adapted to upland forest and the Jobi Manucode* (M. jobiensis) *to lowland forest, with extensive geographical overlap but little or no sharing of specific habitat.*

[*Manucodia chalybatus*, near Brown River, SE New Guinea. Photo: Brian J. Coates]

from other paradisaeines about 4 million years ago, all possess a distinctive metallic-looking breast shield, display on a log or stump, and have similar typical advertisement song and static display posturing. Flagbirds and riflebirds have been linked, as sister forms, to a larger assemblage in which the sicklebills are located as a sister-group to a grouping that includes the *Paradisaea* clade (*Cicinnurus*, *Seleucidis*, *Semioptera*, *Paradisaea*).

While the group of four sicklebills is defined by the possession of a long, sickle-shaped bill, the erectile pectoral plumes of the males, and the mantle and upperwing colouring of the females, the four species do, in fact, form two closely related but distinct lineages. The two *Epimachus* "sabretail" sicklebills are defined by marked sexual dimorphism, a grossly elongate and pointed tail, a brightly coloured iris, an iridescent mantle and crown in adult males and an unbarred chin and throat in both sexes. In contrast, the two *Drepanornis* sicklebills have far less marked sexual dimorphism, a much shorter and rounded tail, bare facial skin, a brown iris, no iridescence on the mantle and crown, and a barred chin and throat in females and immature males. In addition, *Drepanornis* shares several traits with *Cicinnurus* that *Epimachus* does not.

The fourth and final clade of plumed species contains several sublineages and is the most complex. Its constituent genera, *Cicinnurus*, *Semioptera*, *Seleucidis* and *Paradisaea*, are linked by several shared characters, including iridescent green and brilliant red and/or yellow areas of feathering in the adult male nuptial plumage, *Paradisaea*-type advertisement vocalizations and display postures, and an absence of or limited extent of black in the adult male plumage. Within this clade, adult males of the three diminutive *Cicinnurus* sickletails have the central pair of rectrices modified into recurved "wires", and exhibit iridescent green ventral plumage, red dorsal plumes, and bright blue legs and feet. The genus *Paradisaea* is defined by the presence of both filamentous elongated flank plumes and grossly elongated wire-like or tape-like central rectrices in adult males. As a matter of fact, although commonly termed "flank plumes", the elongated plumes arise from beneath the wing and are strictly, therefore, pectoral plumes. This genus contains the seven "true" plumed bird-of-paradise species, namely the Lesser Bird-of-paradise (*Paradisaea minor*), Greater Bird-of-paradise (*Paradisaea apoda*), Raggiana Bird-of-paradise (*Paradisaea raggiana*), Goldie's Bird-of-paradise (*Paradisaea decora*), Red Bird-of-paradise (*Paradisaea rubra*), Emperor Bird-of-paradise (*Paradisaea guilielmi*) and Blue Bird-of-paradise (*Paradisaea rudolphi*). The last three of these are the least typical or the most aberrant.

Completing the "*Paradisaea* clade" are the two monotypic genera *Semioptera* and *Seleucidis*. The Standardwing Bird-of-paradise (*Semioptera wallacii*), an aberrant member of the family restricted to the Moluccas, appears to be a sister form of the sickletail–*Paradisaea* group, a theory supported by its green adult male ventral plumage and the fact that the sickletails and *Paradisaea* are geographically the closest higher paradisaeines. Although the Twelve-wired Bird-of-paradise (*Seleucidis melanoleucus*) is less aberrant, a full resolution of its affinities is complicated by the fact that it exhibits two character suites. One of these (including black adult male plumage, its female plumage, bill morphology, and tree-stump display sites) links it to the riflebirds and the other (including filamentous yellow flank plumes, *Paradisaea*-type advertisement vocalizations and displays, and pale leg and iris colours) to the *Paradisaea* lineage. It has been suggested that the latter characters are derived and the former primitive, and thus of less taxonomic significance.

Hybridization is a well-documented feature of this family. Thirteen intergeneric hybrid crosses and seven intrageneric crosses are known in the wild, their existence emphasizing the close genetic relationships between the paradisaeine species, despite extreme morphological differences between the adult males of the genera and species concerned. Only polygynous species are implicated in hybridization in the wild, but there is a contemporary instance of a male Trumpet Manucode and a female Crinkle-collared Manucode (*Manucodia chalybatus*) interbreeding in captivity. The phenomenon of hybridization within this family is not surprising given that the promiscuous males of polygynous species show no discrimination in mate choice, but will readily mount almost any female-looking bird that visits their display sites. Presumably, young and naive female birds-of-paradise sometimes mate with males of another species in error, and any female may do so if conspecific mates are not available, as, for example, at the geographical or elevational limits of the species' distribution.

Finally, it must be noted that the correct spelling of the genus *Paradisaea*, the type genus of the family, has recently been the subject of considerable discussion (see page 46).

Morphological Aspects

The cnemophilines do share some traits with typical birds-of-paradise, examples being the egg and nestling characters, the feeding of the young by regurgitation, nest materials, the female's

Brightly coloured bare skin is confined to adult males in most birds-of-paradise, but both male and female ***Short-tailed Paradigallas*** *have the large bright yellow wattle on the foreface, and a less conspicuous sky-blue wattle at the base of the lower mandible. The sexes are generally alike in both paradigalla species, although females are slightly smaller and duller. The nesting habits of paradigallas are like those of the most typical birds-of-paradise, but the black plumage of both sexes, and the egg morphology, link them to basal taxa such as* Manucodia, *although unlike the manucodes and like most of the other paradisaeids, they are polygynous.*

[*Paradigalla brevicauda*, Tari Gap, EC New Guinea. Photo: Nick Athanas]

In many bird-of-paradise the adult males have their plumage highly modified for nuptial display, particularly the central pair of rectrices. In the ***Ribbon-tailed Astrapia*** *this pair of feathers is grossly elongated into two cotton-white "ribbons", 2 cm wide, which can be more than a metre in length in some individuals. The terminal quarter of the shaft of each feather is blackish, and 3–4 cm at the tip are blackish-brown. The average length of male birds is 32 cm to the end of the sharply pointed, graduated tail, or 125 cm when the central rectrices are included. With increasing age, the central rectrices become progressively longer as the other rectrices become progressively shorter. One male Ribbon-tailed Astrapia in captivity took at least six years to acquire full adult plumage, and studies of a number of polygynous, sexually dimorphic species show that males take at least five to seven years to acquire their full adult dress. Female Ribbon-tailed Astrapias are smaller than males, at 53 cm, including their much less elongated central rectrices; there is no overlap between the sexes in the lengths of wings and tails. The predominantly black plumage of both sexes, and the fact that both are long-tailed, link* Astrapia *to the basal Paradisaeinae taxa such as* Manucodia*; but the male's ornate erectile head and mantle feathering, the ventral barring of the females, and the egg morphology all ally this genus to the plumed lineage. The Ribbon-tailed Astrapia is a bird of upper montane and subalpine moss forests in the New Guinea Highlands, mostly above 2450 m. Where it overlaps with Stephanie's Astrapia* (A. stephaniae)*, which ranges from middle to upper montane forest, hybridization can occur.*

[*Astrapia mayeri*,
Mount Hagen,
EC New Guinea.
Photo: Brian J. Coates]

While the males display, the females choose amongst them—and later, in the polygynous species, incubate the eggs and raise the chicks alone. This may partly explain why females of the vast majority of the polygynous species are cryptically coloured in subdued browns and dull yellows. This ***Huon Astrapia*** *shows the characteristic ventral barring of female astrapias. Female parasaeids develop their adult appearance within a year of fledging. Immature males are identical in plumage to the adult females, or at least so similar that they cannot be sexed by outward appearance alone.*

[*Astrapia rothschildi*, Huon Peninsula, New Guinea. Photo: Tim Laman]

wing coloration, the specialized mouth colouring and contour feathers of the adult males, evidence of delayed plumage maturation among males, polygynous reproduction with courtship at traditional perches by promiscuous males, and paradisaeine-like vocal advertisement. In bill and leg morphology, however, the two groups are entirely different. In marked contrast to the narrow or stout but powerful bills of the typical birds-of-paradise, adapted to a diverse omnivorous diet, the cnemophilines have a small, fine-tipped, weak bill with an exceptionally wide gape, as adaptations to an exclusively fruit-based diet consisting largely of simple drupes. Similarly, in contrast to the powerful and crow-like legs and feet of the former group, the cnemophilines have fine, weak legs and feet, which they do not use for manipulating food items. The cnemophiline genera are, as a group, typically shorter-winged than the other genera of the family (see also Systematics).

Size varies greatly within the family, ranging from a total length of 15 cm and a body weight of 50 g, as for the King Bird-of-paradise (*Cicinnurus regius*), to a basic length of 44 cm and a weight of 450 g for the Curl-crested Manucode (*Manucodia comrii*). The adult male Black Sicklebill (*Epimachus fastosus*), if its long sabre-like tail feathers are included in the measurement, reaches 110 cm in total length. Males are larger and heavier than females except in the case of the Yellow-breasted Bird-of-paradise (*Loboparadisea sericea*), the females of which are the slightly larger and heavier of the two sexes. The male-to-female weight ratios vary considerably, from as low as 0·87 for the Yellow-breasted Bird-of-paradise to as high as 1·56 for the Raggiana Bird-of-paradise. Juvenile and immature individuals are generally smaller than the subadults and adults of the same species. The male is the sex that displays, and the female is the one that chooses. Courtship display will almost certainly be more impressive to females if performed by a larger individual male. The Yellow-breasted Bird-of-paradise, however, provides a curious exception in exhibiting a reversal of the normal situation with regard to sexual size dimorphism.

The bills of the various genera vary from being short to being long, from slim to stout, and from straight to strongly decurved, reflecting strong adaptive radiation. Many taxa, such as, for example, the genera *Paradigalla*, *Astrapia* and *Cicinnurus*, exhibit a small slim bill. Figures for the mean adult female bill length and width as a percentage of those of adult males reveal that, in general, the bills of adult males are on average about 5% larger than those of adult females. Relative sexual dimorphism in bill size is, with a few notable exceptions, typically constant within a genus or among the species of closely related genera; examples can be found by comparing the sexes of *Lycocorax* and *Manucodia*, or those of *Paradigalla*, *Parotia* and *Pteridophora*, or those of *Cicinnurus* and *Paradisaea*. Within the subfamily Paradisaeinae, sexual dimorphism in bill size is most diverse among the riflebirds. Males of the Magnificent Riflebird have the longer bill, a situation which is typical of the family as a whole, whereas in the other two riflebird species it is the females that have the longer bill, a case of reversed dimorphism. This latter phenomenon is apparent also, to a lesser degree, with Buff-tailed Sicklebills (*Drepanornis albertisi*). All of the species showing reversed dimorphism in bill size excavate in dead wood, tree crevices and bark, a specialized foraging method that is closely correlated to marked sexual bill-size dimorphism in a few other bird families, notably some woodpeckers (Picidae). In the genera *Lycocorax*, *Manucodia*, *Ptiloris*, *Epimachus* and *Paradisaea*, female bills are on average narrower than those of the males, whereas they are on average slightly broader than those of males in *Paradigalla*, *Astrapia*, *Parotia*, *Pteridophora*, *Lophorina*, *Drepanornis*, *Cicinnurus* and *Seleucidis*.

In most paradisaeid genera, the wings are rounded and, on adult males of several, some of the outer primaries are modified in shape, probably to produce mechanical sound. The mean wing length of most adult females is on average 85–95% that of the males of the species; exceptions include the wide-gaped, cnemophiline species, for which the corresponding figure is 96–102%, the manucodes, with 95–97%, the Splendid Astrapia (*Astrapia splendidissima*), for which it is 99%, the small *Drepanornis* sicklebills, at 97%, and the sickletails, at 96–99%. Sexual size dimorphism as expressed by female wing length as a proportion of the male wing length is greatest in Magnificent Riflebirds, for which the proportion is 81%, Greater and Lesser Birds-of-paradise, with figures of, respectively, 83% and 85%, and the large *Epimachus* sicklebills, the female wing of which is 85–86% the length of the male wing. Sexual dimorphism in body size tends to be reduced in the smaller species of polytypic genera, as found with the paradigallas, the astrapias, the sicklebills, the riflebirds, the sickletails and, particularly, the seven

All the parotias have the alternative name "six-wired bird-of-paradise", after the three long, erectile, wire-like occipital plumes with small spatulate tips, which emerge from the ear-tufts behind each eye. ***Carola's Parotia*** *also has a short, erectile blackish-bronzed frontal crest, tipped silver-white. The top of the skull of Lawes's Parotia* (Parotia lawesii) *is conspicuously "dished", apparently to accommodate the large muscles required to manipulate the six occipital plumes. Similar cranial modifications are found in the rest of the parotias, and in the other "flagbird" species, the King of Saxony Bird-of-paradise* (Pteridophora alberti). *The crown of Carola's Parotia is covered with iridescent coppery-gold feathering and is slightly concave. Adult males of both the Magnificent* (Cicinnurus magnificus) *and the Superb Birds-of-paradise* (Lophorina superba) *have an extensive cape of elongated feathers, originating from the lower nape; this cape is elevated and held against the back of the head in display, and the rear part of the skull is abruptly square-ended to accommodate it. Although smaller, and having rather drab plumage which lacks the head plumes and iridescence, the female Carola's Parotia, as in other paradisaeids, has a longer tail than the male. The iris is sulphur-yellow in the adult male, and pale grey or cream to yellow in the female, this colour difference in the female possibly being age-related. The iris of Lawes's Parotia, which overlaps geographically with Carola's, is distinctly different, being cobalt-blue with a narrow cream-yellow outer ring. The plumage of immature male birds-of-paradise is very similar to that of the adult female, including the longer tail, which decreases in length with age. During successive moults, adult male plumage begins to appear a few feathers at a time, initially on the head.*

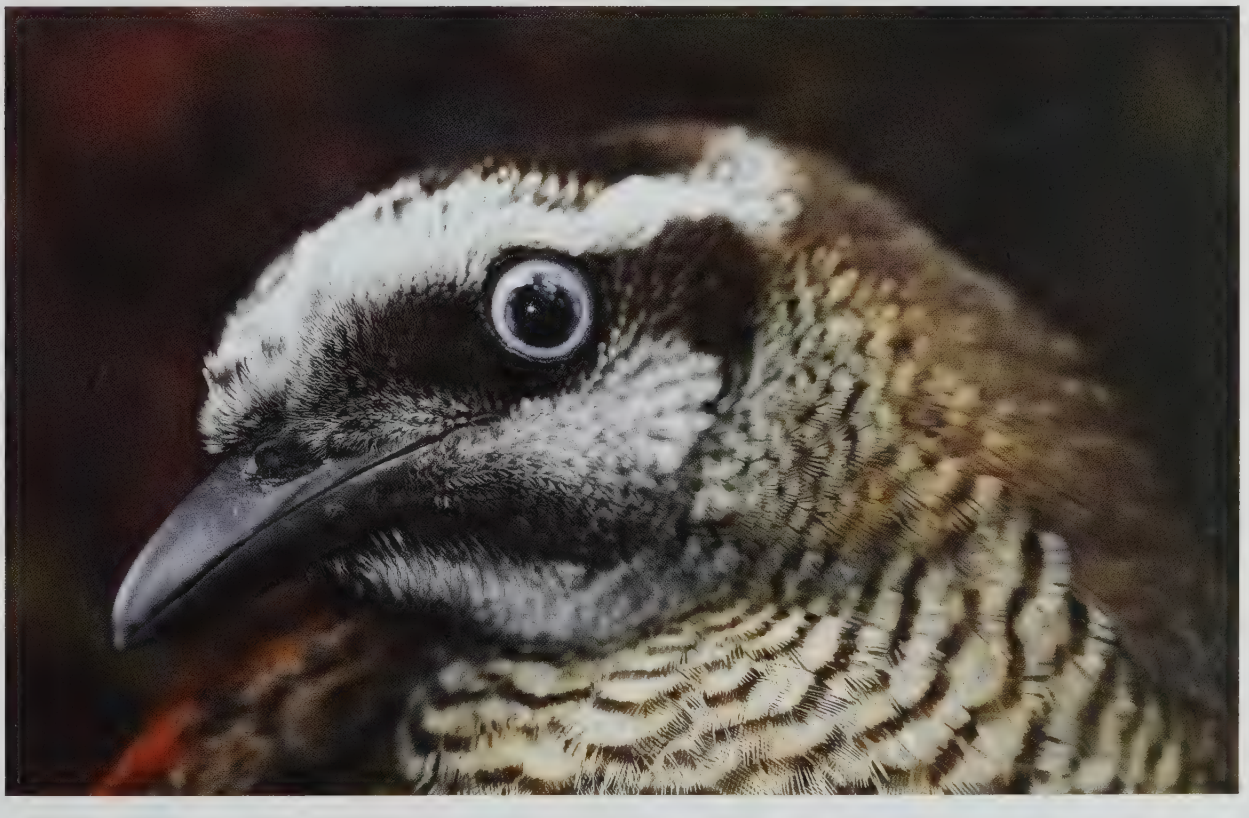
Paradisaea species. It is notable that the Blue Bird-of-paradise, the only non-lekking *Paradisaea* species, not only is the least sexually dimorphic in size, as well as in appearance, but also is overall the smallest member of its genus.

Within the Paradisaeinae, the manucodes and the Paradise Crow are generally longer-winged than one would expect in relation to their mass. The astrapias and the riflebirds tend, on average, to have proportionately shorter wings, the parotias (*Parotia*) are of average wing length, and the King of Saxony Bird-of-paradise (*Pteridophora alberti*), the Superb Bird-of-paradise (*Lophorina superba*) and the sickletails (*Cicinnurus*) are relatively short-winged. Not surprisingly, some island-isolated species, such as the Curl-crested Manucode, have wings proportionately shorter in relation to their weight than those of their mainland relatives. The length of the tarsus as a proportion of the wing length is 21–29% for most members of the family, but is longer in the genus *Parotia*, at 31–32%, and in the cnemophilines, at 33–36%.



Birds-of-paradise are typical passerines in having ten primaries, the outermost of which is fairly well developed, ten to twelve secondaries and twelve rectrices. The adult males of many of the species have the plumage highly modified for nuptial display, particularly so with the central pair of rectrices, which may become significantly longer or shorter and ornate with increasing age. While most of the species have forward-pointing feathering over the nostrils, a feature also of the corvids, a few have stiff rictal bristles. The erectile head plumes of *Parotia* and *Pteridophora* are associated with cranial modifications that facilitate the large muscles required to manipulate them in display. Adult males of both the Magnificent (*Cicinnurus magnificus*) and the Superb Birds-of-paradise wear an extensive cape of elongated feathers, originating from the lower nape; this cape is elevated and held against the back of the head in display, and the posterior skull is abruptly square-ended to accommodate this. Similarly, the top of the skull of Lawes's Parotia (*Parotia lawesii*) is conspicuously "dished", apparently to accommodate the large muscles required to manipulate the six occipital plumes sported by this species.

The five manucodes and the Paradise Crow, all of which are socially monogamous, and the two paradigallas, which are polygynous, are sexually monomorphic, both sexes being basically all black with degrees of blue and/or green iridescence. The remaining 31 members of the Paradisaeidae are extremely sexually dimorphic, the adult males being adorned with colourful and elaborate plumage. Few other avian families exhibit such diversity of feather form, structure and colour. Some modified feathers of the adult male plumage are not displayed in courtship, but appear to be utilized for the production of sound or to support or strengthen other feathering that is presented in display (see Breeding). An ephemeral yellow pigment, possibly derived from certain foods, which colours the plumes of living adult male Twelve-wired Birds-of-paradise rapidly fades in captivity or in museum specimens. In an examination of more than 6000 bird-of-paradise museum specimens, fewer than 1% were found to show any sign of aberrant plumage, this mostly in the form of partial albinism.

Aside from their elaborated plumage, adult males of many of the species have bright colouring of the legs, eyes, or facial, narial or gape wattles, and brightly coloured bare skin on the face or crown or on the inside of the the mouth. Loria's Bird-of-paradise (*Cnemophilus loriae*) has small gape-flanges, while the Yellow-breasted Bird-of-paradise possesses bulbous narial wattles, which, because they are peculiar to adult males, are probably the result of sexual selection. In contrast, the facial wattles of the paradigallas are present on both sexes, and in this case, therefore, they may play a part in species recognition. Moreover, and uniquely within the family, the thighs of adult male Twelve-wired Birds-of-paradise are bare and deep coral-pink in colour, as are the legs, and they are featured in courtship.

Iris colour varies, probably because it is an important signal distinguishing species, sex and age. With most members of the family, the adults of both sexes have the same iris colour, the exception being the Black Sicklebill, the iris of which is red in adult males and brown in females and immature males. The two parotia species that overlap geographically, namely Lawes's and Carola's Parotias (*Parotia carolae*), have distinctly different iris colours. The bill is typically blackish or black in both sexes, with a few striking exceptions; both sexes of the Magnificent Bird-of-paradise have a pale blue bill and legs, and both sexes of the *Paradisaea* species have the bill pale bluish-grey or yellowish. Pale or colourful legs are possessed only by the sickletails, the Standardwing and Twelve-wired Birds-of-paradise, and most *Paradisaea* species.

The trachea of some manucode species is remarkably modified, for sound production, in being greatly elongated, coiled, and displaced to sit subcutaneously on the pectoral muscles. These

*The **Foja Parotia** differs from Carola's Parotia* (Parotia carolae) *in having a blue, rather than a yellow, iris, and a slightly shorter bill, with the upper mandible more decurved. These two taxa were until recently considered conspecific, but are now treated as forming a superspecies. The bills of the various paradisaeid genera vary from short to long, from slim to stout, and from straight to strongly decurved, reflecting strong adaptive radiation. The bills of adult males average about 5% larger than those of adult females. In the genera* Parotia, Paradigalla, Astrapia, Pteridophora, Lophorina, Drepanornis, Cicinnurus *and* Seleucidis, *the bills of females average slightly broader than those of males; in other genera, they are narrower.*

[*Parotia berlepschi*, Foja Mountains, New Guinea. Photo: Bruce Beehler]

Within the subfamily Paradisaeinae, sexual dimorphism in bill size is most marked among the riflebirds (Ptiloris). *Males of the* ***Magnificent Riflebird*** *have the longer bill, which is typical of the family as a whole, but in the other two species it is the females that have the longer bill, a case of reversed dimorphism. To a lesser degree, this is also the case with Buff-tailed Sicklebills* (Drepanornis albertisi). *All these species excavate in dead wood, tree crevices and bark, a specialized foraging method that is closely correlated to marked sexual bill-size dimorphism in other bird families. In most paradisaeids, female mean wing length averages 85–95% of that of males, with the greatest difference in the Magnificent Riflebird, where the proportion is only 81%. Male riflebirds all possess a distinctive metallic-looking breast shield. In the Magnificent Riflebird this takes the form of a delta-shaped shield of scale-like, intensely iridescent greenish-blue feathers, which in certain lights appears washed with violet-purple and magenta sheens. The lower shield edge is bordered by a narrow band of velvety jet-black feathers with a violet-purple sheen. Below this is an even narrower band of iridescent bronzed yellow-green. The range of the Magnificent Riflebird extends from New Guinea to north-east Australia, whereas the other two riflebird species are found in the north-eastern to mid-eastern coastal region of Australia. The three races of the Magnificent Riflebird differ only minimally, mainly in biometrics such as a more curved or shorter bill. However, they differ in the advertisement vocalizations of their respective males. The distinctive guttural vocalizations of the eastern New Guinea race,* intercedens, *have gained it the alternative name of "Growling Riflebird".*

[*Ptiloris magnificus.* Photo: Alain Compost/Bios]

The sole species in the genus Lophorina, *the* ***Superb Bird-of-paradise*** *forms a clade with the* Ptiloris *riflebirds. Like them, it has throat feathers that are scale-like and greatly elongated laterally, forming a shallow, "winged" delta-shaped shield of intensely iridescent metallic greenish-blue. Its nape feathers are also greatly elongated and modified to form a large, erectile nuchal "cape". The female is markedly smaller than the male, and is similar in appearance to the females of the Magnificent Riflebird* (P. magnificus) *and of the Western* (Parotia sefilata) *and Carola's Parotias* (P. carolae). *The Superb Bird-of-paradise is known to interbreed with all three of these species, along with species from three other genera.*

[*Lophorina superba*, EC New Guinea. Photo: Brian J. Coates]

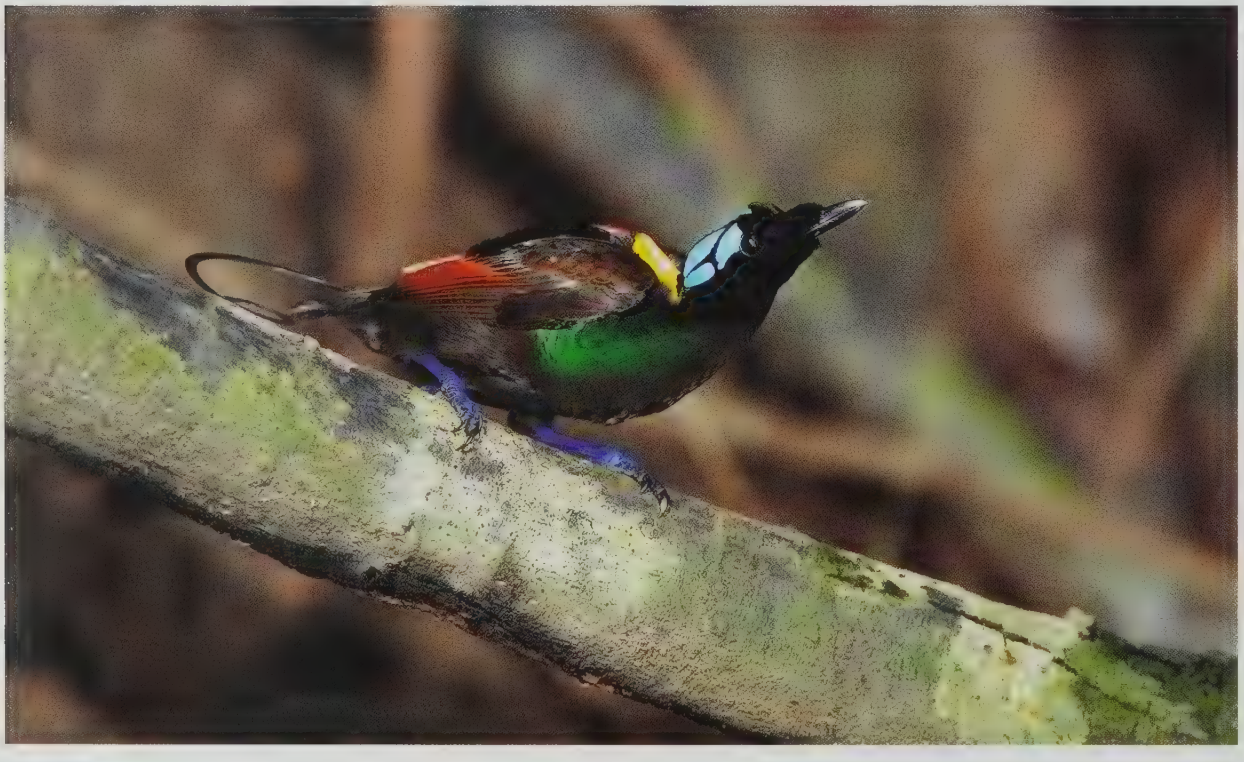
tracheal modifications are thought to enhance the distance-carrying capacity of calls by significantly lowering their pitch. This is a phenomenon unique among passerines, although similar adaptations can be found in a variety of non-passerines. It may take a minimum of five years for an individual manucode to develop each complete tracheal loop, but this requires confirmation. Tracheal coiling increases with age, is more greatly developed in males than in females, and is correlated with distinct differences between the sexes in vocalizations. The trachea of adult male Twelve-wired Birds-of-paradise, too, is modified, again in a unique way and with little doubt as a means of enhancing advertisement vocalizations, but in a much less dramatic way than with the manucodes.

Studies of a few polygynous, sexually dimorphic species show that the plumage characters of adult males develop over several years, the males taking at least 5–7 years to acquire their full adult dress. This gradual development to full adult nuptial plumage, over a period which is, for a passerine, greatly protracted, provides strong evidence for longevity among these species, some individuals of which certainly do live for a long time. For example, several species are known to have lived for more than 15 years in the wild, and in captivity a 33-year-old male Raggiana Bird-of-paradise successfully fertilized a 13-year-old female, two offspring being reared. Females develop their adult appearance within a year of fledging, and limited evidence suggests that they may commence breeding when as young as a year or two. Females of the vast majority of the polygynous species are drably coloured in subdued browns and dull yellows, or are brown and/or rufous above and dully paler and barred below, to give an overall cryptic appearance. Immature males are identical in plumage to the adult females, or are so similar to the latter that they cannot be sexed on the basis of outward appearance alone. In the year before attaining full adult male plumage, at least some individuals wear an intermediate or subadult plumage; this ranges from just a few feathers of the adult plumage intruding into the otherwise female-like plumage to almost full adult plumage with a few remaining feathers of the female-like plumage, the latter being indicative of an individual that will almost certainly acquire full adult dress later in its present moult or with its next one. This remarkably long period of years spent in cryptic female-like plumage may be a response to severe competition among promiscuous males for access to females. If so, it certainly would be advantageous for young males to be less conspicuous to predators, by retaining cryptic plumage, until reaching maturity. It has also been suggested that this scenario, in which the sexes are heterochronous in acquiring full adult plumage, might in fact reflect an evolutionary strategy that permits young males to approach adult males, to visit their traditional courting sites, and perhaps even to impregnate some of their female visitors, under the "false colours" of female plumage.

Heterochrony refers to temporally unequal development of the sexes within a species, and is broadly described above with regard to birds-of-paradise. Taking the genus *Paradisaea* as a specific example, the males first assume female plumage and fun-

The sicklebills are defined by the possession of a long, curved bill, the erectile pectoral plumes of the males, and the mantle and upperwing colouring of the females. However, the four species form two closely related but distinct lineages. The two Epimachus *"sabretails", the* ***Brown Sicklebill*** *and the Black Sicklebill* (E. fastosus) *are distinguished by marked sexual dimorphism; a greatly elongated tail; a brightly coloured iris; an iridescent mantle and crown in adult males; and an unbarred chin and throat in both sexes. If their elongated central rectrices are included, adult male Brown and Black Sicklebills reach 110 cm in length.*

[*Epimachus meyeri bloodi*, Mount Hagen, EC New Guinea. Photo: Phil Gregory]



In comparison to the genus Epimachus, *the two* Drepanornis *sicklebills show far less marked sexual dimorphism. The female* ***Buff-tailed Sicklebill*** *is similar to the male in size and weight, and, although lacking the male's iridescent feathering, is otherwise similar above. However, female* Drepanornis *sicklebills differ from males in having the underparts barred with dark brown or blackish-brown.* Drepanornis *species also differ from* Epimachus *in having much shorter, rounded tails, bare facial skin, a brown iris, and no iridescence on the mantle and crown.*

[*Drepanornis albertisi*, Crater Mountain, EC New Guinea. Photo: William S. Peckover]

damentally retain that appearance for up to six or seven years. The first discernible indication that an individual is a male, however, is when an annual moult produces central rectrices longer than the rest of the tail feathers and typically with paddle-shaped tips, together with some green throat feathers and some yellow crown feathering. Increasingly wire-like central rectrices then appear with subsequent moults, in which the young male also acquires a densely feathered, darker breast "cushion" and short flank plumes. With each subsequent year the flank plumes are longer, until finally reaching adult proportions, but even then both they and the central tail wires continue to grow slightly longer with the passing years. Thus, these plumage traits probably signal to conspecifics the age, and therefore the survival ability or fitness, of individual male birds-of-paradise. The primaries are moulted progressively from the innermost outwards, and the rectrices from the central pair outwards (centrifugally). The moult of the tail and body starts at about the time when the renewing of the primaries begins.

Typical birds-of-paradise do not have a distinctive, visually discernible, juvenile plumage, whereas the cnemophilines do. The two members of the genus *Cnemophilus*, namely Loria's Bird-of-paradise and the Crested Bird-of-paradise (*Cnemophilus*

Adult males of the three diminutive Cicinnurus *sickletails have the central pair of rectrices modified into recurved "wires". They have iridescent green ventral plumage, red dorsal plumes, and bright blue legs and feet. The male* ***Wilson's Bird-of-paradise*** *has a largely unfeathered crown and nape, the bright blue exposed skin criss-crossed with lines of fine, velvety black feathering. The female is similar in size, with a longer tail, which lacks the wires. Her nape and crown are also bare, but the skin is a darker blue. Otherwise she is cryptically drab-coloured.*

[*Cicinnurus respublica*, Batanta Island, Indonesia. Photo: Konrad Wothe]

*The **Standardwing Bird-of-paradise**, the only member of the genus* Semioptera, *is an aberrant species restricted to Halmahera and two nearby islands, in the north Moluccas. It appears to be a sister form of the sickletail–*Paradisaea *group, a theory supported by its green adult male ventral plumage. Two grossly elongated white lesser coverts form the "standards" after which the bird is named; these can be as long as the rest of the wing or even longer. The feathering of the chin and throat becomes increasingly dense to form an extensive breast shield of iridescent emerald-green.*

[*Semioptera wallacii halmaherae*, Halmahera, Moluccas. Photo: Tim Laman]

macgregorii), have a distinct grey juvenile plumage, unlike the brownish-olive of the females and very different from the adult male. This grey juvenile plumage, however, is worn for only a brief period, before the moult into the more female-like immature plumage. The juvenile of the third member of this subfamily, the Yellow-breasted Bird-of-paradise, has not yet been described, but it is suspected that it may have a grey plumage, like that of the two *Cnemophilus* species.

When moving over longer distances, paradisaeids use a typically distinctive undulating flap-and-glide action, the wings held closed against the body during upward intermissions between bouts of flapping. The wings of adult males of many genera produce a characteristic sound during flapping flight, and adult males of some polygynous species are capable of controlling the production and volume of wing noise during flights and courtship flights around their display courts. Most species performing the latter have blackish to black, dense and glossy flight-feathers that produce a dry rustling sound as they move against each other. Adult male Magnificent and Wilson's Birds-of-paradise (*Cicinnurus respublica*) make a sharp and clear clacking noise as they fly about their courts, but how this is produced remains to be studied. It is possible that the slightly to highly modified outer

*The **Twelve-wired Bird-of-paradise** is the sole member of the genus* Seleucidis. *It has affinities with the riflebirds* (Ptiloris), *through its male and female plumage and bill morphology, while another set of characters, including filamentous yellow flank plumes and pale legs, link it to the* Paradisaea *lineage. The white central shafts of six flank plumes on each side are elongated beyond the webs into black "wires", which after curving upwards become white again. The elongated, inward-curving yellow plumes of the male fade rapidly in captivity and in museum specimens; this ephemeral pigment may be derived from certain foods. Uniquely among the family, the thighs of the male are bare; they are pink, like the legs.*

[*Seleucidis melanoleucus*. Photo: Brian J. Coates]

Paradisaea *is the genus of the seven "true" plumed birds-of-paradise, of which the* ***Red Bird-of-paradise*** *is among the least typical. This genus is defined in adult males by both the filamentous elongated flank plumes, and the greatly elongated, wire-like or tape-like central rectrices. In the Red Bird-of-paradise, the central rectrices have been modified into gently twisting, concave, shiny black tapes of plastic-like appearance and texture, 3–4 mm wide. The slightly stiffened, downward-curving flank plumes are carmine to crimson, and variably dark brown to medium-brown on the upper surface, with off-white filamental tips.*

[*Paradisaea rubra*. Photo: Brian J. Coates]

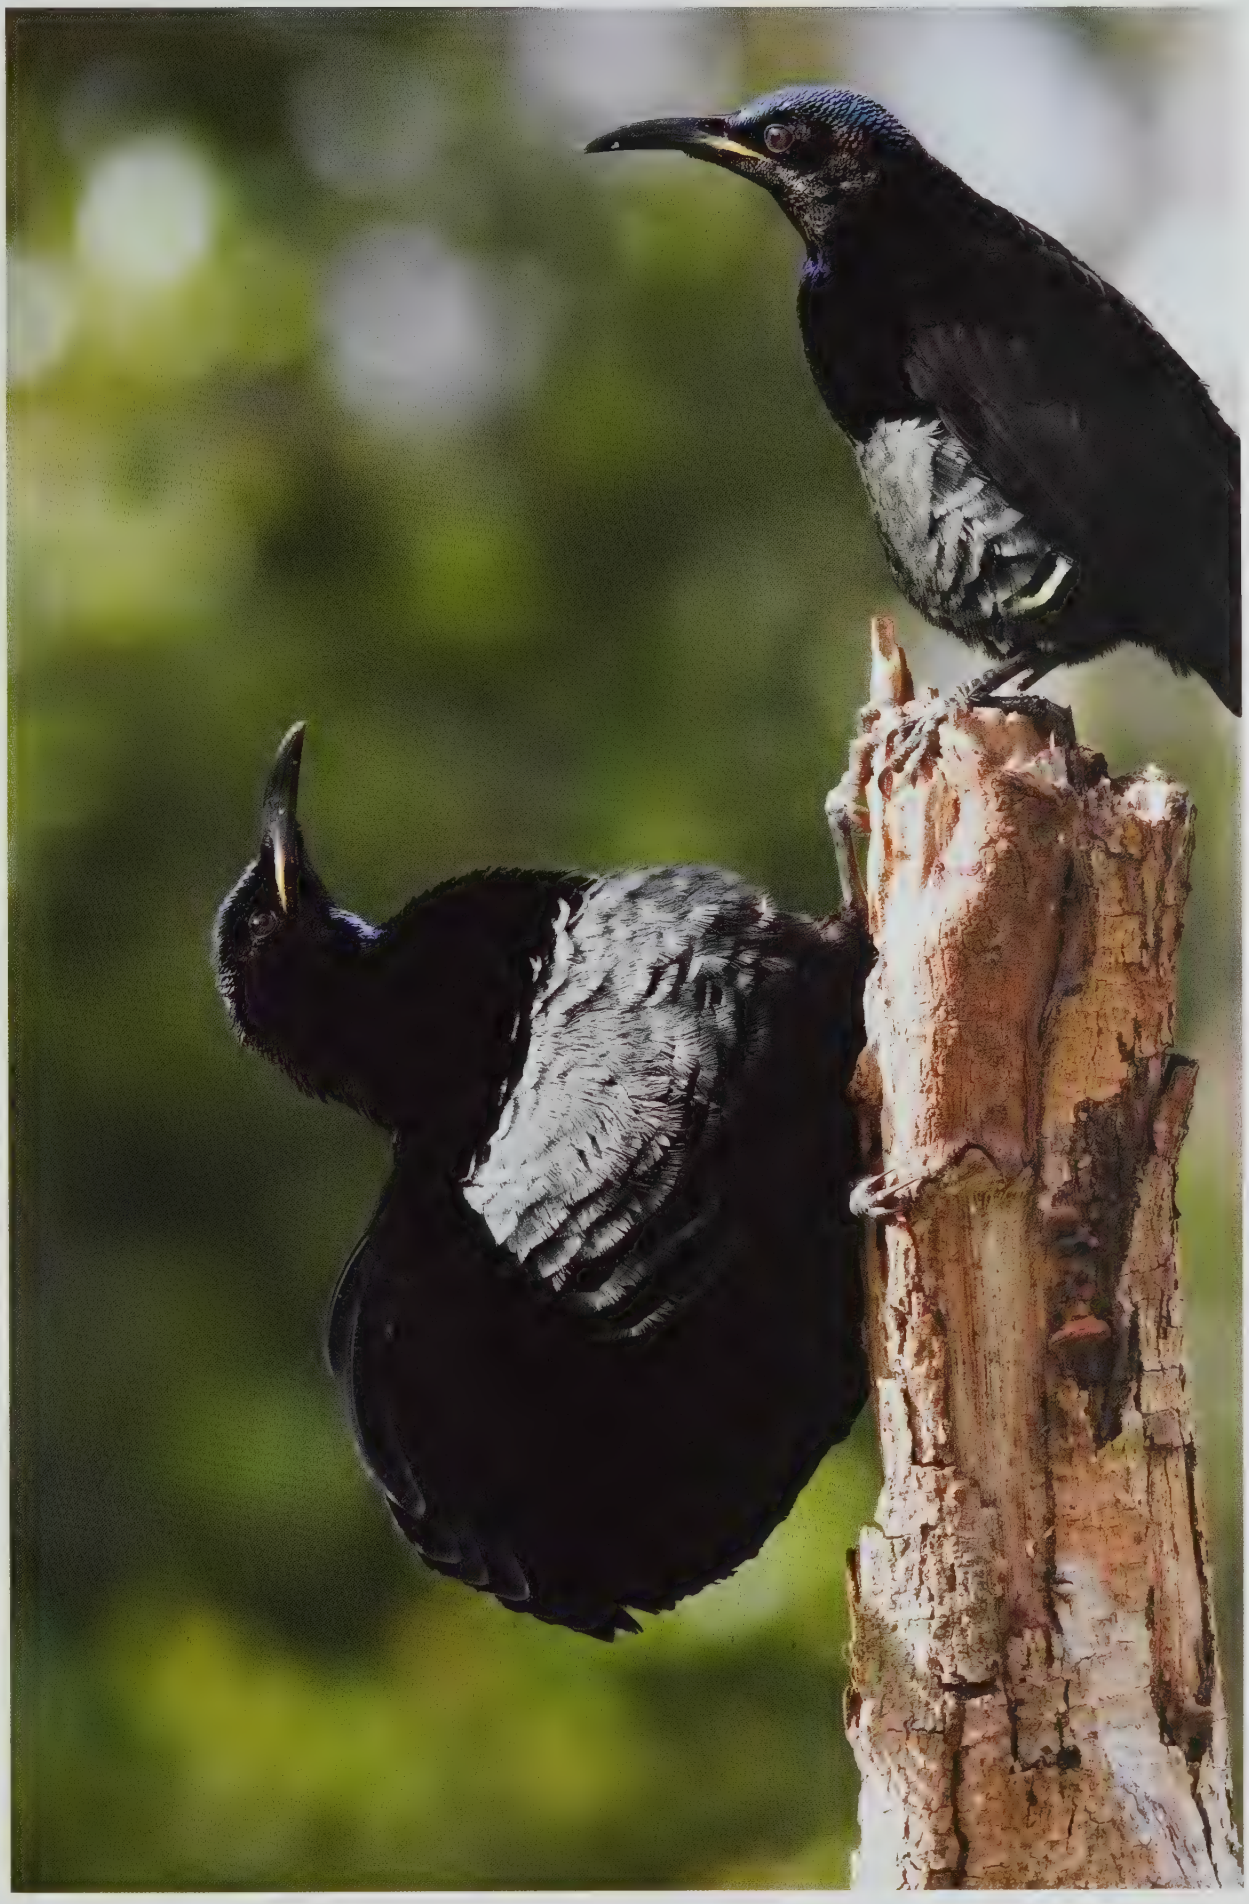
primaries of adult males of several genera create wing noise during flight, but this is yet to be confirmed.

Courtship display-flights are of rare occurrence within this family, and the few that have been noted are, for the most part, inadequately described. Certainly, the long white central rectrices of flying or hopping adult male Ribbon-tailed Astrapias (*Astrapia mayeri*) and the white standards of Standardwing Birds-of-paradise can be seen from considerable distances (see Breeding).

Habitat

Birds-of-paradise are predominantly restricted to tropical closed wet forests from Wallace's Line eastwards and then south-eastwards to the east coastal zone of Australia. The four species living in Australia are restricted to small remnant rainforest patches. One species, the Paradise Riflebird (*Ptiloris paradiseus*), is found in subtropical and temperate rainforests, extending also to wet sclerophyll forest adjacent to rainforest and to dry sclerophyll forest more than 1 km from rainforest. An exception to this general picture of paradisaeid habitat selection is the widespread Glossy-mantled Manucode (*Manucodia ater*), which commonly inhabits open savanna woodland, as well as rainforest, over large areas of New Guinea. Similarly, Curl-crested Manucodes inhabit both dense rainforest and open savanna-like plant communities of the D'Entrecasteaux Archipelago, off the south-east corner of that island.

All members of the family depend upon closed humid forest over most, if not all, of their geographical range. Indeed, most species are habitat specialists, this being true especially of the montane ones. Ten species occupy a single environment, and only three or four typically utilize more than three habitats, mostly lowland ones, as typified by the Raggiana Bird-of-paradise, which ranges into hill habitats. The geographically most restricted species live in mid-montane forests, at 1200–2500 m, and it is here that the greatest number of species occur sympatrically. For example, nine paradisaeid species co-exist at around 1480 m on Mount Missim, in east New Guinea.



Manucodes in New Guinea are far more tolerant in terms of habitat than other birds-of-paradise. Some lowland forests support as many as three manucode species, but it is not known how they co-exist ecologically (see Food and Feeding). The clearly defined and altitudinally limited distributions of different forest habitats dictate the geographical distributions of the various species in New Guinea, with the largest number concentrated in the range 1000–2000 m. The Trumpet and Curl-crested Manucodes may have wider elevational ranges than those of any other family-members. The distributions of the Crinkle-collared and Jobi Manucodes (*Manucodia jobiensis*) indicate the importance of altitude, with the former adapted to upland forest and the latter to lowland forest, with complete and broad geographical overlap, but also with little or no sharing of specific habitat.

Magnificent and King Birds-of-paradise occupy marginally overlapping habitat zones, the former living in upper hill and lower montane zones and the King Bird-of-paradise in lowlands and hills. Black and Brown Sicklebills (*Epimachus meyeri*) demonstrate a similar example of limited overlap in mid-montane forest, the former at lower elevations and the latter at higher ones, and the Raggiana and Blue Birds-of-paradise provide another, with the Raggiana below the Blue but, in this case, with considerable overlap. In the Huon Peninsula of north-east New Guinea, the Emperor Bird-of-paradise inhabits the uplands and the Raggiana Bird-of-paradise the lowlands, their populations meeting in upper hill forests. Further, Ribbon-tailed Astrapias meet Stephanie's Astrapias (*Astrapia stephaniae*), and hybridization between them occurs, where the otherwise discrete elevational ranges of the two species abut.

Within the Paradisaeidae, only ancestors of the manucode and Paradise Crow lineage, comprising the genera *Manucodia* and *Lycocorax*, and members of the plumed paradisaeine clade, containing *Cicinnurus*, *Semioptera*, *Seleucidis* and *Paradisaea* (see Systematics), show evidence of the ability to colonize islands across deep-water barriers. The present distributions of some montane New Guinea taxa, including apparently anomalous ones incompatible with usual dispersal models of New Guinean biogeography, may reflect the dramatic geological movements, both vertical and lateral, of various parts of the island.

General Habits

Apart from the breeding behaviour of this family, which has been well studied for several of the species, the behaviour of the Paradisaeidae is not particularly well known. The majority of the species are normally seen as singles, although the monogamous ones are often found in pairs or, in some cases, in

Apart from the breeding behaviour of the Paradisaeidae, which has been well studied for several species, the behaviour of this family is not particularly well known. Most species are normally seen singly, although the monogamous ones are often found in pairs or, in some cases, in small groups. A few species will sometimes assemble at sources of food. The riflebirds, for example, occasionally gather in small flocks at fruiting trees, and gatherings of up to 50 ***Victoria's Riflebirds*** *have been recorded in orchards during the winter months. The degree of intraspecific aggression apparently varies. Fights and chases may occur when an individual male encroaches on the range of another. Some species appear to be less aggressive. Although they are solitary, sedentary and territorial during the breeding season, it is by no means unusual for up to five adult male Victoria's Riflebirds to forage together, with no signs of aggression among them, even when in the core area of another male. Among the species that gather to display at leks, however, fights between males are not uncommon, and it seems likely that some level of fighting is necessary to maintain the mating hierarchy. Recently formed leks tend to have fewer males demonstrating more aggression. Once the hierarchy is established, aggression is reduced, and older leks tend to have more males and less aggression.*

[*Ptiloris victoriae*, Atherton Tableland, NE Queensland, Australia. Photo: Clifford & Dawn Frith]

*The **Emperor Bird-of-paradise** is an atypical member of the genus* Paradisaea, *with its sparse filamental flank plumes ventrally and basally pale orange-yellow but predominantly white. This species also has a patch of elongate white feathers on either side of the belly, giving an impression of flank plumes expanding across the underparts and almost meeting centrally. Birds-of-paradise are typical passerines in having ten primaries, the outermost of which is fairly well developed, ten to twelve secondaries, and twelve rectrices. Little has been documented with regard to the maintenance behaviour of the Paradisaeidae, although they are known to visit forest pools and flooded tree knotholes in order to bathe. Bathing is generally followed by preening. In Australia, riflebirds* (Ptiloris) *have been observed to bathe in shallow pools and in other suitable sites. A male Magnificent Riflebird* (P. magnificus) *was watched while it bathed several times in a riverside pool, and between bathes perched nearby on a sunlit log and preened. On subsequent days, several individuals of both sexes bathed in the same pool at about midday. For several months during a severe drought, a male Paradise Riflebird* (P. paradiseus) *regularly bathed in the late afternoon in an artificial pool in a garden. His visits ceased as soon as a storm broke and relieved the harsh conditions. Paradise Riflebirds often perch in trees in the morning, and proceed to sunbathe and preen.*

[*Paradisaea guilielmi.* Photo: Brian J. Coates]

*The adult male **King of Saxony Bird-of-paradise** has a characteristic advertisement song: a dry rattling jumble of insect-like notes poured out at a rapid pace (suggestive of bad radio static), which briefly turns into a twittering at its climax. Most birds-of-paradise produce distinctively loud and harsh vocalizations. While both sexes of the monogamous species call regularly, only the males of the polygynous species typically produce vocalizations, in the form of advertisement calls. There are few records of vocal mimicry by wild birds-of-paradise, but a King of Saxony Bird-of-paradise may have incorporated the calls of smaller passerines into its courtship subsong.*

[*Pteridophora alberti*, Tari Gap, EC New Guinea. Photo: Pete Morris]

small groups. A few will sometimes assemble at sources of food, the riflebirds, for example, occasionally gathering in small numbers at fruiting trees, and gatherings of up to five Victoria's Riflebirds (*Ptiloris victoriae*) have been recorded in orchards during the winter months.

From the little information available, it would seem that most birds-of-paradise are sedentary within small, permanent home ranges. They are for the most part rather shy, and can be difficult to observe. Indeed, some, such as the Trumpet Manucode, are extremely secretive and very hard to locate, but they often reveal their presence by the distinctive calls which they utter (see Voice). All members of the family are markedly arboreal, keeping mostly to the middle and upper levels of the forest, although they will also, particularly when foraging in mixed flocks, descend to lower levels and occasionally, as with the Paradise and Victoria's Riflebirds, forage on the ground. Promiscuous adult males advertise the location of their leks, courts or display perches mostly during the early morning and late afternoon, but by no means exclusively so during peak courting months.

One or more bird-of-paradise species are typically present in mixed foraging flocks in the New Guinea lowlands and hill forest. These include, at least, manucodes, Stephanie's Astrapia, Western (*Parotia sefilata*) and Lawes's Parotias, the Magnificent Riflebird, the Superb Bird-of-paradise, all sicklebills, the Magnificent Bird-of-paradise, the King and Twelve-wired Birds-of-paradise, and the *Paradisaea* species. In such flocks male birds-of-paradise call regularly, as if maintaining flock cohesion. Flocking is more important to lowland-forest species than to those in upland forest, partly because of the less species-rich bird and insect communities at higher altitudes.

The medium-sized to large bird species that typically form mixed foraging flocks are generally brown and/or black in plumage, and this common appearance may facilitate social cohesion, as well as possibly confusing potential predators. All female birds-of-paradise and some males that join mixed flocks fit this pattern. It is conceivable that some kind of "social mimicry" has played a part in this similarity in appearance across taxonomically diverse flocking species. It was suggested that this might specifically involve mimicry of the appearance of New Guinea Babblers (*Pomatostomus isidorei*) and various pitohuis (*Pitohui*), the most typical of flock-leaders. This suggestion is particularly interesting because it preceded the amazing discovery that the Hooded Pitohui (*Pitohui dichrous*) and other pitohui species have toxic feathers and skin. In this regard, it is noteworthy that, in earlier times, some birds-of-paradise, including Buff-tailed Sicklebills and Raggiana Birds-of-paradise, eaten by hungry zoological collectors were found to be distasteful.

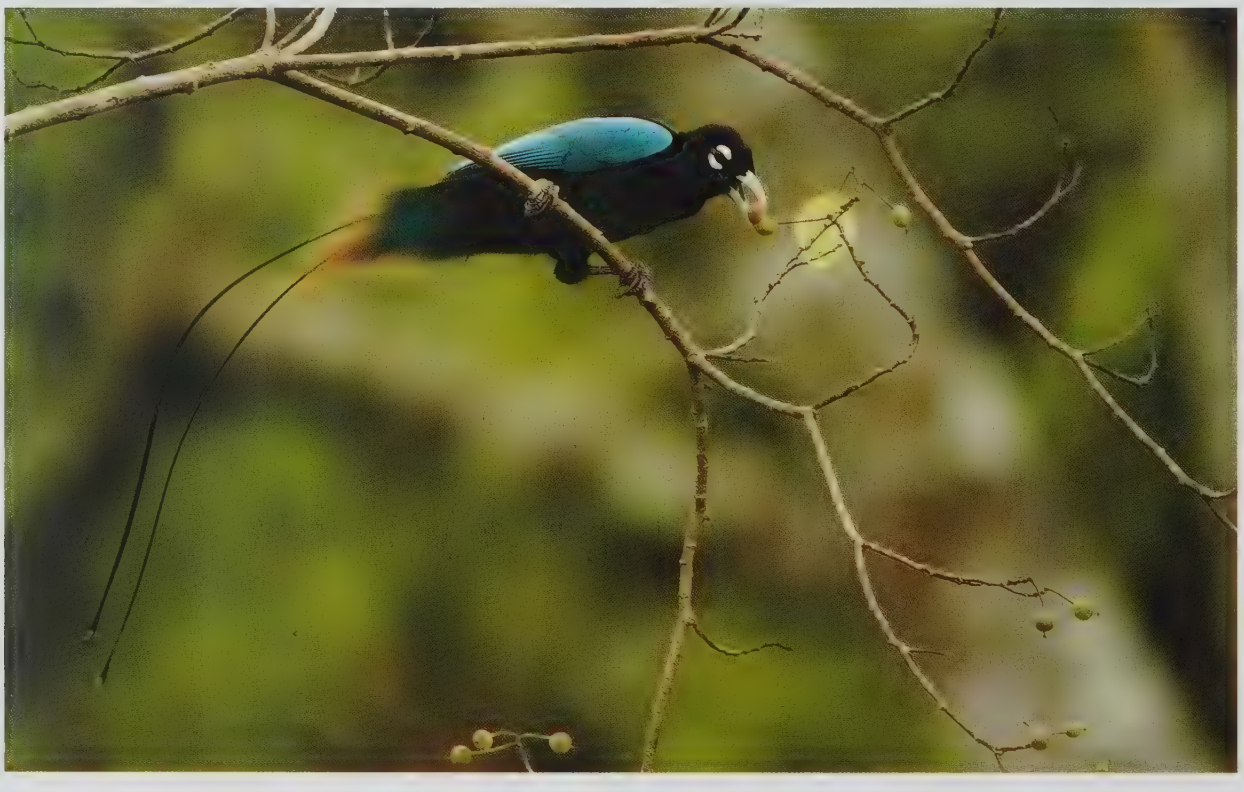
The discovery of defensive toxins in brownish and brown-and-black pitohuis provided the basis for a speculative explanation of the conspicuously atypical bird-of-paradise plumages found in the genus *Paradisaea*. In this genus, most female and immature plumages differ distinctly from the plumages of most other birds-of-paradise, the females and immatures of which are typically brownish above and barred below. A tentative explanation for this striking exception within the Paradisaeidae is that female-plumaged *Paradisaea* broadly mimic the appearance of typically mixed-flocking and/or toxic species in order to participate in mixed flocks, if not to look like toxic birds. Among the adaptive advantages of mixed-species flocking are that of an anti-predator strategy, whereby many pairs of eyes, including those of "sentinel" species, make it safer for individuals to maximize the time spent in foraging, and that of a mutually beneficial foraging effect, whereby small mobile prey may be flushed by one flock-member into the field of view of another.

The degree of intraspecific aggression apparently varies. Fights and chases may occur when an individual male encroaches on the range of another. Some species, however, appear to be less aggressive. Male Victoria's Riflebirds, for example, are not territorial during the winter period, and very little or no fighting seems to occur when they assemble at foraging sites. During the breeding season, too, it is by no means unusual for up to five adult males of this species to forage together with no signs of aggression among them, even when in the core area of another male.

While most birds-of-paradise are armed with a powerful bill and feet, and can pugnaciously use them, their many natural enemies include such dangerous predators as hawks, including *Accipiter* species, and snakes. Nevertheless, few documented records of natural predation exist.

Little has been documented with regard to the maintenance behaviour of this family. These birds visit forest pools and flooded tree knotholes in order to drink or bathe. In Australia, riflebirds have been observed to bathe in shallow pools and in other suitable sites, and for several months during a severe drought a male

The range of bill shapes reflects the wide range of dietary preference among the birds-of-paradise. Some, such as the wide-gaped and weak-billed cnemophilines, may be entirely or almost entirely frugivorous, but most species for which information is available consume both fruits and arthropods. ***Stephanie's Astrapia*** *eats mostly fruits, but also insects, spiders, frogs and skinks. This species forages mostly in the middle and upper forest strata, usually singly, or in small loose groups. It will also join mixed-species feeding flocks with Brown Sicklebills* (Epimachus meyeri)*, with which it hybridizes extensively in the west of its range.*



[*Astrapia stephaniae*, Tari Gap, EC New Guinea. Photo: Tim Laman]

Paradise Riflebird regularly bathed in the late afternoon in an artificial pool in a garden, his visits ceasing as soon as a storm broke and relieved the harsh conditions. A male Magnificent Riflebird was watched while it bathed several times in a river-side pool, and between bathes perched nearby on a sunlit log and preened; several individuals of both sexes bathed in the pool at about midday on subsequent days. A male of this species was seen to chase off two Graceful Honeyeaters (*Meliphaga gracilis*) from a pool where they were bathing, and then to enter the pool himself. Preening generally follows bathing, and Paradise Riflebirds often perch in trees in the morning and proceed to sun-bathe and preen. In New Guinea, Papuan hunters used to set artificial perches at pools and, when the birds came to bathe or drink, they were able to kill them for their plumes or for food (see Relationship with Man).

There appears to be little information on the roosting behaviour of the family. Twelve-wired Birds-of-paradise are known to roost relatively low down, whereas male Standardwing Birds-of-paradise roost above their leks.

Voice

Birds-of-paradise produce distinctively loud and harsh vocalizations that have been described as corvid-like. Adults of both sexes of the monogamous species call regularly. Among the

Species that depend more on fruit tend to range more widely in search of food, and are non-territorial, or defend only their display site rather than an all-purpose territory. Female ***Blue Birds-of-paradise*** *will however defend a food resource such as a branch, vine or small fruiting tree, and will aggressively expel other birds that try to forage there. This is unusual behaviour for frugivores. Adult male Blue Birds-of-paradise usually forage alone, but are sometimes found with individuals in female-type plumage, and with other species of bird-of-paradise. Paradisaeids in mixed flocks usually interact little with other birds, and typically leave the tree after having consumed a relatively small quantity of fruit.*

[*Paradisaea rudolphi margaritae*, Tari Gap, EC New Guinea. Photo: Tim Laman]

When seeking animal prey, most species hop about foliage, boughs and tree trunks, repeatedly lifting and tearing at dead foliage, epiphytic growth and bark. The relative proportions of fruit and animals in the diet of the ***Twelve-wired Bird-of-paradise*** *are estimated to be 50:50. The animal component is mostly arthropods, but also small vertebrates such as frogs, and lizards. This species forages acrobatically, hanging upside-down to probe holes in tree branches. Manucodes* (Manucodia) *forage for animal prey by upright gleaning among twigs and foliage, a technique that is a little unusual for such large birds, and far more typical of considerably smaller gleaners.*

[*Seleucidis melanoleucus*, New Guinea. Photo: Roland Seitre]

polygynous species, on the other hand, it is typically only the males that produce vocalizations, these in the form of loud and regular advertisement calls some of which may carry 1–2 km, the females being mute other than when alarmed. The relative range of vocalizations of the two sexes of polygynous species is, however, difficult to ascertain, as many young males wear female-like plumage for several years.

Exceptions to the typical loud corvid-like male calls include weak and rather pathetic-sounding high-pitched notes, given by some manucodes and Loria's Bird-of-paradise; a staccato series of explosive notes remarkably like the sound of a machine-gun, uttered by the Brown Sicklebill; a complex "fizzing" song sounding like radio-static, by the King of Saxony Bird-of-paradise; a loud clear "popping", by the Emperor Bird-of-paradise; and an almost unbelievable humming-like sound as if from an electric motor, emitted by the courting Blue Bird-of-paradise. When courting, as distinct from prior advertisment-calling, males of the *Paradisaea* species are relatively quiet, sometimes giving just a few brief soft notes accompanied, in some species, by a sharp clicking sound produced with the mandibles; a similar clicking is made also by the Magnificent Bird-of-paradise, in the genus *Cicinnurus*. The elongate and coiled trachea of manucodes produces unique low tremulous notes (see Morphological Aspects).

While there have for a long time been few, if any, convincing records of vocal mimicry by wild birds-of-paradise, some recent recordings indicate the possibility that vocalizations of a court-

The ***Black Sicklebill*** *is just one of several species that feed on* Pandanus *fruits. Others include the Twelve-wired Bird-of-paradise* (Seleucidis melanoleucus), *for which this plant is known to be important, as it is suspected to be, too, for the Arfak Astrapia* (Astrapia nigra). *Sicklebills often use their long, curved bills to probe for animals among debris at the bases of* Pandanus *fronds, behaviour that has likewise been recorded for the Ribbon-tailed Astrapia* (A. mayeri).

[*Epimachus fastosus*, Arfak Mountains, New Guinea. Photo: Richard Kirby/ naturepl.com]

*With the exception of marginal habitats such as those at highest altitudes, most of the forests inhabited by birds-of-paradise support hundreds of species of fruit-bearing tree, vine, liana and shrub. This **Victoria's Riflebird** appears to be feeding on nectar from these trumpet-shaped flowers, which are cauliflorous—coming directly out of the tree trunk and limbs rather than from branches or twigs. Nectar-feeding in this species is known but is rarely observed, and this may be the first published photograph of it.*

[*Ptiloris victoriae*, Jullaten, Australia. Photo: Rohan Clarke]

ing male King of Saxony Bird-of-paradise and a Wilson's Bird-of-paradise may have involved mimicry of the calls of smaller passerines, notably of *Sericornis* scrubwrens. This does, of course, require confirmation. A male Raggiana Bird-of-paradise, which was hand-raised from a nestling and which lived for many years in a wildlife sanctuary, did mimic a few words and whistling of local people, apparently in the context of "courting" humans, upon which it was imprinted.

Male Black Sicklebills vocalize during courtship, whereas male Pale-billed Sicklebills (*Drepanornis bruijnii*) have not been recorded as doing so, the latter giving, instead, a bill-rattle. Although courting parotias display largely in silence, male King of Saxony Birds-of-paradise produce a continuous varied busy whisper-song while perch-bouncing and in pre-copulatory display. In the latter context, sickletails, too, vocalize softly. Unique among the *Paradisaea* species is the mechanical-sounding buzzing given by the male Blue Bird-of-paradise in inverted display (see Breeding).

Courting male Standardwing Birds-of-paradise emit vocalizations characteristic of both *Cicinnurus* and *Paradisaea*, with additional high-pitched twittering noises. During their display, they also repeatedly beat their carpal joints sharply together to produce loud cracking or snapping sounds, which is analogous to the beating of the carpal joints by courting males of several *Paradisaea* species, in the latter producing a softer audible thud (see Breeding). Various other non-vocal sounds that displaying paradisaeids produce may act as auditory advertisement: These include wing-beating, bill-rattling, primary-rustling and wing-snapping.

Food and Feeding

There is a wide range of dietary preference among the birds-of-paradise, as is in part reflected by their range of body sizes and bill shapes (see Morphological Aspects). The majority of the species for which relevant information is available consume both fruits and arthropods, but some, such as the Buff-tailed Sicklebill and the Superb Bird-of-paradise, are primarily insectivorous and others, such as the cnemophilines, are entirely or almost entirely frugivorous. Something is known of the diets of 25 of the members of the family, and there is fragmentary knowledge for all other species except Wilson's Bird-of-paradise. All of the species for which information is available are known to take fruit. Thus, birds-of-paradise are first and foremost frugivores, arthropods comprising the second major component of the diet. Species that depend more on fruit tend to range more widely in search of food, whereas the more insectivorous ones are more sedentary. As a generalization, therefore, adult males of some polygynous species, notably the predominantly insectivorous ones, defend all-purpose territories, whereas most other species are non-territorial or defend only their display site.

Frugivores forage mostly in the canopy of fruiting trees, whereas insectivores search for food in bark and foliage in the forest canopy or middle storey, by gleaning and by probing rotten wood. The former tend to be more sociable, whereas the insectivores are generally more solitary and, furthermore, territorial.

*A common technique when foraging for insects is the probing and tearing of dead wood. The **Brown Sicklebill** takes a similar approach to epiphytic plants. This bird appears to be using open-bill probing, a technique that involves inserting the closed bill into soft wood or debris, and then opening the bill and exposing prey. Buff-tailed Sicklebills* (Drepanornis albertisi) *sometimes open the bill wide before probing, and insert only the lower mandible into wormholes and knotholes in order to spear prey. Adult male Brown Sicklebills appear to forage within a home range from which they exclude other adult males, but in which they permit individuals in female-type plumage to feed.*

[*Epimachus meyeri bloodi*, Mount Hagen, EC New Guinea. Photo: Tim Laman]

Beyond fruits and arthropods, the diet contains only minor additional constituents, small vertebrates, flowers and, apparently, nectar being consumed at times. Several species eat leaves when in captivity, and this is probably an uncommon but regular activity in the wild.

Fruit is the most common dietary component among the birds-of-paradise, foraging individuals typically feeding solitarily by plucking and consuming fruit from trees in the middle and upper storeys of forests. They may also join other frugivorous birds in fruiting trees, but usually interact little with them and typically leave the tree immediately after having consumed a relatively small number of fruits (see also General Habits). The most complex aspect of frugivory is that of fruit selection. With the exception of some marginal habitats, such as those at highest altitudes, most forests where birds-of-paradise live support hundreds of species of fruit-bearing trees, vines, lianas and shrubs. Several studies have revealed that each paradisaeid species consumes the fruit of only a small number of the available plant species. Preference for particular structural types, for drupe/berry, figs (*Ficus*) or capsules, differs from one species to another. For example, the Trumpet and Crinkle-collared Manucodes eat mostly figs, while Magnificent Riflebirds and the Superb, Magnificent and Raggiana Birds-of-paradise take more capsular fruits, and Lawes's Parotias eat more drupe/berry fruits.

The members of Paradisaeinae use their feet as tools with which to hold and manipulate foods, and they are thus able easily to extract the edible "reward" from capsular fruits. They harvest fruit while perched, rarely plucking it while in flight, and they are one of the most important groups of vertebrate dispersers of fruit seed in New Guinea; this is because they do not digest seeds, and are therefore not seed predators. The family Paradisaeidae contains more seed-dispersing mainland New Guinea frugivore species, 35 in total, than any other family of vertebrates, the pigeons (Columbidae), with 24 primarily frugivorous species, coming second. A single individual of some bird-of-paradise species will defend a compactly restricted fruit resource, such as a branch, vine or small tree, and spend a significant part of each day in foraging, resting and aggressively expelling other birds that try to forage upon it. This is unusual behaviour for frugivores at fruit resources.

There are no exclusively insectivorous species in this family, and even the primarily insectivorous ones take, in combination, a range of fruits typical of their more frugivorous relatives. Although observations are limited, arthropods eaten by birds-of-paradise include caterpillars, beetles (Coleoptera) and their larvae, katydids (Tettigoniidae) and their relatives in the order Orthoptera, and ants (Formicidae). Three fundamental methods of insectivory have been described: these are bark-gleaning, the probing and tearing of dead wood and foliage, and the generalized gleaning of twigs and foliage. The first two are common among most paradisaeine birds-of-paradise, and the last appears to be more typical of the manucodes. When seeking animal prey, the majority of species hop about foliage, boughs and tree trunks scansorially, repeatedly lifting and tearing at dead foliage, epiphytic growth and bark. In upper montane forests, which support ubiquitous moss and epiphytic growth, birds-of-paradise commonly seek prey by pulling apart,

Riflebirds (Ptiloris) *are remarkable among paradisaeids in clinging to substrates with their powerful feet and claws, enabling them to use their long, strong decurved bills to probe and tear bark and dead wood, in a manner reminiscent of woodpeckers (Picidae). They also use open-bill probing into soft wood or debris.* ***Victoria's Riflebird*** *forages mostly in canopy, but also close to and even on the forest floor. It probably takes more arthropods than fruits overall, including spiders, centipedes and millipedes, as well as insects such as cockroaches and cicadas, although the relative proportions vary seasonally.*

[*Ptiloris victoriae*, Atherton Tableland, NE Queensland, Australia. Photo: Clifford & Dawn Frith]

There have been few observations of the feeding behaviour and dietary preferences of the ***Greater Bird-of-paradise****, but these are probably similar to some of its congeners which seem to eat mostly fruit, particularly capsular fruit and figs, but also arthropods. This bird is spitting out a nutmeg* (Myristica) *seed, having consumed the flesh around it. Because they do not digest seeds, the birds-of-paradise play a major role in seed dispersal. The family contains 35 seed-dispersing species on mainland New Guinea, more than any other family. The pigeons (Columbidae) come second, with 24 species.*

[*Paradisaea apoda*, Aru Islands, Indonesia. Photo: Loïc Degen]

or probing into, mossy clumps. While typical birds-of-paradise use their feet to hold prey, in order to tear it apart, this behaviour has not been recorded for the weak-footed cnemophilines, which are obligate frugivores (see also Morphological Aspects).

Manucodes forage for animal prey by upright gleaning among twigs and foliage, which requires no specialized physical abilities. This foraging method is a little unusual for birds as large as the manucodes, being far more typical of considerably smaller gleaners of twigs and foliage. Riflebirds are remarkable in clinging to substrates with their powerful feet and claws, enabling them to use the long, strong decurved bill to probe and tear bark and dead wood, in a manner reminiscent of the woodpeckers (Picidae), when seeking animal prey. They also use open-bill probing into soft wood or debris; this technique, sometimes referred to as "*Zirkeln*", involves the insertion of the closed bill into a substrate and then opening the bill and thus exposing prey. Buff-tailed Sicklebills sometimes utilize the narrow sickle-shaped bill to probe into wormholes and knotholes, at times opening the bill wide and inserting only the lower mandible in order to spear prey. Short-tailed Paradigallas (*Paradigalla brevicauda*), Brown Sicklebills, Splendid Astrapias and Ribbon-tailed Astrapias will occasionally consume frogs or skinks (Scincidae), and it seems probable that most larger birds-of-paradise also do so to a greater or lesser extent.

Adults representing at least seven or eight paradisaeine genera and one cnemophiline, the Yellow-breasted Bird-of-paradise, regurgitate food into the bill before reswallowing it, or to feed their offspring, or simply to drop seeds, and this behaviour is probably typically performed by all family-members. Seeds dropped or excreted on or around terrestrial display courts of the Magnificent Bird-of-paradise and the parotias attract ground-foraging granivorous pigeons. In this interaction, the pigeons obtain food as they clean the courts of the birds-of-paradise.

In the Crested Bird-of-paradise, both the parent female and her offspring eat exclusively simple fruits, and this may well prove to be true of all three species in the Cnemophilinae (see Breeding). Paradisaeine parents discriminate in the matter of food items to be fed to their young on the basis of the latter's age, most initially feeding the nestlings with arthropods. After the chicks reach a certain age, they are fed predominantly with fruit or with both fruit and insects. The arthropods presumably provide calcium, which is necessary for bone formation, provide structural proteins, which are critical for tissue growth, organ and feather production, and contain lipid, for energy. Once nestlings reach a certain mass, a range of fruits can probably meet their dietary needs. In a study of the nesting biology of the Trumpet Manucode, however, an unexpected finding was that these monogamously pair-bonding birds are frugivorous specialists that raise their nestlings on a diet almost exclusively of fig fruits. For these nestlings to be provided with the necessary macro-nutrient building blocks required for their growth, massive amounts of low-nutrition figs must be supplied to them; the nestlings apparently receive an oversupply of sugar and carbohydrate, but insufficient lipid and protein, the last two being found in good quantities in arthropods.

A largely frugivorous diet is considered a main pre-condition of polygyny among rainforest birds, the males of which spend most of their time in advertising, attending and defending a traditional courting site, solitary or communal, at which they perform elaborate displays. Annual seasonal fruit abundance in these birds' habitats appears adequate to enable males to be emancipated from nesting duties, thus permitting male promiscuity and the evolution of court-based or lek-based behaviour, and sufficient to enable females to raise offspring unaided. It is probable that the sexes of the adults, because they have differing needs in terms of energy and time budgets, face differing foraging demands, the females requiring more arthropods while nesting, and the males seeking foods, such as fruits, that minimize foraging time, allowing them to maximize the time spent at display sites. Some recent fieldwork on birds-of-paradise has focused on the importance of dietary ecology and specialized frugivory in the evolution of court and lek behaviour (see Breeding).

Breeding

Annual cycles of birds-of-paradise are little studied. Combining various pieces of evidence of breeding for an extensively distributed species results in the perception of a misleadingly long nesting season, because it includes populations that must, perforce, follow differing cycles according to local conditions. Despite this, a review summary of breeding seasonality does indicate some useful broad patterns, revealing that more breeding occurs during August–January than during February–July, with March–June the least productive period. Breeding presumably coincides with

Birds-of-paradise are found almost exclusively in humid forest habitats. They visit forest pools, flooded knotholes and stumps to drink, although some species may also come to artificial pools in gardens. The ***King Bird-of-paradise*** *forages at various levels of the forest; the proportions of fruit to arthropods in its diet are not known. It joins mixed-species foraging flocks that may include its congener, the Magnificent Bird-of-paradise* (Cicinnurus magnificus), *and also* Paradisaea *species. Flock members can gain from the mutually beneficial foraging effect, capturing prey flushed by other members.*

[*Cicinnurus regius*, near Brown River, SE New Guinea. Photo: Brian J. Coates]

Males of the polygynous species exhibit a variety of forms of behaviour, from solitary and non-territorial through to true communal lekking, with a range of intermediate strategies. The commonest system, adopted by males of at least ten species, is solitary and non-territorial display, but within this there exists considerable variation in terms of dispersion and behaviour. Some of these species, such as the ***Magnificent Bird-of-paradise****, establish cleared terrestrial display courts, which they modify, most commonly by simply removing leaves from the immediate vegetation. This "gardening" may have several functions. By removing foliage that hinders display, the male can provide better visibility, improving his view of approaching females or predators, providing better illumination of the display site, and creating a conspicuous visual marker of the display site for conspecifics. The courts of the Magnificent Bird-of-paradise are found on steep slopes, notably in treefall or landslip areas, beneath a gap in the forest canopy. Court owners spend much of their time perched on vertical saplings within the court, which they defoliate and wear smooth with use. The male of this species is non-territorial, but maintains a home range around the court, which overlaps with the home ranges of one or more other adult males. The mean nearest distance of five males at courts on Mt Missim, in south-east New Guinea, was 209 m. Males maintain auditory contact by calling while moving about their home ranges. A court may be maintained for at least three consecutive years.*

[*Cicinnurus magnificus*, Mount Hagen, EC New Guinea. Photo: Jean-Paul Ferrero/ Auscape]

greater abundances of fruit and arthropod foods, as appears to be the case on Mount Missim, in eastern New Guinea, and as confirmed for Victoria's Riflebird of Australia. Relatively brief breeding seasons indicated for some species may reflect inadequate information and/or seasonal biases in observation, because, for some better-known members of the family, nesting has been recorded in virtually every month of the year.

The various mating systems within the Paradisaeidae can be classified according to male–female interactions and the kinds of male dispersion involved, the major dichotomy being between monogamous and polygynous species. While pairs of the monogamous species form social bonds and forage together, the lives of the sexes of polygynous species are far more divergent.

The five sexually monomorphic manucode species and the Paradise Crow are known, or are presumed, to reproduce as socially monogamous pairs, with the task of brood care shared by the two parents. The Glossy-mantled and Trumpet Manucodes maintain year-round pair-bonds, both sexes attending the nest and provisioning the offspring; at one Trumpet Manucode nest, both sexes also incubated the clutch. Male and female manucodes forage together and maintain contact by counter-calling. With the Trumpet Manucode, at least, males and females give sex-specific call notes, whereas this is apparently not so with polygynous species. Monogamous birds-of-paradise appear to be non-territorial, highly frugivorous and wide-ranging, having little opportunity to defend a foraging area.

Courting males of the monogamous manucodes perform brief and simple solitary displays on a randomly used forest-canopy perch. The courtship of the male Trumpet Manucode includes a chase followed by a frontal lunging display in which the head and bill are raised and the head, neck and throat feathering is erected; the opened wings are raised and tilted forwards so that the entire surface of each upperwing is directed towards the female, while the tail is widely fanned and a loud harsh call is uttered. One male of this species dropped his wings, cocked his tail, and gave a shivering display for 5–10 seconds before mounting the female. What little is known of the displays of other manucode species suggests that they are broadly similar to that just described.

The remaining 37 bird-of-paradise species, two of which are sexually monomorphic and 35 sexually dimorphic in plumage, are polygynous. The promiscuous males display and the females nest alone, the sexes meeting only briefly for courtship and mating. Males of these species provide the females with no foraging rights, nesting site, or help with nesting and brood-rearing. Males strive to rise in the mating hierarchy in order to be able to mate with as many females as possible; females struggle to produce one or two offspring per year. Males focus on intrasexual competition and on gaining favoured display sites; females focus on selection of the fittest mate, but they must invest most of their time and effort in nesting, incubating, and raising offspring. Court-holding males maximize the time at or near their court, in order to be able to court and mate at every opportunity. The females tend to range more widely, being restricted to a single location only when nesting. The promiscuous males advertise themselves by vocalizations and display posturing to attract as many females as possible.

Promiscuous males use traditional, or perennial, sites for advertisement, display and mating. These sites range from simple branches in the forest canopy or understorey to vertical tree-trunk stumps, fallen logs, or terrestrial courts cleared by the birds themselves. Males of most of the polygynous species modify display sites, most commonly by simply removing live leaves from the immediate vegetation. This "gardening" may function in one or more ways. By removing foliage that hinders display, the male can provide better visibility, improving his view of approaching females or predators, provide better illumination of the display site, create a conspicuous visual marker of the display site for conspecifics, and so on.

Males of all parotias and of the Magnificent and Wilson's Birds-of-paradise create cleared terrestrial display courts. Those of the latter two species encompass the bases of several sapling stems, from which leaves are plucked, and they become well worn with repeated use. The males constantly clean the court floor of plucked or fallen leaves, exposing a uniformly clean area of bare ground that contrasts with surrounding litter and the birds themselves. Parotias do not merely clear courts, but they then also "decorate" them with specific items such as pieces of chalk, sloughed snakeskin or mammal dung. While nesting females will carry such items away from courts, the presence of these items may also provide information about relative male fitness, as do bower decorations for the bowerbirds (see page 368).

*The courtship of the **Western Parotia** involves static and leg-flexing postures, with complex movements of flank plumes, pectoral shield, mantle cape, nuchal crest and occipital plumes. Intermediately dispersed breeding systems, in which males cluster loosely over a larger area, usually not in visual contact with one another, are termed "exploded leks". The male Western Parotia clears leaves and debris from a court roughly 2 m in diameter. The branches above are often stripped of leaves to make perches, where the male begins his display, before hopping to the court to perform his complex dance.*

[*Parotia sefilata*,
Arfak Mountains,
New Guinea.
Photo: Konrad Wothe]

*The solitary, court-based display of the **Magnificent Bird-of-paradise** involves dancing up and down the stem of a sapling with a complex, ritualized progression of movements of the nuchal cape, the pectoral shield, the curled, wire-like central rectrices, and the pale green gape. There are four display phases, two of which can be seen here. In the Back Display (upper left), the male turns upside-down on his vertical display perch, with the tail uppermost and the head lifted slightly upwards; he holds this position briefly before he turns his head uppermost. In the Breast Display (lower left), the breast-shield plumage appears to inflate and deflate as it is raised and lowered, the upper margins rising on each side of the head while undulations of the breast feathers send iridescent shimmers across it. The silent Cape Display is performed if a female moves closer, whereupon the male leans towards the horizontal, with the extended neck and bill directed at her, the cape erect and fully fanned, and the breast shield flattened and elongated. The slightly trembling male may maintain this posture for many seconds, as the female hops closer down the sapling. When she is within about 30 cm, he may suddenly perform the Dancing Display. In this, he pulls his head and neck back into his body, puffs and expands most of the plumage, including the pulsating breast shield, lowers his fanned cape, and cocks his tail over his back to present the iridescent upper surface of the central tail wires to the female. He then jerks his head from side to side, opening and closing the bill to expose the pale green inside of his mouth, and quivers his tail from side to side as he dances forwards up and then backwards down the sapling, with short, jerky movements of the body and head that emphasize his yellow cape.*

[*Cicinnurus magnificus hunsteini*, Sogeri Plateau, SE New Guinea. Photos: Brian J. Coates]

*The inverted phase of the display of the male **King Bird-of-paradise** follows the Horizontal Open Wings Display. His wings vibrating, he briefly rocks silently from side to side several times, before suddenly dropping to cling below his perch in the same pose, and repeating the display. He holds his bill open and turns his head from side to side for a few seconds, before he closes his wings and tightly sleeks his plumage, while remaining suspended. He peers around him, and then swings several times from side to side at a steadily increasing tempo, in the brief and silent Pendulum Display. He ends his display by righting himself atop his perch, or by simply dropping down and away from the perch. The King Bird-of-paradise is one of a number of species that uses the wings conspicuously in courtship. The Pendulum Display is the culmination of seven display phases, which focus mainly either on open and vibrating wings, or on movements of the pectoral fans and tail wires. A promiscuous, polygynous species, the King Bird-of-paradise has a system intermediate between a non-territorial one, and an exploded lek. Its arboreal courts are in the thick subcanopy vines of the shaded forest interior. The dispersion of courting males ranges from solitary individuals, 150–530 m or more apart, to a number clustered together. They are predominantly found in twos, 45–90 m apart, but an occasional group of four may gather to form a lek. The males vocalize persistently throughout the day.*

[*Cicinnurus regius regius*, Salawati Island, off NW New Guinea. Photos: Konrad Wothe]

Males of the polygynous species exhibit a variety of court-based behaviour, from solitary and non-territorial through to true communal lekking, with a range of intermediate strategies. The most common system, adopted by males of at least ten species, is solitary and non-territorial display, but within this there exists considerable variation in dispersion and behaviour. Some of these species, such as the Magnificent Bird-of-paradise, establish cleared terrestrial display courts, while others, such as the Magnificent Riflebird, display from a tree stump or fallen bough requiring little or no modification or tending. Some species display high above the ground, the Twelve-wired Bird-of-paradise being one such example, while most do so in the understorey or on the ground. Some appear to defend an exclusive all-purpose territory around their court, as illustrated by the Buff-tailed Sicklebill. Solitary courts result from the male's desire to avoid rivals, this system thus producing the greatest distances between each displaying male. Such solitary males tend to display less frequently in the absence of females than do those of species with communal display courts, the average solitary male spending more time in vocal advertisement and court maintenance and less time in male–female interaction. Courtship by solitarily displaying promiscuous males typically includes surprise elements of vigorous advance at females, including dramatic changes of size and appearance, attitude or sound, and it may even involve the pecking of females or the beating of them with the open wings.

Intermediately dispersed systems, in which males cluster loosely over a larger area, usually not in visual contact with one another, are termed "exploded leks". Males of at least two parotia species, Lawes's and Carola's Parotias, and of the King Bird-of-paradise, in the genus *Cicinnurus*, are known to form exploded leks or suspected of so doing. Male King Birds-of-paradise sometimes disperse as twos, each such group perching some 50–70 m apart from the next, but a range of dispersion exists, from solitary individuals to as many as four clustered together. Similar variation in male dispersion is found with Lawes's Parotia.

In true lekking species, of which there are least seven, namely Stephanie's Astrapia, the Standardwing Bird-of-paradise and five *Paradisaea* species, as few as two to as many as 40 or more males display within visual contact of each other, separated by distances of 0·5 m to 5 m, on small limbs with a diameter of about 2–4 cm in the canopy of one tree or, more rarely, several trees. Such leks tend to be several hundred metres to a kilometre or more apart. Males and females of these lekking species interact mainly or solely at leks, and these leks tend to be traditional, some being known to have been seasonally active at precisely the same location for more than two decades. Communal display systems promote competitive interaction among males. Older, more dominant males tend to control the social structure of the lek, younger and subordinate males associating with more experienced conspecifics. Fights between males are not uncommon on leks, and it seems likely that some level of fighting is necessary in order to maintain the mating hierarchy. The adult males displace immature males from the central part of the lek, if not from the entire lek. Once the hierarchy is established, aggression is reduced, and females can visit without excessive harassment by unruly males. Recently formed leks tend, therefore, to have fewer males performing more aggression and fewer female visitors, whereas older leks have more males, less aggression, and more female visitors. Females tend to choose to mate with centrally located males, which are older and more dominant, and copulating pairs are thus "protected" from predators by peripheral, subdominant and younger males, which are more exposed to possible predation.

Courting promiscuous males of the polygynous species use their brightly or contrastingly coloured plumage as a means of visually advertising themselves on their display perches. Some of them perform displays that are static and simple or involve simple chases or hopping from limb to limb, while others perform more discrete courtship movements in a highly stereotyped and ritualized sequence. The display perch of some species, exemplified by the vertical stump apex of Victoria's Riflebird, the Black Sicklebill and the Twelve-wired Bird-of-paradise, dictates that males perform a static courtship display or one limited to hopping up and down or over a limited area. A stout horizontal vine stem or tree limb permits a linear hopping or dancing display, as demonstrated by, for example, the Magnificent and Paradise Riflebirds, whereas a large fallen log or the surface of the ground allows semicircular hopping dances, as illustrated by, among others, the Superb Bird-of-paradise. Displays by males of solitary species are not universally different from those of com-

In order to attract females the displaying male ***Victoria's Riflebird*** *uses advertisement calls, which are accompanied by conspicuous wide gaping, to expose the bright yellow mouth. The solitary males are territorial with regard to their traditional display perches, at the tops of broken-off tree or tree-fern stumps, which may be many metres tall. Confined to the apex of the stump, the displays involve a static posture, dance, leg swaying, wing-clapping, wing movements and movements of the pectoral shield, and gaping. Courtship commences with the Circular Wings and Gape Display, shown here, directed at a female, the male turning so that he continuously faces her from the top of his stump.*

[*Ptiloris victoriae*, Atherton Tableland, NE Queensland, Australia. Photo: Clifford & Dawn Frith]

*Each adult male **Black Sicklebill** frequents a home range with singing and display perches on the tops of broken-off vertical tree trunks. The advertisement calls, which vary regionally, are audible over a kilometre away. The display, performed mostly in pre-dawn twilight, involves leg-flexing while leaning to the horizontal, and swaying with erect pectoral fans, flank and tail plumes, and possibly also gaping the bright yellow mouth. The Black Sicklebill will also stretch forwards and sway from side to side, while giving a quiet rattling call.*

[*Epimachus fastosus*, Arfak Mountains, New Guinea. Photo: Richard Kirby/ naturepl.com]

munally displaying males, but many of the former do clearly employ more static displays. Unique to true lekking species are "convergence" displays, in which dispersed males quickly and noisily return to, or converge upon, their lek perches at the approach of a female or females.

Courtship display is more complex among the more ornately plumed groups of paradisaeids. The elaborate nuptial plumage characters of adult males are specifically presented to females in a stereotyped manner during courtship. Thus, astrapias limb-hop, fly, and hang from perches in ways that best emphasize the long tail of these species; parotias raise the flank plumes to form a skirt, and erect the occipital and nuchal plumes; the King of Saxony Bird-of-paradise manipulates the occipital plumes, raises a mantle cape, and emphasizes its contrastingly pale wing patches by vibrating its wings; the riflebirds fully open the highly modifed wings; the Superb Bird-of-paradise raises an enormous nuchal cape and breast shield; and the sicklebills erect pectoral fans, raise the flank plumes, and fan the long tail. For every plume form there is a posturing and/or a movement to present it at its best. A diversity of species within the family uses the wings conspicuously in courtship, while others do not. Courting King and Standardwing Birds-of-paradise, along with most *Paradisaea*

*The male **Buff-tailed Sicklebill** defends a large, exclusive foraging territory around his court throughout the year. One male used a site of around 14 ha, with an average distance of 450 m from his display area to those of five adjacent males, for at least four years in succession. The courts include several perching sites, the males descending to the saplings below to court females. At the beginning of courtship, the male suddenly leans backwards to about 50 degrees, giving a convulsive jerk to spread his flank plumes into a perfect disk around the body, while opening his bill. The upper pectoral fan-plumes are held so that they become contiguous with the flank fan-plumes.*

[*Drepanornis albertisi*, Crater Mountain, EC New Guinea. Photo: Tim Laman]

*Little is known of the courtship behaviour of the **Crested Bird-of-paradise**, or indeed of any of the three cnemophilines. These species are polygynous. The male Crested Bird-of-paradise, presumed to be solitary, attends traditional advertisement-singing perches. One bird studied appeared to patrol a territory about 200 m in diameter, although territoriality in this species remains unconfirmed.*

[*Cnemophilus macgregorii*, Mount Hagen, EC New Guinea. Photo: Otto Plantema]

species, partly or fully open the wings in a motionless pose, and also flutter or flay them and/or beat their carpal joints together.

The brilliant flank plumes of adult males of the Twelve-wired Bird-of-paradise and the *Paradisaea* species are made more conspicuous by the raising of the wings, and in the case of lekking *Paradisaea* males this is followed by a static pose with the plumes raised and the head deeply lowered. During this communally static display of competing males, the females have the opportunity to inspect and compare their size and plumage while all males hold the same posture. This situation is developed one step further by lekking Emperor Bird-of-paradise males, which hang completely inverted, and motionless, from their perches. The solitary-displaying male Blue Bird-of-paradise similarly hangs upside-down, but with the wings tightly closed, as opposed to the open and raised wings of its lekking close relatives. In their inverted courtship postures, the males of the two last-mentioned species present plumage patterns of the abdomen that thereby become specifically visible to their female audience.

Leg-flexing is incorporated into many courtship displays, causing a statically perched or standing bird's body to rise and fall, or resulting in the individual leaping vertically up and down, and in some cases causing it to sway and/or rotate to one side or from side to side. Courting male King Birds-of-paradise invert themselves from perches in a remarkable manner that may involve an unusual form of leg-flexing. Not only do males hang suspended, but they also hold the much elongated body rigid, with the plumage tightly sleeked, while swinging rapidly from side to side like a pendulum.

Elaborate and vigorous use of the wings by courting riflebirds has resulted in remarkable modifications of the wing and component feather shape and texture, which produce loud and characteristic noises during certain stages of the display. During its courtship dance, the adult male Superb Bird-of-paradise's wings are rapidly flicked open and closed to produce a sharp loud clicking. Males of other solitary-displaying promiscuous males do not typically use their wings in courtship, and this general pattern is exemplified by the Blue Bird-of-paradise.

Other singular characters specifically presented by courting adult males include the pectoral fans of the sicklebills and the King Bird-of-paradise, the pale primaries of the Standardwing Bird-of-paradise, and the flank-plume wires and bare thighs of the Twelve-wired Bird-of-paradise. The tail is used in limited ways by courting males. The sicklebills and Wahnes's Parotia (*Parotia wahnesi*) have a graduated tail, which they repeatedly fan; with the longer-tailed Western and Wahnes's Parotias, the tail is, perforce, held to one side during terrestrial dancing movements. In the case of courting riflebirds, Superb Birds-of-paradise and all three sickletails, the tail is conspicuously cocked, and typical *Paradisaea* species, unusually, hold the elongated undertail-coverts well away from the tail.

Males of several paradisaeids possessing a brightly coloured mouth open the bill widely so as to present this signal in courtship, and, of course, they expose it when calling. Advertisement and courtship gaping is typical of adult male Loria's Bird-of-

*Display-flights appear to be rare within this family. Known exceptions include the **Ribbon-tailed Astrapia**. The long white central rectrices of the flying adult male can be seen from considerable distances. As well as drawing attention to itself with its white ribbons, the displaying male Ribbon-tailed Astrapia produces significantly louder wing noise than in normal flight. One or more male Ribbon-tailed Astrapias will jump back and forth between tree branches, their tail ribbons held up and arched, and their wings drooped. This is apparently lekking behaviour, although for this genus lekking has only been confirmed in Stephanie's Astrapia* (Astrapia stephaniae).

[*Astrapia mayeri*, Mount Hagen, EC New Guinea. Photo: Phil Gregory]

*The male **King of Saxony Bird-of-paradise** is assumed to be solitary, although there are unconfirmed reports suggestive of exploded leks. Courtship starts with singing from traditional perches, often beneath the foliage of emergent trees in the forest canopy, accompanied by open-bill gaping, and waving of the extraordinarily elongated occipital flag plumes. These plumes, which emerge from ear-tufts of elongate feathers, are up to 50 cm long—more than twice the length of the bird—and consist of a bare central feather shaft, with 40–50 plastic-looking "flags" decorating the outer side only. The upper surface of each flag is an enamelled-looking blue, and the underside dark brown. At a female's approach, the male drops into the understorey to a traditionally used vine 2–5 m above the ground. He perches up to 50 cm below the female, and emits a continuous hissing or whirring subsong, sometimes with gaping. In what is called the Understorey Bouncing Display, he repeatedly pumps or flexes his legs to bounce up and down, with the mantle cape and the breast shield erect, and the occipital plumes held over his back. The female is bounced about by the undulations of the vine. The occipital plumes are mostly held out horizontally behind him, swaying up and down as he bounces, but occasionally he brings them widely apart to a position in front of his head, and then back again. During a final, stiffly swirling display in which the occipital plumes are raised to about 45°, brought around the sides of the head and projected forward, the male progressively approaches the female, and copulation follows.*

[*Pteridophora alberti*, Mount Hagen, EC New Guinea. Photos: Tim Laman]

On Halmahera, leks of the ***Standardwing Bird-of-paradise*** *typically consist of 5–7 adult males, but 30–40 birds have been reported. The display involves limb hopping, with static postures, and flight displays with movements of the wings, pectoral shield and wing standards. The perch displays are like those of* Paradisaea, *but the Aerial Display is unique. This involves an "explosive" vertical leap from extended legs, and a nearly vertical ascent flight. At the peak of the flight, the wings are held fully extended and the bill turned downwards, then the birds "float" down while rapidly vibrating the conspicuously white primaries. Males perform this display one after another, sometimes in immediate succession.*

[*Semioptera wallacii*, Halmahera, Moluccas. Photo: Tim Laman]

paradise, and this species' conspicuous whitish gape-flanges may also function to enhance its display. Adult males of all riflebirds and the larger two of the sicklebills have small but visible gape-flanges that are as bright yellow as is the mouth of these species. Parotias, the Standardwing Bird-of-paradise and the members of the genus *Paradisaea* appear not to gape in display.

As the bright yellow legs and feet of the Standardwing Bird-of-paradise, the deep coral-pink ones of the Twelve-wired Bird-of-paradise and the blue ones of the three sickletails, as well as the bright blue bare head skin of Wilson's Bird-of-paradise, are brighter in colour on the males than on the females, this sexual difference may relate to courtship display. The Twelve-wired Bird-of-paradise has in addition, and uniquely within the family, pigmented bare thigh skin, which also features in display. Adult males of this species perform a tactile courtship display in which they brush their recurved flank-plume wires across the face of females. This fact may provide a clue to a possible function of similarly bare plume shafts of the central pair of rectrices of most *Paradisaea* species, although there appears to have been no remark on or discussion of such a potential use of this plumage feature.

Clearly, the polygynous birds-of-paradise include some of the most striking examples of extreme sexual dimorphism, such extremes apparently being related to the degree of reproductive competition among males, as reflected by the mating system concerned, which involves a display court or lek. This is emphasized not only by several male physical features, including size, coloration, ornate nuptial plumes and vocalizations (see Morphological Aspects and Voice), but also by sexual differences in reproduction-related behaviour, namely mate selection, competition for mates, nesting, and care of the offspring. Their elaborate male plumages are, therefore, reflected in highly complex courtship displays that involve both their extraordinary feather adornments and their elaborate dance and body movements. In the present work, limited available space prohibits detailed descriptions of all known displays of the Paradisaeidae. The following paragraphs provide what is a broad summary, but, as the main features tend to be fundamentally similar for all species within a genus, the courtship display of the best-known species of each is detailed, unless those of some congeneric species are extremely dissimilar. Displays of the three cnemophilines, the monotypic genus *Lycocorax* and the two *Paradigalla* are excluded, because little is known about the behaviour of these six species.

During the communal courtship display of Stephanie's Astrapia, the adult males erect the modified head and breast feathering. In low-intensity display, they hop between perches on the same level, with the body near-vertical and the tail swung forwards in an inverted "V" beneath each perch; a flicking sound is produced. In high-intensity display, males hop nine or ten times between two perches, the tail streaming behind, rather than swinging below the perch; the body is held horizontal, with the shoulders hunched and the bill pointed slightly upwards. Sometimes the wings are lifted, as though being stretched, so that the primaries are at right angles to the body, and the head is held downwards in the shape of a crook.

Whether the courtship of the Huon Astrapia (*Astrapia rothschildi*) is solitary or communal has not been confirmed, but it is known to include both low-intensity and high-intensity displays. During a silent low-intensity display, a male perches upright, with the slightly spread tail pushed forwards beyond the perpendicular and the breast feathering erected; the tail is sometimes rapidly and repeatedly fanned. In high-intensity display, he drops backwards under his perch, so that he is at right angles to it, with his body held almost horizontal but its anterior portion slightly lower than the posterior one, and with the head and neck turned upwards at one extremity and the tail upturned at the other. In this inverted posture, his elaborated plumage is again raised and expanded and the wings pressed tightly against the body, and his back feathers are expanded to cover the wings partly; the tail is held upright and first widely expanded, but then rapidly opened and closed. Males in the inverted position may also sway gently from side to side.

The solitary court-based courtship of Lawes's Parotia begins with a Bounce Display on a perch, followed by four terrestrial displays elements. The male, perched above his court as a female approaches, may bounce on his perch, sometimes reversing direction, while flicking his wings. Terrestrial courtship starts with the male clearing court debris at an increasingly rapid rate, his movements becoming more ritualized until he lowers his bill, but does not remove anything; he may adopt an Upright Sleeked Pose during court-clearing, but not immediately prior to further display. Suddenly, he briefly performs an Initial Display Bow as he brings the black frontal crest feathers forwards and above the

The polygynous and solitary adult male ***Twelve-wired Bird-of-paradise*** *displays at traditional perches, typically one or more adjacent vertical, leafless, often dead tree stumps protruding from the forest canopy. The perches are defended from other males; three vocal males mapped at two sites in eastern New Guinea were at a mean nearest-neighbour distance of 730 m. The display includes bill-fencing with the female, and the unique Wire-wipe Display, in which the male swipes the female across the face with his flank wires. The male's advertisement calls are accompanied by the raising of the open wings to expose his yellow flanks. When a female lands on his vertical display stump, the male initially erects various plumes as he approaches her. He pecks at her to entice her to perch beneath him, then turns his bill downwards to parry at her upward-pointing bill, and pursues her with a jerky gait. The male may perform the Wire-wipe Display as the female clings to the side of the perch beneath him. He stops pecking her, turns himself head uppermost, and performs slow body-swaying movements by hopping to alternate his foot positions. The body-swaying presents his yellow flank plumes, and causes the twelve flank-plume wires to brush across alternate sides of the female's face, neck or breast. He watches the female from over his shoulder as he directs his flank wires to best effect. At some stage, the female flies up over the male on to the perch apex, at which the male turns to face her, bill uppermost, and hops up to continue bill-fencing with her. He pulsates his breast shield rhythmically, and conspicuously exposes his bare pink thighs. Copulation may take place after a brief pursuit, or after many pursuits up and down the perch, with or without one or more Wire-wipe Displays.*

[*Seleucidis melanoleucus*, Karawari River, New Guinea. Photo: Tim Laman]

narial tufts. From this, he flicks his wings slightly out from the body to free his flank plumes, and stretches his body fully upwards on extended legs as his "skirt" is raised and spread and his occipital plumes raised, separated and brought above his head to project forwards while he shakes his head from side to side. Continuing to shake his head, he commences his Ballerina Pose dance from this point on the court, referred to as "point one". He moves sideways, with minute mincing steps, in a semi-circle, while rotating and bowing slightly to face point one, as he dances backwards to stop about 0·5 m away at "point two", and now facing point one; he pauses momentarily, but continuously shakes his head so as to wave his occipital plumes about. He then dances backwards to start a Back–forward Dance phase consisting of stepping backwards from point two to a position less than 0·5 m directly behind ("point three"), and then immediately forwards to point two again; he repeats this back–forward dance twice more in rapid succession. During the backward steps he holds the front of his "skirt" lowered, as in a curtsey, and then raises it to a level parallel to the ground during the forward steps; the occipital plumes remain forward-projecting throughout. Back at point two, the male then enters a brief stationary phase by crouching, bringing his skirt closer to the ground, and remaining momentarily motionless while bringing his occipital plumes upwards and backwards to nearly or just beyond the vertical, and then immediately forwards and downwards to an angle of 45°, as he draws himself stiffly upright and freezes in this posture. Suddenly, he crouches again, snapping his head directly downwards several times as he flicks his breast shield outwards and upwards so that it flashes an iridescent colour. Remaining crouched, he then bobs his head rapidly three or four times, first to one side and then to the other; the bill is held pointing forwards, and at the low point of each bob the head is central and the breast shield flicks out and upwards. This bobbing suddenly stops and, after a brief pause, the male Lawes's Parotia draws himself erect into a momentarily frozen posture as he brings his gathered occipital plumes around and backwards to a position over his back and then immediately forwards again, to just forward of vertical, and holds them widely separated. He then crouches again and pumps his head and neck vigorously up and down two to four times, during which the separated "flags" remain almost vertical and the frontal crest projects forwards over the narial tufts and bill. As his head reaches its lowest point, the breast shield is conspicuously but rapidly flicked upwards and outwards at its lower edge, this rapid movement resulting in flashing iridescent colours. The complete performance always ends, after the final head-pumping, with the male suddenly lowering all feathers to their normal positions and flying to a perch above or adjacent to his court, either immediately or after a brief bout of preening or court-clearing. A successful high-intensity display is concluded when the male lunges across its court, with the plumage sleeked and the head thrust forwards and horizontal to the ground, before hopping up on to a court perch to copulate. The complete courtship display of Carola's Parotia was recently described, and was observed to be the most complex of any known avian display.

The solitary courtship of the King of Saxony Bird-of-paradise starts with singing and display in the forest canopy, a male singing and adopting simple postures on traditional perches beneath the foliage of emergent tree perches, accompanied by open-bill gaping and the waving of the extraordinarily elongated occipital flag plumes. At a female's approach, he drops into the understorey to a traditionally used vine or vines about 2–15 m above the ground. He perches on his vine, up to 50 cm below the female, and emits a continuous hissing or whirring subsong, sometimes with gaping. He repeatedly pumps or flexes his legs vigorously to bounce up and down, with the mantle cape and breast shield erect and the occipital plumes held over his back, in the Understorey Bouncing display; the female being bounced about by the undulations of the vine. His occipital plumes are mostly held out behind him, roughly parallel to the ground, swaying up and down as he bounces, but occasionally he brings them widely apart to a position in front of his head and then back again. The female may hop up her perch a little, which causes the male to stop his bouncing, but not his hissing, and to hold his closed wings slightly away from the body and rapidly tremble them while holding his head low, the bill directed at the female, and the occipital plumes just above his back. If a female approaches again, he continues the Understorey Bouncing display. At some point he starts, initially slowly, to rotate his upper body stiffly and, simultaneously, to waggle his increasingly upright head and neck from side to side; he erects his mantle cape, breast shield and head feathering, and raises the occipital plumes to an angle of about 45° and holds them widely apart, only to bring them around on each side of the

Six of the seven Paradisaea *species display communally on leks, but the male* ***Blue Bird-of-paradise*** *is solitary. His displays are performed on a slim branch, or bamboo, grass or vine stem, within 1–3 m of the forest floor, and with foliage directly above. The display involves only one of the three fundamental phases recorded for the other* Paradisaea *species. The perched male lowers himself backwards to hang upside-down, and spreads his flank plumes, with the wings held closed. He looks upwards and starts to call, jerking his head and moving his plumes while his central tail ribbons hang down on each side. His black central abdominal patch becomes oval and expands as he moves his body from the hips.*

[*Paradisaea rudolphi margaritae*, EC New Guinea. Photo: Brian J. Coates]

In the genus Paradisaea, *the communal courtship of lekking males of several species, including the* ***Lesser Bird-of-paradise****, involves three fundamental phases: the Convergence Display; the Static Display; and the Copulatory Sequence. In the Convergence Display, which is unique to lekking species, the dispersed males quickly and noisily return to their lek perches at the approach of a female or females. In the Static Display, the brilliant flank plumes are made more conspicuous by the raising of the wings, followed by a static pose with the plumes raised and the head deeply lowered. While all males hold the same posture, the females have the opportunity to inspect and compare their size and plumage. Up to twelve adult male Lesser Birds-of-paradise may be found in a single lek tree, but most copulations are performed by centrally located males. Strongly skewed mating, whereby a few males perform the vast majority of a species' matings in a season, is documented both for this species and for Raggiana Bird-of-paradise and also, to a lesser extent, for Lawes's Parotia* (Parotia lawesii). *When the mating process diverges from the more random pairing of individuals and includes only a small proportion of the males in the population, there is a significant impact on sexual selection and sexual dimorphism, with a rapid selection of traits exhibited by those males favoured by females.*

[*Paradisaea minor*. Photo: Brian J. Coates]

*The leks of the **Raggiana Bird-of-paradise**, shown here in the Static Display, are located in the upper branches of a canopy tree in the forest interior, or a forest remnant. Occasionally a lek may extend to more than one tree. The lek may hold as many as ten adult males, and may also be shared with Greater Birds-of-paradise* (Paradisaea apoda). *Lek sites may be used for many years in this last species, for more than 20 years in the Raggiana Bird-of-paradise, and possibly up to a century in the Lesser Bird-of-paradise* (P. minor). *Taking five to seven years to reach maturity, these birds live a relatively long time; several species exceed 15 years in the wild.*

head and finally to project them forward of and above him. He hops, progressively more quickly, up the vertical vine in this stiffly swirling display, and mounts the female for copulation.

During the solitary courtship of the Magnificent Riflebird in north-east Australia, a male, upon sighting a female, initially becomes stiffly sleeked and agitated, sometimes gaping to expose the yellow interior of his mouth. Stretching his head and bill in her direction, he makes small, abrupt side-to-side hops as he sharply flicks his wings and runs his bill down the underside of a wing. As the female approaches more closely, he adopts a sleeked upright bill-up posture, his breast towards her, while sharply jerking his body and/or wings and making his breast shield pulsate. Then, his wings are suddenly outstretched on each side of the body, with a sharp loud rustling sound, as his upward-pointed neck and bill are rhythmically swung back and forth at increasing speed between his wings, which may almost touch each other above his head to form a disc with a central hole. The displaying male raises and lowers himself, at times with a side-to-side rocking motion, and raises and lowers his wings at increasing speed, which produces a loud rustling sound; he cocks his tail to about the horizontal. In this posture he may hop along the perch for a few metres, using a deeply bouncing action, towards and sometimes also backwards away from a female on his perch. As well as facing her, he may also hop along sideways, the wings in alignment with his perch.

The solitary courtship of a male Victoria's Riflebird commences with a Circular Wings and Gape Display directed at a female, the male turning so that he continuously faces her atop his tree stump and accompanying his advertisement calls with wide bill-gaping to expose his yellow mouth. At high intensity the wings meet, or even overlap, above the male's head and are held rigidly still as his mouth gapes, while his tail is cocked to or just above horizontal and his abdomen feathering is raised; now, the only movement involves him in repeatedly, raising and lowering himself slowly and rhythmically on his legs, or turning to follow the moving female, and he does not give any call. When a female arrives on the male's display stump, he initially greets her briefly by leaning back and away in Circular Wings Display, his head and bill hidden behind the leading edge of one wing, after which he holds his raised wings toward the female, their concavity forming a shallow "dish". He then commences the Alternate Wings Clap by sharply raising and fully extending one wing towards the female and slightly closing and lowering the other, hiding his upward-pointing bill behind the leading edge of the raised wing; during this he extends his right leg, to raise that side of his body, while lowering his left. He then suddenly raises his left wing to hit the right one above his head with a thud, and instantaneously swings his upright head and bill across to conceal them behind its leading edge, simultaneously half-closing and lowering his right wing and extending his right leg while lowering his left. This sequence is then repeated numerous times. Display intensifies as the tempo of the male's wing and head movements and associated body-swaying and body-twisting increases until his movements become amazingly rapid; the throat shield appears as a bright shining green or blue vertical line shot with white highlights. He leans progressively towards the female, twisting each wing more and more with each body sway so that they become more horizontal, as does his swinging head. If a female holds her ground, the male advances and adjusts his violently rapid Alternate Wings Clap so that the concave primaries of his wings almost beat the female, which is now "embraced" by each wing alternately. A receptive female rapidly flutters her wings, whereafter the male makes his last sway more extensive so as to hop on to her and copulate.

Initial display activity of the solitary-courting Superb Bird-of-paradise starts when the male adopts a crouched posture with the breast shield sleeked tightly, the cape down against the back, the wings and tail held normally, the head pointed upwards with the eyes fixed on the female, and the narial tufts projecting forwards. This is followed by sudden and repeated upward and outward extension of the breast shield, interspersed with which is a cape-flicking action, whereby the male flicks the closed cape forwards above and over the head with an exaggerated downward movement of the head, thereby presenting the crown to the female. This "flashing" of the breast shield and cape-flicking increase in tempo, bouts of each alternating while the wings and tail retain their normal positions; the erected forecrown feathering reflects white light, and the male may occasionally gape to expose his pale mouth. In high-intensity display, the male thrusts his expanded breast shield forwards, erects the narial tufts, and flicks the cape forwards and spreads it laterally to form a complete concave semi-circle over his head and down each side to below the breast shield. Black cape feathers extend around and inwards to meet the body feathers below the lower breast shield,

The Paradisaea *species have their own variations on the three fundamental display phases, involving additional postures and movements. One of the more complex courtship displays is that of the* ***Greater Bird-of-paradise****. The Convergence Display of this species involves an upright Wing Pose, which begins with one or more males giving rapid "wauk" calls on their lek. The male extends and holds his wings in a rigid position in front of his body for a few seconds, and holds his flank plumes erect over his back, tucks his tail forwards under the perch, and orientates his body perpendicular to the perch. In the Pump Display, often given as a female visitor arrives on the lek, the male's body is lowered and turned almost in alignment with his perch, the wings extended and cupped around it, the flank plumes erected almost vertically, and the head and bill pointed down. In this pose he hops along the perch, bouncing up and down, his vertical motion exaggerated by leg-flexing, and his tail moving rapidly sideways with each bounce. In calls given during the Pump Display, the rapidly repeated "wauk" notes are often run together, as "wa-wa-wa-wa". The Pump phase may be performed prior to the Wing Pose, as the males dash about the lek perches. At the end of the Pump, males perform the Static Display with a Bow, by tipping the body well forwards and down so that the head is below the perch and the back humped; the wings held out and cupped down around the limb; the tail brought forwards and under the limb; and the flank plumes held erect over the back. Display often ends at this point, the males making a few rapid bill-wipes, rising up, and shaking their wings as they lower the flank plumes.*

[*Paradisaea apoda apoda*, Aru Islands, Indonesia. Photos: Loïc Degen]

A summary of breeding seasonality indicates some broad patterns. More breeding occurs during August–January than February–July. But combining various pieces of evidence of breeding for an extensively distributed species can result in the perception of a misleadingly long nesting season, because it includes populations that follow differing cycles according to local conditions, such as peak availability of arthropods and fruit. The ***Red Bird-of-paradise*** *has a very small total range. The males display at least during July and September. On Waigeo, a lek in one gigantic tree in a small forest clearing was attended by up to ten adult males, which displayed on high, defoliated limbs, usually after dawn. The males are most vocal in early mornings and late afternoons*

[*Paradisaea rubra*. Photo: Brian J. Coates]

thus forming a complete, if irregular, ellipse of black relieved only by the iridescent breast shield. The male's eyes can only just be seen below the lower edge of two conspicuous white spots, these being created by light refracted by the elevated forecrown feathers, the black narial tufts and bill bisecting these to form the two white spots; the tail is cocked at about 35–45° and the mouth is closed. In this posture, the male proceeds to dance in short, sharp, deeply bouncing hops around the female, each hop accompanied by an abrupt double flick or flutter of the briefly partly opened wings as the tail is sharply raised, these wing movements causing ticking or clicking sounds.

Courtship by the male Brown Sicklebill involves three display phases. In the Pumping phase, the bird adopts an upright position, with the breast feathers spread, and the tail repeatedly jerked wide open and then shut while the closed wings are moved up and down along the sides, their upward movements coinciding with the tail-opening. In Leaning, the male leans backwards to about 45° and expands his breast feathers, while extending the short flank plumes outwards to form a fringe around the sides; he gives a rattling call and turns the breast upwards, the feet retaining their original position. The breast feathers are now fully spread, making the body look flattened. The modified upper breast feathers are erected around the throat and head so closely that the iridescent black of the face and throat are much enhanced, the beak being held closed; the wings are closely folded, and the tail is slightly spread but not moved; the long pectoral shields are folded beneath the contour plumage, playing no part in this display. The male then leans to one side to rotate the body so that the breast is directed upwards, the breast feathers spread as widely as possible, concealing the tightly closed wings, and the tail partly fanned. Now the third display phase, the Upright, is suddenly started, as the male, without calling, draws its body erect, with the tail slightly opened and the wings still tightly closed. The breast feathers, encircled by the decorative flank plumes, are widely spread, the pectoral shields thrown upwards to extend above the head and wrapping it closely, and the bill widely opened to expose the bright yellow mouth-lining, this position usually being rigidly held for about five seconds. Sometimes the male enhances this display by rotating his body in a series of short jerks, pausing for several seconds between each one, until he is at right angles to the perch, and then jerking slowly in the opposite direction until he has again come to a right angle with the perch and is facing the other way; this may be continued for 2–5 minutes, with no movement of the tail, wings or ornamental plumes, and with no sound uttered.

At the beginning of the solitary courtship of the Buff-tailed Sicklebill, the male suddenly leans backwards to about 50°, giving a convulsive jerk to spread his flank plumes into a perfect disk around the body, and opening his bill for approximately 25 seconds. He holds the upper pectoral fan-plumes behind the head and sloping down across to the front of the body, where they become contiguous with the flank fan-plumes. Returning to upright, he continues singing for several minutes, before dropping back until entirely inverted and then spreading all plumes while vibrating his body for about 30 seconds and perhaps giving a display song.

The solitary court-based courtship of Magnificent Birds-of-paradise involves four display phases. In Back Display, the male turns upside-down on his vertical display perch, with the tail uppermost and the head lifted slightly upwards; he holds this position briefly before he turns the head uppermost. In Breast Display, the breast-shield plumage appears to inflate and deflate as it is raised and lowered, the upper margins of it rising on each side of the head, and undulations of breast feathers send iridescent shimmers across it; iridescent spots in front of the eyes at times become conspicuous. The silent Cape Display is performed if a female moves closer, whereupon the male leans, to as far as horizontal, with the extended neck and bill directed at the female, the cape erect and fully fanned, and the breast shield flattened and elongated, while the tail wires remain in the normal position. This display posture is often maintained by the slightly trembling male for many seconds as the female hops closer down the sapling, and when she is within about 30 cm he may suddenly perform the Dancing Display. In this, he pulls his head and neck

back into his body, puffs and expands most of the plumage, including the pulsating breast shield, lowers his fanned cape, and cocks his tail over the back to present the iridescent upper surface of the central tail wires to the female. He then jerks his head from side to side, opening and closing the bill to expose his mouth coloration, and quivers his tail from side to side as he dances forwards up and then backwards down the sapling with short jerky movements of the body and head that emphasize the yellow cape; during this performance, he emits a peculiar low, rhythmic, hard, clicking, buzzing song with higher and lower notes.

The courtship of the King Bird-of-paradise, which is performed solitarily or enacted co-operatively in twos, involves seven display phases, focusing mainly either on open and vibrating wings or on movements of the pectoral fans and tail wires. A male begins a sequence with the upright Wing-cupping Phase, a brief partial spreading and vibrating of the cupped wings; this is followed by the Dancing Display, in which he holds his body parallel to the perch, the plumage fluffed, and squats low on the perch, spreading and raising his pectoral fans, and cocking his tail so that the central wires reach above his head. He then dances, vibrating his body and shaking his tail wires, while singing a soft song. This display is given when the male is facing away from any female present. The pectoral plumes may be fanned, sometimes to extend higher than the head, and the male may step along his branch to lunge at and strike it with his beak. This Dancing Display lasts for many seconds to several minutes, before he turns around and, still singing in the same pose, briefly performs the Tail Swinging Phase, in which he swings his tail widely from side to side. This typically ends a display, but, if not, the male follows it by spreading both wings out and forwards, with his body parallel to the branch, in the Horizontal Open Wings Display; his wings vibrating, he briefly rocks silently from side to side several times, before suddenly dropping to cling below his perch, in the same pose, and repeating the display. In this latter, the Inverted Phase, he holds his bill open and turns the head from side to side, this inverted display lasting just a few seconds before he closes his wings and tightly sleeks the plumage to hang suspended. He peers around him and then swings several times from side to side like a pendulum, at a steadily increasing tempo, in a brief and silent Pendulum Display. He ends his display by

During the Static Display of the ***Emperor Bird-of-paradise****, the lekking males hang completely inverted and motionless from their perches, for inspection and comparison by the females. The male may perch still and silently upright for a few moments, or suddenly call loudly, before turning under the perch, to hang upside-down with flank plumes expanded, forming a white disc with two central yellow patches. The wings and tail are partly spread, and the head turned upwards. The inverted bird rocks slowly, while twisting from side to side, using his legs as a fulcrum. A female may perch directly above an inverted male to look down at him as he looks up at her. Leks of this species consist of up to six adult males, congregating in one or two adjacent trees within sight of each other. Several males will display synchronously. At one lek, activity was most intense from mid-afternoon, with individuals displaying as low as 3–6 m above ground. The "pop pop" calls of lekking males of this species can be extremely loud, and when delivered rapidly are said to sound like exploding firecrackers. Hybridization of this species with the Lesser* (Paradisaea minor) *and Raggianas* (P. raggiana) *Birds-of-paradise has been recorded. The phenomenon of hybridization within this family is not surprising, given that the promiscuous males of polygynous species show no discrimination in mate choice, but will readily mount almost any female-looking bird that visits their display sites. Presumably, young and naive female birds-of-paradise sometimes mate with males of another species in error, and any female may do so if conspecific mates are not available, as for example, at the geographical or elevational limits of the species' distribution.*

[*Paradisaea guilielmi.* Photos: Brian J. Coates]

*The lek of the **Greater Bird-of-paradise** consists of the larger, exposed horizontal boughs of one or more large spreading trees, immediately beneath the canopy. The lek may contain 15 or more adult males, which defoliate the immediate area of the display perches. Lekking males display both in absence of females and as the females approach the lek. Males in Wing Pose may suddenly turn, bill lowermost, to hop down a perch for a metre or so, and then turn again, bill uppermost, and hop back up to their original position and adopt a static upright Wing Pose, but with the flank plumes erected over the back. This posture is held rigidly, or with only occasional brief wing-fluttering, until the bird again turns, bill lowermost, and hops down the perch again, remaining at the bottom of its descent in inverted pose, with plumes erected in Static Display.*

[*Paradisaea apoda apoda*, Aru Islands, Indonesia. Photo: Loïc Degen]

righting himself atop his perch or by simply dropping down and away from his perch. One copulation followed only an elaborated Dancing Display, the male having his bill open.

The communal courtship of Standardwing Birds-of-paradise involves four display phases. In Convergence Display, one or several males charge about the lek branches, beating their partly opened wings with a rowing-like action and giving rapidly repeated sharp call notes; the breast shield is not utilized and the wing standards are only slightly raised, but this sometimes includes the Wing Pose or, less often, the Wing Standard Display. The Aerial Display is performed by adult males one after another, sometimes in immediate succession. A male, perching upright with the wings closed, and the standards and breast shield relaxed, leans forwards as he stretches his head and neck upwards and opens his breast shield slightly; he calls for 2–4 minutes, with increasing speed and intensity, until leaping vertically upwards by "explosively" extending his legs, and beating his fully open wings in a vertical or nearly vertical ascent flight. At the apex of the flight, he holds his wings fully extended, turns his bill downwards, and "floats" down while rapidly vibrating the conspicuously white primaries, so that they appear as a pale blur at each wingtip. In most descents the tail is closed, but occasionally it is fanned for the latter part of the drop. Males typically return to the perch from which they took off or to an adjacent one. Static Display follows. This consists of the Wing Standard Display, in which the male holds his body rigidly upright and the bill slightly raised as he repeatedly changes the position of the vibrating wings, from only partly opened and slightly lifted out and away from the body, with the carpal joints conspicuously wide apart, to half-open or nearly fully open and with the carpal points held together. The sudden alternating of these two positions causes striking movements of the raised carpal standards. A cracking sound is produced by the sharply clicking mandibles, and a "rowing" motion of the vibrating primaries makes their white tips conspicuous; the crown feathering is raised and lowered, enhancing its iridescent lilac-purple colour, and the upper breast shield is extended so that its two sides meet behind the neck.

Several display phases constitute the solitary courtship of the Twelve-wired Bird-of-paradise. A male initially erects various plumes as he approaches a female that has landed on his vertical display stump; he pecks at her to entice her to perch beneath him, and he then turns the bill downwards to parry at her upward-pointing bill and pursues her in a jerky gait. At some stage, the female flies up over the male on to the perch apex, at which the male turns to face her, bill uppermost, and hops up to her to continue bill-fencing with her. He pulsates his breast shield rhythmically, and conspicuously exposes his pink bare thighs. This scenario may be repeated six or more times, but an additional display phase, the unique Wire-wipe Display, is often performed by the male as the female clings to the side of the perch beneath him. In this, he stops pecking at the female, rotates himself to be aligned head uppermost directly above the female, and performs slow body-swaying movements by hopping so as to alternate his foot positions. During this, he watches the female from over his shoulder as he directs his flank wires to best effect; the body-swaying presents his yellow flank plumes and causes the twelve flank-plume wires to brush across alternate sides of the female's face, neck or breast. Copulation may take place after a brief pursuit or after many pursuits up and down the perch, with or without one or more Wire-wipe Displays. If the female solicits, by flicking or shuddering her outer primaries, the male mounts her to mate.

In the genus *Paradisaea*, the communal courtship of lekking males of the Lesser, Greater, Raggiana, Goldie's and Red Birds-of-paradise involves three fundamental phases, namely the Convergence Display, the Static Display and the Copulatory Sequence. The ritualized Copulatory Sequence remains unknown for lekking Emperor Birds-of-paradise and for solitary-courting Blue Birds-of-paradise, and only the Static Display is recorded for the last-named species. Additional postures and movements are, however, performed by some of these *Paradisaea* species. One of the more complex courtship displays is that of the Greater Bird-of-paradise, which features the above three display phases with some additional postures. The Convergence Display of this species

involves an upright Wing Pose and Pump postures. The upright Wing Pose begins with one or more males giving rapid "wauk" calls on their lek. During this, a male extends and holds his wings in a rigid position in front of his body for a few seconds, and holds his flank plumes erect over the back, tucks his tail forwards under the perch, and orients his body perpendicular to the perch; he may droop or rapidly flap the wings between calling bouts. Males in Wing Pose may suddenly turn, bill lowermost, to hop down a perch for a metre or so, and then turn, bill uppermost, and hop back up to their original point and adopt a static upright Wing Pose, but with the flank plumes erected over the back. This posture is held rigidly, or with only occasional brief wing-fluttering, until suddenly the bird again turns, bill lowermost, and hops down the perch again, remaining at the bottom of its descent in inverted pose, with plumes fully erected in Static Display. In Pump Display, often given as a female visitor arrives on the lek, the male's body is lowered and turned almost in alignment with his perch, the wings extended and cupped around it, the flank plumes erected almost vertically, and the head and bill pointed down; in this pose he hops along the perch, giving the pump call while bouncing up and down, his vertical motion exaggerated by leg-flexing and his tail moved rapidly sideways with each bounce. The Pump phase may be performed prior to the Wing Pose, as males dash about lek perches and/or between these. At the end of the Pump, males perform the Static Display with a Bow, by tipping the body far forwards and down so that the head is below the perch and the back humped, the wings being held out and cupped down around the limb, the tail brought forwards and under the limb, and the flank plumes held erect over the back; the bird may give a "baa" call while in this position. Display often ends at this point, the males making a few rapid bill-wipes, rising up, and shaking their wings as they lower the flank plumes. The Copulatory Sequence dance phase usually starts from the Bow when a female is perched directly above the inverted male, often touching his tail wires. He quickly turns upwards to face her and starts rhythmically bouncing and shufflling back and forth or up and down along the limb, his flexing legs exaggerating the vertical motion. The "click" call is given with the slow and rhythmic movement of this. When immediately beneath or beside the female, he hops or bounces on the spot and claps the female between his open cupped wings as he bills her nape and/or bill while swaying from side to side, all at an increasing tempo, prior to suddenly hopping up to mount and copulate.

During the courtship of the Blue Bird-of-paradise, the male, from a normal perched position, lowers himself backwards so as to hang upside-down and spreads his flank plumes, with the wings held closed. He looks upwards and starts to call, and he jerks his head and moves his plumes while his central tail ribbons hang down on each side. His black central abdominal patch becomes oval and expands as he rhythmically moves his body from the hips. As the display progresses, his eyes close, leaving only slits, and the white patches above and below them become enlarged. If a female is now on his perch, he twists his head and body towards her to direct as much as possible of his nuptial plumage at her; his black abdomen patch may change in shape from a longer oval to a shorter one, or vice versa. If the female holds her ground, he then stiffly draws his body upwards by his legs, and raises it upwards and forwards towards the female as the black abdomen patch becomes more ovate, while his head and bill point directly up the centre of his body, and the central tail ribbons may or may not be rapidly swung side to side. Copulation is achieved when the inverted male suddenly regains a normal upright perching position beside the female, by lifting himself forwards head first, and returning his plumage to the normal position; the female turns away from him, with head held downward, and solicits by flicking her tail several times, before the male mounts her.

Strongly skewed mating, whereby a few males perform the vast majority of a species' matings in a season, is documented for the Lesser and Raggiana Birds-of-paradise and also, to a lesser extent, Lawes's Parotia. When the mating process diverges from the random pairing of individuals and, instead, includes only a small proportion of the males in the population, this has a significant impact on sexual selection and sexual dimorphism. It results in a rapid selection of traits exhibited by those males favoured by females. In the case of the Magnificent Bird-of-paradise, the ratio of court-holding males to females is strongly skewed in favour of females, but the sex ratio across an entire local population is nevertheless 1:1. Thus, the functional sex ratio in such species is skewed as a product of their mating system, largely because of the high proportion of immature males wearing female-like plumage, as found in any population of polygynous, sexually dimorphic bird species.

Major gaps exist in our knowledge of basic bird-of-paradise nesting biology. Nothing is known of the monotypic genus *Loboparadisea*, little is known of the *Manucodia* species, and little information other than nest and egg descriptions is available for the genera *Lycocorax*, *Parotia*, *Epimachus*, *Semioptera* and *Seleucidis*. Moreover, there are no details at all of the breeding of ten species, including some of those longest known to western science, examples being the Arfak Astrapia (*Astrapia nigra*), the Black Sicklebill and Wilson's Bird-of-paradise. For 17 of those species for which some knowledge is available, this is limited to descriptions of nests and eggs. Despite these limitations, however, great advances have been made in the past three decades, in part as a result of studies of breeding captives.

Several interrelated factors are potentially relevant to the nesting ecology of birds-of-paradise. These include their small clutch sizes, the cryptic nature of their nests, potential nest-content predation, the need to provision nestlings efficiently, and the fact that, with most species, only the females attend the nest. Only the manucodes and probably, albeit as yet unconfirmed, the Paradise Crow provide biparental care at the nest. For the remaining, polygnous, species, it is the responsibility of the female alone to build the nest, incubate the eggs, brood the chicks and provision the nestlings until they reach independence.

All members of the family whose nests are known are solitary nesters, and it is unlikely that any paradisaeid species nests gregariously, colonially, or with the involvement of individuals additional to the parents or parent and acting as helpers. The known nests of the cnemophilines are built in relatively exposed terrestrial or low-vegetation sites and are highly cryptic, the moss and fern materials matching the nest-site vegetation. Those of the Paradisaeinae are built in tree branches with the exception of that of the King Bird-of-paradise, a single nest of which was found within a tree crevice. Some riflebirds and the Superb and the

In the genus Paradisaea, *the first indication that an individual is a male is when an annual moult produces central rectrices longer than the other tail feathers. In subsequent moults the young male, like this* ***Greater Bird-of-paradise****, also acquires a densely feathered, darker breast "cushion", and short flank plumes. With each subsequent year the flank plumes are longer, until finally reaching adult proportions. The remarkably long period spent in cryptic female-like plumage may be a response to severe competition among promiscuous males for access to females. It might also reflect an evolutionary strategy that permits young males to approach adult males, to visit their courting sites, and perhaps even to fertilize some of their female visitors.*

[*Paradisaea apoda apoda*, Aru Islands, Indonesia. Photo: Loïc Degen]

*The solitary male **Wilson's Bird-of-paradise** holds a court up to a metre wide, usually in dense forest, and preferably in a small well-lit clearing around a fallen tree or landslide. The male keeps the court clean of litter, and removes leaves from sapling display stems growing within the court. The male initially responds to a female-plumaged visitor with a "frozen" posture on the base of a vertical sapling. The male's display involves static and leaning postures and dance, with movements of the nuchal cape, pectoral shield, head and central rectrices, and gaping to show the bright yellow to green mouth. During the display, the male emits complex, squeaky twitterings in a subsong punctuated with guttural burring notes. Several other postures and movements have been observed, and some elements are similar to those of the congeneric Magnificent Bird-of-paradise* (Cicinnurus magnificus), *but the complete, successful courtship of this species is apparently undocumented. There is no other information on breeding in this species, even though it was one of the first paradisaeids known to science. The contrast between the bright blue bare skin on the male's crown and the darker skin of the female's can clearly be seen here.*

[*Cicinnurus respublica*, Batanta Island, Indonesia. Photo: Tim Laman]

As the female approaches, this male ***Magnificent Bird-of-paradise*** *has begun his Cape Display, leaning to the horizontal, with his cape erect and fully fanned, and his breast shield flattened. The male holds this position, trembling and silent, while the female approaches. Across the large range of this species, displays may be performed throughout the year, but mostly between July and February. The immature male is like the adult female, but with a blackish-brown, rather than pale blue, bill. Older birds in female-type plumage develop narrow, pointed central rectrices which increase in length with each moult, prior to acquiring the wire-like sickles of the adult male. Full adult plumage is not acquired until at least six years old. Females acquire their adult appearance within a year of fledging, and may commence breeding when only a year or two old. As a result of this "heterochrony" (unequal development of the sexes over time), the ratio of court-holding males to females in the Magnificent Bird-of-paradise is strongly skewed in favour of females, even though the sex ratio across an entire local population is 1:1.*

[*Cicinnurus magnificus*, Arfak Mountains, New Guinea. Photo: Tim Laman]

*When a female arrives on the display stump of a male **Victoria's Riflebird**, he greets her by leaning back and away in Circular Wings Display, his head and bill hidden behind the leading edge of one wing, after which he holds his raised wings toward the female, their concavity forming a shallow "dish". He commences the Alternate Wings Clap by raising his left wing to hit the right one above his head with a thud, and swings his upright head and bill across to conceal them behind the wing's leading edge. The sequence is repeated at a rapidly increasing tempo. If a female holds her ground, the male advances and adjusts his rapid Alternate Wings Clap so that the concave primaries almost beat the female, which is now "embraced" by each wing alternately.*

[*Ptiloris victoriae*, Atherton Tableland, NE Queensland, Australia. Photo: Stanley Breeden/ Lochman Transparencies]

Twelve-wired Birds-of-paradise frequently nest in pandanus (*Pandanus*), in palms (Arecaceae) or in plants of similar structure. Most nests of the Trumpet Manucode, the Short-tailed Paradigalla, the Ribbon-tailed Astrapia and Victoria's Riflebird are built in the densely foliaged small crown of a sapling, pandanus or other plant typically growing within a small forest gap having sky, not foliage, directly above. Thus, they are placed out of the way of arboreal pathways for climbing predators.

A nesting association apparently exists between pairs of Trumpet Manucodes and Black Butcherbirds (*Cracticus quoyi*) in rainforests in Cape York Peninsula, in north-east Australia. The assumption is that the manucodes situate their nests adjacent to these pugnacious and predacious butcherbirds, which are efficient nest predators, in order to gain some protective advantage, but this, as well as the manucode's ability to prevent the butcherbirds from preying on its own nest, remains to be demonstrated and studied.

Females of Loria's Bird-of-paradise, the Short-tailed Paradigalla, the Ribbon-tailed Astrapia and the Paradise and Victoria's Riflebirds not uncommonly build a nest upon, immediately adjacent to or near their nest of the previous season or seasons. Thus, some females nest in consecutive years at the same site, which becomes known as a traditional site. This raises the possibility that such females may mate with the same male over several years, and some female Lawes's Parotias have already been found to do so over two seasons. Unfortunately, no detailed observations of the nest-building process of any paradisaeid species have been made.

Nests are constructed in three different forms, being domed, or a suspended shallow open cup, or a supported bulky open cup. Known cnemophiline nests are domed structures of orchid stems with a lush moss and fern exterior, and with a few short sticks haphazardly incorporated into the foundation. Other than this instance of the use of sticks, by a group now considered by many not to be members of the Paradisaeidae (see Systematics), the birds-of-paradise, unlike the bowerbirds, do not incorporate sticks into their nests. There is a clear dichotomy in type of basic nest structure within the paradisaeines. The manucodes construct a sparse, relatively shallow, open cup predominantly of vine tendrils, sometimes including leaves and pieces of rotten wood in the egg-chamber, suspending this in a horizontal forking branch; Paradise Crow nests are similar but bulkier, with numerous dry wood chips between the lining and the outer vine tendrils. In contrast, all other known paradisaeine nests are deep, dense, bulky, entirely stickless open bowl-shaped structures, supported below by vertically forked branches, and are composed of orchid stems, leaves, mosses and ferns. This nest type rarely includes wood debris in the egg-chamber and is remarkably constant across genera.

Female Victoria's and Paradise Riflebirds typically decorate the rim of the nest with sloughed snakeskin, and it is suggested that this may deter some potential predators. Although no direct evidence exists, females Lawes's Parotias may ingest some of the items that the male uses to decorate its terrestrial court, such as chalk, for their mineral and calcium content, and they may also use snakeskin as female riflebirds do.

Bird-of-paradise clutches are typically of one or two eggs and rarely of three eggs, but for most members of the family there are few data on this aspect of reproduction. Clutches containing two eggs are typical of monogamous manucodes, which do, rarely, lay three-egg clutches. A clutch of only one or two eggs is more to be expected in the polygynous species, because, with male emancipation, only the female is available to incubate the eggs and to provision the young; three-egg clutches do, however, occur on rare occasions among some lowland polygynous species, such as the riflebirds. Known clutches of highland species are of a single egg and, while this may reflect colder climates and therefore sparser animal-prey availability, numerous other factors, including latitude, length of daylight, habitat type, diet, body size, parent age, egg size, nest-site and nest type, and social structure of the nesting birds, may influence the evolution of clutch size. Eggs of most multi-egg clutches are laid on consecutive days.

Eggs of paradisaeids are typically elliptical ovate, or a long oval, in shape, the odd one tending towards oblong oval, or elliptical. The few known eggs of the Cnemophilinae are pale pinkish, most markings consisting of reddish-brown fine spotting, predominantly around the larger end. In the Paradisaeinae,

The four phases of the terrestrial courtship of ***Lawes's Parotia*** *start with the male clearing debris from his court with his bill at an ever-increasing rate, his movements becoming more ritualized until he is no longer picking anything up. Suddenly, he performs a brief Initial Display Bow as he brings the black frontal crest feathers forwards and above the narial tufts. He then flicks his wings slightly out from the body to free his flank plumes. He stretches his body fully upwards on extended legs as his "skirt" is raised and spread. His three wire-like occipital plumes are raised, separated and brought above his head to project forwards, while he shakes his head from side to side. He commences his Ballerina Pose dance, moving sideways in a semi-circle, with minute, mincing steps. The male Lawes's Parotia decorates his court with sloughed snakeskin, mammal dung, chalk, fur, feathers and bone. He may steal decorations from neighbouring courts, which in the exploded lekking system found in this species, may be as close as 15 m away, in full view. Neighbouring males disrupt each other's courtship. The decorations are not used in the display, but removed by females throughout the nesting season. The females may ingest some of the decorative items, such as chalk, for their mineral content. They may also decorate the rims of their nests with sloughed snakeskin, as female riflebirds* (Ptiloris) *do. The number and quality of these items may provide information about relative male fitness, in the same way as bower decorations do for the bowerbirds (Ptilonorhynchidae). Some females show fidelity to a particular male, returning to mate with him year after year.*

[*Parotia lawesii*,
New Guinea.
Photo: Günter Ziesler]

manucode eggs vary from whitish and pinkish to buff, variably heavily spotted to blotched with browns to black throughout, but more densely so at the larger end, whereas the buff to beige egg of the Paradise Crow is unique in being more pointed at the small end and is scrawled and scribbled throughout with swirling fine blackish lines or vermiculations. Of the remaining paradisaeine species, paradigalla eggs are like the spotted, rather than blotched, eggs of manucodes, and those of astrapias may be similar but are more usually marked with longer broad blotches, these tending to become more elongated down the egg length. In all other genera the eggs vary in ground colour, but all typically have broad brushstroke-like elongate markings down their length.

Incubation periods have been documented for only some of the members of this family, all of them polygynous species, and these span 14–27 days. Notwithstanding such variables as uniparental versus biparental nestling care, nest type, and diets ranging from exclusively frugivorous, as with *Cnemophilus*, through mixed, to one consisting predominantly of arthropods, a general correlation between increasing altitude and longer incubation periods is apparent. Both sexes of monogamous species are presumed to incubate, but this is confirmed only for the Trumpet Manucode. In all observed polygynous species only the female incubates. Birds species in general typically spend 60–80% of each day in incubating, this being true both of species in which only females incubate and of those in which both sexes do so, and the six paradisaeid species for which relevant information is available fit this pattern.

A striking characteristic of bird-of-paradise hatchlings is that they are naked or have only the sparsest of down, their dorsal skin being already pigmented dark blue-grey to blackish-grey or else becoming so within a few days. On hatching, paradigallas have well-developed facial and mandibular wattles, typical features of the adults. Nestlings and juveniles of the relatively long-billed genera *Ptiloris*, *Seleucidis*, *Epimachus* and *Lophorina* have a shorter, broader and blunter bill that grows longer, narrower and finer as they mature. It is not known if this implies that the young of such species are dependent on the parent for speciality foods for a longer period than are short-billed species.

Nestling periods vary from 14 days to more than 30 days, and they are, as with incubation, generally longer for higher-altitude species than they are for lowland ones. For the few species studied, the nestling growth rate indicates that the eyes first open when the chick is about six days old. At about 8–10 days the contour feathers of *Paradisaea* nestlings just burst from the pin tips, and the primary coverts and primaries burst from pin at about two weeks of age. Growth curves for nestling birds-of-paradise in the wild show that the larger species grow at a fast rate, and also that all such curves are virtually linear over much of their length, except for the downturn just prior to the chicks' departure from the nest. Nestlings regularly lose some weight at this time because of the energetic cost of rapid growth of the tail feathers and flight-feathers.

The few measures of the percentage of daily time that wild-living females spend in brooding a single nestling varies from about 14% to 48%. The Crested Bird-of-paradise, which builds a domed nest, devotes far less time to the brooding of the young, this suggesting that the more cryptic, protective and presumably better-insulated nest enables a parent to be less attentive, notwithstanding a relatively cold habitat.

The rate at which single-nestling broods of polygynous species are fed by the female parent has been recorded for five species, and it, too, varies, from about one to three meals per hour. Of these five paradisaeids, the Crested Bird-of-paradise has by far the highest feeding rate, doubtless a reflection of this species' low-protein nestling diet, which consists exclusively of fruit. A pair of nesting Trumpet Manucodes, observed during four days as it provisioned the brood of two nestlings, made an average of 3·4 feeding visits per hour.

Parents feed their nestlings by regurgitating fruit and/or animal items (see Food and Feeding). The only exception to this is that some species will carry in the bill the last item gathered, this being the first item to be offered to the young, usually in the form of animal prey. In all species for which nest-sanitation behaviour

While males maximize the time at their courts, to attract and mate with as many females as possible, females range more widely, being restricted to a single location only when nesting. Recent research has revealed the courtship of ***Carola's Parotia*** *to be as complex as that of any other avian species, involving 58 distinct elements. The male performs a Hopping-on-the-spot display on a court perch as the females approach. Some courtship elements are similar to those described for Lawes's Parotia* (Parotia lawesii)*, including the Ballerina Display, although some which feature the white area of flank plumes and fine detail of the elaborate head plumage are not found in other adult male pariotias.*

[*Parotia carolae clelandiae*, Crater Mountain, New Guinea. Photo: Tim Laman]

*The courtship of **Goldie's Bird-of-paradise** involves the same three display phases as for other* Paradisaea *species, with additional postures and movements. This is the inverted Static Display. A lek of this species on Fergusson Island, in the D'Entrecasteaux Islands, consisted of four main trees. Eight to ten males used this lek, usually two to a tree, but no more than two females and six unplumed males were seen at any one time. The advertisement calls of lekking males include "wok-wok" or "wark", usually given in the absence of females. A soft "whick-whick" is possibly a male-to-male contact call, but a loud, liquid, ringing version of this is given when a female is on the lek.*

[*Paradisaea decora*, Fergusson Island, New Guinea. Photo: Tim Laman]

has been noted, the parent or parents swallow the nestlings' faeces throughout all or most of the nestling period. Only when the young are near the time when they will leave the nest do their parents carry faeces and seeds away from the nest.

Some parents do perform a distraction display and aggressive nest defence, but documented instances of this are few. During intensive observation of nesting females of Loria's Bird-of-paradise, the Crested Bird-of-paradise, the Short-tailed Paradigalla, the Ribbon-tailed Astrapia and Victoria's Riflebird, instances of mobbing, distraction or other active anti-predator behaviour were rarely seen. Incubating or brooding females will chase away conspecifics that venture into even the more general nest area, and an anti-predator freezing posture has been recorded for Victoria's Riflebird and the Raggiana Bird-of-paradise, females of which simply freeze on a perch at the sight or sound of a potential predator. Clearly, some birds-of-paradise do, however, perform a distraction display and aggressive nest defence, as exemplified by a captive female King Bird-of-paradise that both vigorously distracted and physically attacked its human owner while nesting, but not at other times.

Little is known about the care of dependent young once they have left the nest. A female Short-tailed Paradigalla was seen to

*The Copulatory Sequence dance phase of the **Greater Bird-of-paradise** usually follows the Wing Pose–Pump–Bow sequence. It starts when a female is perched directly above the inverted male, often touching his tail wires. He quickly turns upwards to face her, and starts slowly and rhythmically bouncing and shuffling back and forth along the limb, his flexing legs exaggerating the vertical motion. During the dance display, the male Greater Bird-of-paradise produces a slow rhythmic "click" in time with his movements, and sometimes also a faint nasal "bonk" as the wings are raised for a dance step.*

[*Paradisaea apoda apoda*, Aru Islands, Indonesia. Photo: Loïc Degen]

*A successful high-intensity display is concluded when the male **Lawes's Parotia** lunges across his court, with plumage sleeked and head thrust forwards and horizontal to the ground, before hopping up on to a court perch to copulate. The courtship of the congeneric Wahnes's Parotia* (Parotia wahnesi) *is highly complex, involving eleven diagnosable behaviour patterns, including some of up to 46 elements, within a highly structured framework. The basic display pattern is similar to that of Lawes's Parotia. It differs mainly in that little court-clearing precedes it; there is no crest to extend forwards to cover the narial tuft; the occipital plumes are thrown forwards before the bird stands erect; and it uses its tail and wings when crouched.*

[*Parotia lawesii*, New Guinea. Photo: Günter Ziesler]

feed an immature of her own size, but with duller plumage and less pure yellow facial wattles, for 108 days, but she apparently ceased doing so a week later. A young Victoria's Riflebird was fed by a female 74 days after leaving the nest. In captivity, young of the Greater Bird-of-paradise began to feed independently of the adults at 29–32 days.

There is one documented case of a Common Koel (*Eudynamys scolopacea*) laying an egg in an active nest of Victoria's Riflebird. This appears, however, to be the only known instance of nest parasitism being suffered by any member of the bird-of-paradise family.

Movements

It has been claimed that Trumpet Manucodes migrate between south-eastern New Guinea and north-eastern Australia, but there is no evidence of this and indeed different races occupy the two areas, so the claim is clearly without foundation. Most species do, in fact, appear to be sedentary forest-dwellers, with permanently fixed home ranges. The species that are primarily insectivorous have small home ranges which seem, in the case of adult males, to be exclusive foraging areas, whereas the mainly frugivorous ones appear to occupy larger, non-exclusive home ranges.

*After a male **Victoria's Riflebird** has begun to "embrace" a female during the latter stages of his Alternate Wings Clap, a receptive female will rapidly flutter her wings, whereupon the male makes his last sway more extensive, so as to hop on to her and copulate. Detail of the sequence of the display prior to mating in the Paradise Riflebird* (Ptiloris paradiseus) *is lacking, but the courtship is much as for Victoria's Riflebird. In the Magnificent Riflebird* (P. magnificus), *the male displays with initially static sleeked postures, then raises his fully opened wings high to each side, swinging his head and neck between them.*

[*Ptiloris victoriae*, Mount Lewis, NE Queensland, Australia. Photo: Hans & Judy Beste/ Lochman Transparencies]

When the Copulatory Sequence dance has brought him to a position immediately beneath or beside the female, the male ***Greater Bird-of-paradise*** *hops or bounces on the spot and claps the female between his open cupped wings. He strokes her nape, and sometimes also her bill, with his bill, while swaying from side to side, all at an increasing tempo, prior to suddenly hopping up to mount and copulate. Females tend to choose to mate with centrally located males, which are older and more dominant. Copulating pairs are thus "protected" by peripheral, subdominant and younger males, which are more exposed to predation. As well as providing females with the opportunity to choose the "best" male, communal display systems promote competitive interaction among males. Older, more dominant males tend to control the social structure of the lek, and displace immature males from the central part, if not from the entire lek. Once the hierarchy is established, aggression is reduced, and females can visit without excessive harassment by unruly males. More males are found at established than at new leks, and younger and subordinate males gain the benefit of associating with more experienced conspecifics, as well as occasional opportunities to mate with females attracted by the dominant birds.*

[*Paradisaea apoda apoda*, Aru Islands, Indonesia. Photos: Loïc Degen]

The five sexually monomorphic manucode species and the Paradise Crow (Lycocorax pyrrhopterus) *are known or presumed to reproduce as socially monogamous pairs, with at least some of the tasks of brood care shared by both parents. In the remaining, polygnous, species, it is the female alone that builds the nest, incubates the eggs, and broods and feeds the chicks. The nests of the* ***Curl-crested Manucode*** *and other congeners are open, loose, cup-shaped structures of vinelets and twigs, sometimes with a base of large leaves, and sometimes including leaves and pieces of rotten wood in the cup. The nests are suspended from the fork of a horizontal branch.*

[*Manucodia comrii comrii*, Dobu Island, New Guinea. Photo: Tim Laman]

Limited data suggest that the numbers of Crested Birds-of-paradise found above 2600 m on Mount Giluwe, in eastern New Guinea, increased during the dry season, when the birds moved to their upper altitudinal limit. In Australia, Paradise Riflebirds are seldom seen below 200 m except in the winter months, when individuals may be found at sea-level; males are probably territorial only to the extent of defending their display sites. In the non-breeding season, this species may move from subtropical and temperate rainforests, and wet sclerophyll forest adjacent to rainforest, into dry sclerophyll forest to more than 1 km from rainforest. Most adult male Victoria's Riflebirds are sedentary, but during the austral winter some individuals, which may form temporary feeding aggregations, may move out of rainforest into adjacent wet sclerophyll woodlands, and typically frequent the ecotone to the west of the Great Dividing Range rainforests. Other than these observations, the members of this family are best considered sedentary.

Relationship with Man

For millennia, birds-of-paradise have provided a focus for myth, ceremony, dress and dance for peoples in New Guinea and neighbouring islands. Myths and rituals associated with these birds,

Unlike the typical birds-of-paradise, the three cnemophilines build a globular, domed nest with a side entrance hole. Externally the nest of the ***Crested Bird-of-paradise*** *consists of green mosses and fern fronds, placed on a foundation of woody sticks, 2–4 m above the ground in a mossy tree; typical birds-of-paradise do not use sticks in nest-building. In this species, and possibly all three cnemophilines, the parent female and her offspring eat only simple fruits. Also unlike the typical paradisaeids, both* Cnemophilus *species have a distinct juvenile plumage.*

[*Cnemophilus macgregorii*, Tari Gap, New Guinea. Photo: Clifford & Dawn Frith]

*The nest of the **Magnificent Riflebird** is composed of large dead leaves and vine tendrils loosely put together, and lined with fine leaf midribs and fibres. The clutch is one or, usually, two eggs. A clutch of only one or two eggs is more to be expected in the polygynous species, because only the female is available to incubate the eggs and provision the young. Clutches containing two or sometimes three eggs are typical of monogamous manucodes. Known clutches of highland species are of a single egg, which may reflect colder climates and sparser animal prey availability.*

[*Ptiloris magnificus alberti*, Cape York Peninsula, Queensland, Australia. Photo: Clifford & Dawn Frith]

presumably created thousands of years ago, persist today. For example, Papuan men may perform rituals or speak incantations prior to and during the hunting of birds-of-paradise in order to keep themselves safe and to make their efforts successful. Adult male birds-of-paradise are traditionally hunted for their nuptial plumes, which are worn as part of traditional dress and, particularly, during ceremonies and festivals. The trade in plumes of the adult males has for a long time been important both locally and, during more recent centuries, over an ever-wider area.

The carefully accumulated skins of plumed and long-tailed adult male birds-of-paradise hunted or traded by initiated men were placed between the flattened broad or woven fronds of a palm or pandanus tree, within a length of bamboo tube, or in another such safe storage. These were then placed among the smoky rafters of the men's house, safe from destructive insects, light and damp, the eyes of women, and the reach of children. The brilliant hues and delicate structures of these treasured plumes were exposed to light and the elements only during important cultural events, including sing-sings. A sing-sing is the New Guinean equivalent of a festive social gathering of the community, and it enables all to exhibit wealth, in the form of personal adornment, and to show their social status, dancing prowess, demonstrating their physical vigour and skill, musical ability, wit and other valued social graces. Such gatherings provide a forum

*This female **Ribbon-tailed Astrapia** sitting on her nest is most unusual in that her central tail feathers are greatly elongated, narrow and white, just like those of adult males. There appear to be no other records of female Ribbon-tails with such exceptionally male-like tails. One possible explanation of such an unusual case is that this is a very old female: it is a recognized phenomenon among species that show marked sexual dimorphism that a few old females can acquire traits of the male.*

[*Astrapia mayeri*, New Guinea. Photo: Clifford & Dawn Frith]

The Glossy-mantled (Manucodia ater) *and* ***Trumpet Manucodes*** *maintain year-round pair-bonds, both sexes attending the nest and provisioning the offspring. The nest of the Trumpet Manucode is an open, basin-shaped structure of vine tendrils; the eggs can be clearly seen here through the nest wall. A nesting association apparently exists between Trumpet Manucodes and Black Butcherbirds* (Cracticus quoyi) *in rainforest on the Cape York Peninsula of north-eastern Australia. It is assumed that the manucodes gain some protective advantage from these birds.*

[*Manucodia keraudrenii gouldii*, Iron Range, Cape York Peninsula, Queensland, Australia. Photo: Clifford & Dawn Frith]

for bachelors to exhibit their hoard of plumes, or their access to such a hoard. These may be owned by a bachelor, may be loaned to him by relatives or friends, or may be hired in exchange for goods or return favours, and so on. As a result of widespread plume-trading within New Guinea, a man can wear the plumes of species not found near his home. Men adorn themselves with plumes, at least in part, because they relate closely to the masculinity and vigour of courting male birds-of-paradise.

Papuan aesthetic values, as with fashion anywhere, vary from place to place and over time, and so, too, does the use of plumes of the various species. To this day, adult male bird-of-paradise skins feature conspicuously in the economy of Papuan people, particularly among highlanders. They were, and remain, part of many a "bride price" that men must pay to a future wife's family. Thus, given that people have lived in New Guinea for as long as some 50,000 years, plume-trading may have been practised on the island over tens of thousands of years.

Dried "trade skins" of adult male birds-of-paradise, particularly those species in the genera *Cicinnurus* and *Paradisaea*, have probably been traded from New Guinea to what is now the eastern Indonesian archipelago, the Philippines and the South-east Asian mainland for as long as 5000 years. Certainly, they were valued items in Asia more than 2000 years ago. The earliest voyagers to reach New Guinea were the first to report the birds-of-

The diet of ***Victoria's Riflebird*** *nestlings is up to 80–90% animal items, and the rest fruit. At first, nestlings of most species are fed with arthropods, which provide calcium for bone formation, structural proteins for tissue growth, and lipids for energy. After the chicks reach a certain age, they are fed mainly with fruit. Once nestlings reach a certain size, a range of fruits can probably meet their dietary needs. It is probable that in polygynous species, the adults have different foraging demands. Females require more arthropods while nesting, while males seek foods such as fruit that minimize foraging time, allowing them to maximize time at display sites.*

[*Ptiloris victoriae*, Atherton Tableland, NE Queensland, Australia. Photo: Clifford & Dawn Frith]

*The known nests of the cnemophilines like the **Crested Bird-of-paradise** are built in relatively exposed terrestrial or low-vegetation sites, and are highly cryptic, the moss and fern materials matching the nest-site vegetation. The few known eggs of the Cnemophilinae are pale pinkish, most markings consisting of fine reddish-brown spotting, predominantly around the larger end. Eggs of paradisaeids are typically elliptical ovate, or a long oval, in shape. Incubation periods have been documented for only some of the members of this family, all of them polygynous species; they span 14–27 days. A general correlation between increasing altitude and longer incubation periods is apparent. The clutch of the Crested Bird-of-paradise, which is a bird of upper montane and subalpine forest at 2100–3650 m, is probably one egg, and the incubation period more than 19 days. Nestling periods vary from 14 to more than 30 days, and they are, as with incubation, generally longer for higher-altitude species than for lowland ones. The nestling period for the Crested Bird-of-paradise is more than 30 days. The few measures of the percentage of daily time that wild living females spend in brooding a single nestling vary from about 14% to 48%. The Crested Bird-of-paradise devotes far less time to brooding than some other species, suggesting that the more cryptic, protective and presumably better-insulated nest enables the parent to be less attentive, despite the relatively cold habitat. The rate at which single-nestling broods are fed has been recorded for five polygynous species, varying from about one to three meals per hour. The Crested Bird-of-paradise has by far the highest feeding rate, doubtless a reflection of its low-protein nestling diet, which consists exclusively of fruit.*

[*Cnemophilus macgregorii macgregorii*, Tari Gap, New Guinea. Photo: Clifford & Dawn Frith]

Parents feed their nestlings by regurgitating fruit and animal items, although some species will carry in the bill the first item to be offered to the young, usually an item of animal prey. The nestling period for the single chick at one ***Short-tailed Paradigalla*** *nest was 25 days. On hatching, paradigallas have well-developed facial and mandibular wattles, like the adults. In the few species studied, the eyes open at about six days old; at about eight to ten days, the contour feathers burst from the pin tips, and the primary coverts and primaries burst from pin at about two weeks. One female Short-tailed Paradigalla removed and ate the nestling's faeces; this behaviour has been noted in all species in which nest-sanitation has been studied.*

[*Paradigalla brevicauda*, Tari Gap, New Guinea. Photo: Clifford & Dawn Frith]

paradise and the relationship between them and the Papuan peoples to the wider world. Spanish and Portuguese sailors who brought the first, legless trade skins to Europe in the 1520s recited the story that the birds never land on a firm surface, but float in the air until death. This myth persisted until the end of the sixteenth century. During the early 1600s, complete skins arrived in Europe and confirmed that birds-of-paradise were, after all, typical, if splendid, birds having crow-like feet. During the period 1600–1825, much was written about birds-of-paradise, while precious little was actually known of them. A dozen or so additional species were described from skins reaching Europe, and others were named that subsequently proved to be invalid species, being interspecific hybrids (see Systematics).

All of this stimulated interest in the exploration of the Moluccan Islands, New Guinea and Australia in search of new birds during the first half of the nineteenth century. By the end of that century, growing scientific and public interest resulted in considerable demand for specimens for museums and the millinery trade. During the first decade of the twentieth century, hundreds of thousands of bird-of-paradise skins were exported from New Guinea, as many as 80,000 a year reaching Europe. As the millinery trade declined, in the early twentieth century, a socially restricted worldwide clientele clamoured to obtain live birds-of-paradise for personal, royal or public collections, while small numbers had previously been kept in captivity for some 200 years.

The hunting of birds and other wildlife remains very much a part of the life of many Papuans today. Hunting techniques are inevitably moving quickly away from the traditional, to the use of shotguns, and the plume component of bride prices has diminished. Traditional trade and exchange of birds-of-paradise is still widespread in New Guinea, but commercial trade is now illegal. In remote villages, close affiliations with these birds persist even in the twenty-first century. Today, traditional affinities with the birds have been commercialized: stylized birds-of-paradise adorn national flags, national-airline aircraft, bank notes and coins, postage stamps, beer cans and glasses, packets of coffee, and many other products. The national emblem of Papua New Guinea is a stylized displaying adult male Raggiana Bird-of-paradise perched on a kundu drum and spear.

Status and Conservation

The ever-increasing slaughter of wild birds, as indicated by the importation into Europe and North America of vast numbers of dried skins for the millinery trade (see Relationship with Man), fortunately led to legislation banning it, and the bird-conservation movement was thus born. Since 1924, the birds-of-paradise have been protected from commercial exploitation throughout their range, and they are now formally protected by national laws and by international convention, including fauna acts in Papua New Guinea, Australia and Indonesia, and the Convention on the International Trade of Endangered Species, or CITES, worldwide. In the modern world, however, the exponentially growing human populations and associated resource development, and the fact

Typical birds-of-paradise do not have a distinct juvenile plumage as the cnemophilines do. Juvenile and immature birds are generally smaller than the subadults and adults of the same species. The juvenile ***Black Sicklebill*** *is like the adult female, but with the crown and upperparts more rust-red, and the plumage soft and downy below. The nestlings and juveniles of the* Epimachus *sicklebills and some other relatively long billed genera have a shorter, broader and blunter bill that grows longer, narrower and finer as they mature.*

[*Epimachus fastosus*, Tari Gap, New Guinea. Photo: Clifford & Dawn Frith]

Little is known about the care of dependent young once they have left the nest, which in the ***Ribbon-tailed Astrapia*** *takes place at 25–29 days. This female is feeding a young male, possibly about four months old, which already shows a fairly elongated tail. In captivity, the young of the Greater Bird-of-paradise* (Paradisaea apoda) *began to feed independently of the adults at 29–32 days. Young birds may remain at least partly dependent for much longer than this. A female Short-tailed Paradigalla* (Paradigalla brevicauda) *was seen to feed an immature of her own size, but with duller plumage and less pure yellow facial wattles, for 108 days. A young Victoria's Riflebird* (Ptiloris victoriae) *was fed by a female 74 days after leaving the nest. In July, in the Arfak Mountains, a female-plumaged Arfak Astrapia* (Astrapia nigra) *was observed feeding a juvenile of similar appearance. There are records of individuals living for 15 years or more in the wild. Although the range of potential predators includes snakes and* Accipiter *hawks, there are few documented records of natural predation. During intensive observation of nesting female Ribbon-tailed Astrapia and females of four other genera, instances of mobbing, distraction or other active anti-predator behaviour were rarely seen, although an anti-predator freezing posture has been recorded for Victoria's Riflebird and the Raggiana Bird-of-paradise* (Paradisaea raggiana).

[*Astrapia mayeri*, New Guinea. Photo: Clifford & Dawn Frith]

No bird-of-paradise species appears to be under immediate threat of extinction, but those with small ranges are vulnerable to significant environmental changes. The restricted-range ***Paradise Riflebird*** *is confined to remnant patches of wet forest in the Eastern Australia Endemic Bird Area. The Paradise Riflebird has lost much of its lowland habitat through forest clearance, and its range has consequently diminished. It is reportedly extinct in remnants as large as 60 ha of the Big Scrub Rainforest in north-east New South Wales, but is still described as common in upland forests in the north of its range.*

[*Ptiloris paradiseus*, Australia. Photo: Roland Seitre]

that two political entities, namely Indonesian West Papua and Papua New Guinea, house the majority of bird-of-paradise species, represent a far greater threat than the plume trade ever did. The modern threat results from habitat loss, poaching and illegal hunting, exotic predators, climate change and other adverse factors. This is, of course, particularly true of species with greatly restricted ranges or habitat specialists. Logging practices in New Guinea leave very much to be desired from the point of view of habitat quality and retention, and it is no secret that associated corruption and coercion are rife and widespread. As a result, there exist reports by local people of clearly observable declines in local bird-of-paradise populations. There are also documented past population declines of birds-of-paradise in Australia.

An inevitable effect of what has been the astonishingly rapid modernization of New Guinea is that technology and travel networks have outpaced the ability of landowners to protect and defend what is traditionally and rightfully theirs. As a consequence, people driving along highways can simply stop to shoot birds with little fear of reprisal. The fundamentally important traditionally vested interest in the sustainable harvesting of birds is broken down by people having no long-term interests in the sustainability of their activities.

The recent spread of feral cats and other exotic vertebrates into New Guinea habitats represents a real threat to some birds-of-paradise. At present no bird-of-paradise species appears directly threatened by exotic predators, but terrestrial-displaying ones certainly could be vulnerable, and additional introductions into New Guinea of, for example, macaques (*Macaca*) or other primates, reported already to be in West Papua, could cause catastrophic declines in the populations of native forest animals. Today, global climate change may represent one of, if not the, major threat to the future of birds-of-paradise, most immediately those species confined to zones of higher altitude.

The members of this family most at risk are probably those having a geographically limited range and restricted within a single political entity, with a general sparsity of populations and patchiness of distribution. It is possible, however, for a species with a geographically wide range to have a total population smaller than that of a species with a more restricted range. Within a patchy distribution the various local populations may be abundant to sparse. Both the Red and the Blue Birds-of-paradise are examples of single-nation endemic species, the former confined to Indonesia and the latter to Papua New Guinea. Both are vulnerable to political attitudes and policies, or the lack of policies. Nevertheless, no bird-of-paradise species is known to have become extinct in historical time.

Currently, three of the 42 members of the Paradisaeidae are considered to be globally threatened. These are Wahnes's Parotia, the Black Sicklebill and the Blue Bird-of-paradise. The first two have small global populations, estimated as being in the range 2500–10,000 individuals and, in both cases, declining. The Blue Bird-of-paradise has the same population estimate, but is suffering a continuing decline in the number of mature individuals, with consequent adverse effects on its population structure, over a severely fragmented range. All three of these species are classed

All five astrapias are restricted-range species. The ***Huon Astrapia*** *is confined to the Adelbert and Huon Ranges Endemic Bird Area, which occupies just 14,000 km² above the 1000 m contour line in north-east Papua New Guinea. Within this already very limited area, the Huon Astrapia is found in montane and subalpine forests above 1460 m. Although it is assumed not to be under any immediate threat, there are very few data on this species, and a survey of its current distribution, habitats and status is urgently needed.*

[*Astrapia rothschildi*, Huon Peninsula, New Guinea. Photo: Tim Laman]

*The **Long-tailed Paradigalla** is endemic to the Arfak Mountains of the Vogelkop peninsula, in north-west New Guinea. There are few records, but it is probably not uncommon, and it may occur on other mountain ranges in the Vogelkop. The extensive forests in its range are still generally undisturbed, but deforestation is occurring in the hills, and the species may be suffering local declines. It is currently considered Near-threatened. There are proposals to extend the 683 km² Pegunungan Arfak Nature Reserve, which is considered too small to protect viable populations of this and other members of the Arfak flora and fauna.*

[*Paradigalla carunculata*, Siyoubrig, New Guinea. Photo: Ashley Banwell]

as Vulnerable. In addition to these three globally threatened species, eight paradisaeids are currently considered to be Near-threatened. They are the Yellow-breasted Bird-of-paradise, the Long-tailed Paradigalla (*Paradigalla carunculata*), the Pale-billed Sicklebill, Wilson's Bird-of-paradise, the Ribbon-tailed Astrapia, and the Red, Emperor and Goldie's Birds-of-paradise. The Long-tailed Paradigalla is geographically one of the most restricted species.

Wahnes's Parotia is very poorly known, but it appears to be declining as a result of habitat loss. It is confined to forests in the mountains of the Huon Peninsula and the Adelbert Mountains, in north-east New Guinea, where it is found at 1100–1700 m. Although the human population in this region is relatively small, it is expanding rapidly, and more and more areas of forest are being cleared within the species' elevational range, which is the one preferred for settlement and agriculture by the local people.

The Black Sicklebill, possessing the longest plumes of all paradisaeids, is thought to be declining mainly because of hunting, but also because of forest clearance for agriculture. It has a wide range in the mountains of New Guinea, mainly at 1800–2150 m, but it is very patchily distributed, being seemingly absent over large areas. Where found, it is generally scarce to rare, and in places where it is reported as locally common, for instance on Mount Bosavi, it is often present in low densities. Much of this species' range, however, has not been surveyed in recent times, and the Black Sicklebill may be more common in the large areas of its range which are inaccessible and mostly uninhabited. The species is hunted for its magnificent tail feathers, and also for food. Skins of this species are becoming increasingly valuable, and the wider availability of shotguns and an increase in the human populations within the sicklebill's altitudinal range have led to a increase in hunting pressure. It is, of course, the adult males that are sought by hunters, and the result is an imbalance in the population structure; the species persists in areas where these males are lacking, but nothing is known of the breeding success in such areas. Even so, Black Sicklebill populations at Crater Mountain increased after the introduction of an enforced hunting ban.

Habitat loss and hunting for its pectoral plumes and tail feathers together represent the main threat to the Blue Bird-of-paradise. This eastern New Guinea species is confined to lower montane forest at 1400–1800 m, occasionally going a little higher or lower, and its narrow elevational range is precisely the same as that preferred by the human practitioners of slash-and-burn agriculture. Faced with ever-increasing human populations, this species is at great risk of local extinction in some of the intermontane valleys, although many inaccessible intermontane forests still support this species. Furthermore, although preferring primary forest, it may be able to survive in old secondary forest or fragmented primary forest, but it is often excluded from more degraded habitats as a result of the hunting of males and competition with the Raggiana Bird-of-paradise, which is more adaptable. The Blue Bird-of-paradise has a patchy distribution, in which it is nowhere common. Advertising males were recorded at intervals of about 200 m along one suitable forest ridge and 400 m along another, and at another study site males occupied home ranges each of up to 100 ha. It is interesting that, at this last-mentioned site, hunting pressure was greater and the forest habitat more patchy.

Of the eight Near-threatened members of the family, all appear to have a moderately small population and almost all have a small or very small range. All eight are, or appear to be, declining in numbers. They are potentially threatened primarily by loss or degradation of their habitats. The Yellow-breasted Bird-of-paradise appears to be absent from large areas of seemingly suitable habitat, and its rather small population is declining chiefly as a result of mining and logging activities. It is poorly known, as are several others in this category. The Emperor Bird-of-paradise, for example, is not uncommon within its small range in the Huon Peninsula, but it is poorly known; nevertheless, it is probably declining fairly rapidly, as it tends to be replaced in degraded forest by Raggiana's Bird-of-paradise. Goldie's Bird-of-Paradise, equally poorly known, is probably in decline as a consequence of forest degradation in its restricted range in the D'Entrecasteaux Archipelago, off south-east New Guinea. If the larger islands within its range were to be targeted for large-scale logging activity and development, it might be necessary for this beautiful bird-of-paradise to be moved to one of the globally threatened categories.

Apart from the species discussed above, there are others that deserve to be monitored over the coming decades. These include the Standardwing Bird-of-paradise in the Moluccas, the Arfak and Huon Astrapias and the Western and Foja Parotias (*Parotia berlepschi*) of isolated mountain ranges in New Guinea,

***Wahnes's Parotia** is confined to narrow belts of mid-montane forest in New Guinea's Huon Peninsula and Adelbert Mountains. The human population of this region is growing rapidly, and the habitat of Wahnes's Parotia unfortunately coincides with the optimum altitudes for settlement and agriculture. It has been seen foraging near active gardens and appears tolerant of many human activities, but may require undisturbed habitat for breeding. Its estimated total population is of 2500–10,000 birds, and it is categorized as Vulnerable. As well as investigating population trends at known sites through interviews with local villagers, BirdLife International proposes surveys of other mountain ranges in the Huon Peninsula which have not been visited recently.*

[*Parotia wahnesi*, Huon Peninsula, New Guinea. Photo: Tim Laman]

*Traditional sustainable hunting regimes are breaking down as New Guinea undergoes modernization, with wider availability of shotguns and a growing network of roads. The Vulnerable **Black Sicklebill** is hunted both for the tail feathers of the males, and for food. The species persists in areas where adult males have been hunted out, but nothing is known of the breeding success of these populations. When a hunting ban was enforced at Crater Mountain, numbers increased. A similar ban is now enforced around the Ok Tedi copper mine, where heavy hunting had caused a dramatic decline.*

[*Epimachus fastosus*, Arfak Mountains, New Guinea. Photo: Richard Kirby/ naturepl.com]

and the two Australian endemic riflebird species that inhabit remnant patches of wet forest. Concern was once expressed over the populations of the subspecies *trobriandi* of the Curl-crested Manucode in the face of habitat loss associated with human population growth, and some low coral islands involved may also be vulnerable to sea-level rise resulting from global warming. This taxon is restricted to the Trobriand Group, off south-east New Guinea.

An analysis of comprehensive paradisaeid distributions over New Guinea in the light of terrane tectonics indicates that conservation efforts concerning this family should take into account their apparent primary centre of diversity, which is located in the Mount Hagen–Jimi Valley–Wahgi Valley region.

No bird-of-paradise species would appear to be currently under imminent threat, but those restricted in distribution or having sparse populations are vulnerable to significant environmental changes. It is therefore important that we learn much more about the biology and ecology of these species before circumstances become much worse. Captive-breeding programmes should certainly be considered now, while wild populations remain healthy, rather than waiting until they are not, particularly as dietary problems previously limiting captive-breeding success and DNA sexing have recently been overcome and the necessary changes implemented. As a result, several more easily obtainable species are now frequently bred in Europe, the USA and elsewhere. It should be noted and acknowledged that aviculture has proven to be a significant method in learning of aspects of the biology and behaviour of these birds that are difficult to determine in the wild.

*The Vulnerable **Blue Bird-of-paradise** is a single-nation endemic species, confined to Papua New Guinea. Such species are at particular risk from changes in political attitudes and policies. The Blue Bird-of-paradise is patchily distributed in the eastern central mountain ranges of New Guinea, mostly at 1400–1800 m, with adult males further confined to the middle levels of this elevational range. This corresponds all too well to the optimum range for settlement and agriculture, and the species seems doomed to disappear from the more populous intermontane valleys; it is also hunted for its plumes. Nevertheless, significant areas of its range are inaccessible and largely uninhabited, giving grounds for some optimism for its survival.*

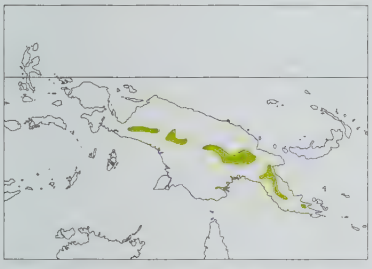
Subfamily CNEMOPHILINAE



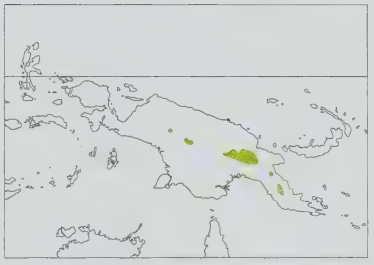
Genus *CNEMOPHILUS* De Vis, 1890

1. **Loria's Bird-of-paradise**

Cnemophilus loriae

French: Cnémophile de Loria **German**: Loriaparadiesvogel **Spanish**: Ave-del-paraíso de Loria
Other common names: Loria's Cnemophilus/Bird

Taxonomy. *Loria loriae* Salvadori, 1894, Moroka, Owen Stanley Range, New Guinea.
This genus and *Loboparadisea* sometimes united in a separate family, Cnemophilidae. Species sometimes placed in a monotypic genus, *Loria*. Sympatric with *C. macgregorii* at c. 2600 m on Mt Hagen and 2200–2650 m in Ambua Range, but hybridization unrecorded. Three subspecies recognized.
Subspecies and Distribution.
C. l. inexpectatus (Junge, 1939) – W & C ranges (including Weyland, Nassau, Oranje, Hindenberg and Victor Emanuel Mts) of New Guinea.
C. l. amethystinus (Stresemann, 1934) – Schraderberg, Wahgi Divide, Bismarck Range, Kubor Range, Mt Hagen and Giluwe Range (also, presumably, Mt Bosavi) in E New Guinea.
C. l. loriae (Salvadori, 1894) – Herzog and Kuper ranges (E of Watut/Tauri Gap) SE through Owen Stanley Range to Mt Dayman, in SE New Guinea.



Descriptive notes. 22 cm; male 75–101 g, female 60–96 g. Dark, with basal upper ridge of culmen sharply keeled, gape wide, and tail graduated. Male nominate race has velvety black plumage with purple and/or magenta sheens; fine scale-like lores; head iridescent metallic green-blue, washed purplish; tertials iridescent green-blue to blue, washed purple to magenta; iris dark brown; bill shiny black, conspicuous bare gape-flanges and mouth interior yellowish-white, sometimes with pale pink or green hue; legs dark olive-brown to blackish. Female differs radically from male in having olive-green plumage, notably browner on wings and tail, more yellowish on belly, and no gape-flanges; also on average fractionally smaller. Juvenile is grey, this plumage worn only briefly; immature male similar in plumage to adult female, has more pointed, longer rectrices than adult male, acquires shorter tail progressively with age; subadult male varies from being like adult female but with few feathers of adult male plumage intruding, to being like adult male with few feathers of female-like plumage remaining. Race *amethystinus* differs from nominate in that male has violet-purple iridescent upper tertials, female slightly longer tail; *inexpectatus* male has much more green iridescence on tertials, female has slightly shorter tail. Voice. Advertisement call of male a monotonous, regularly repeated, ringing "weeep" or "pseep", ventriloquial and far-carrying but not powerful. Alarm once reported, and nesting female gave soft, low rasping scold note, repeated 4–5 times.
Habitat. Middle montane to upper montane forests, forest edge and second growth; 1500–3000 m, mostly 2000–2400 m.
Food and Feeding. Fruits, mostly simple drupes/berries plucked and swallowed whole, without manipulation by bill or feet; earthworms (Oligochaeta) also eaten. Fruits harvested in middle and lower storeys of forest and forest edge. Usually forages alone, but groups of 3–4 (rarely, up to ten) female-plumaged birds, sometimes with an adult male or other bird-of-paradise species, recorded in fruiting tree.
Breeding. Breeding Nov–Feb; an egg laid early Jan near Tari (E New Guinea); display season undefined, but singing noted Mar, Jul and Sept–Jan (various localities), and a display seen in Oct. Polygynous; presumed solitary, promiscuous male attends traditional advertisement-singing perches; females build and attend nest alone. Solitary courtship on bare or foliaged exposed canopy perch; mostly static simple display postures that exhibit iridescent lore feathering and pale gape-flanges and/or mouth interior; an inverted display with regular clicking noise (probably made with bill) and with quivering half-opened wings. Nest a substantial globular domed structure with horizontally ovate entrance hole, externally of fresh moss and filmy fern fronds, inner chamber lined with supple fresh epiphytic orchid stems, c. 20–30 straight sticks placed into and on nest-entrance perch and within moss beneath; built at average of 1·5 m above ground, blends cryptically with plants on adjacent surfaces; habitual use of some nest-sites. Clutch probably 1 egg; incubation at one nest c. 25 days; no information on nestling period.
Movements. Presumably resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in Central Papuan Mountains EBA. CITES II. Common and widespread throughout range; secretive habits, however, may suggest otherwise. Possibly rare in Ilaga forests, in WC New Guinea, as a result of hunting. No apparent short-term threat to any of the races.
Bibliography. Beehler & Pruett-Jones (1983), Diamond (1972), Frith (1987a, 1996), Frith & Beehler (1998), Frith & Frith (1993a, 1994c, 1997b), Gilliard (1969), Gilliard & LeCroy (1961), Gregory (1995), Gyldenstolpe (1955a), Hicks, J.H. & Hicks (1988), Hopkins (1992), Mayr & Gilliard (1954), Mayr & Rand (1937), Melville (1979), Rand (1942b), Ripley (1964), Schodde (1976), Stein (1936), Stresemann (1934b).

2. **Crested Bird-of-paradise**

Cnemophilus macgregorii

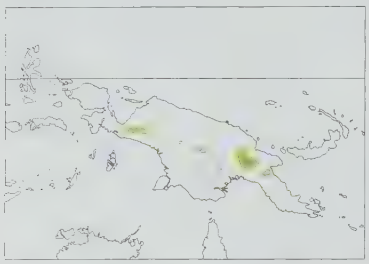
French: Cnémophile huppé **German**: Furchenparadiesvogel **Spanish**: Ave-del-paraíso Crestada
Other common names: Crested Cnemophilus, Sickle-crested/Multi-crested/Macgregor's Bird-of-paradise

Taxonomy. *Cnemophilus macgregorii* De Vis, 1890, Mount Knutsford, Owen Stanley Range, New Guinea.
This genus and *Loboparadisea* sometimes united in a separate family, Cnemophilidae. Sympatric with *C. loriae* at c. 2600 m on Mt Hagen and 2200–2650 m in Ambua Range, but hybridization unrecorded. Birds from Kubor Mts (E New Guinea) described as additional race, *kuboriensis*, synonymized with *sanguineus*. Geographical extent of nominate race uncertain, possibly wider than is listed below. Two subspecies recognized.
Subspecies and Distribution.
C. m. sanguineus Iredale, 1948 – mountains of E New Guinea (Mt Giluwe and Mt Hagen region E to at least Bismarck Mts and Kubor Range).
C. m. macgregorii De Vis, 1890 – SE New Guinea (E at least from Ekuti Divide, E of Watut/Tauri gap).
Also recorded N of L Habbema (sighted) and in West Papua (collected), but neither record diagnosable to subspecies.

Descriptive notes. 24 cm; male 90–120 g, female 79–125 g. Upper ridge of culmen broadly flat towards skull, gape wide, tail graduated. Male nominate race has forehead, upper ear-coverts and entire upperparts brilliant silky flame-yellow with iridescent white highlights, duller on back, and cinnamon on upperwing and uppertail; small erectile (usually concealed) sagittal crest of 4–6 sickle-shaped feathers dark buff with golden iridescent gloss; lores, lower ear-coverts, tiny narrow line above centre of eye, and entire underparts brownish-black with coppery-bronze dull sheen; variable cinnamon feathers on thighs and flanks; iris dark brown to bluish-grey; bill dark brownish-black, mouth pinkish; legs purplish-brown to brown-black. Female is very different from male, fairly uniform brown-olive, underparts slightly paler and buffier, especially on belly and undertail-coverts, with iris dark brown-grey to dark bluish-grey, bill brownish-black, legs dark brownish to brownish-black, mouth pale green, also slightly smaller. Juvenile is briefly grey; immature male like adult female but with paler bill, legs and iris brownish to brown-grey; subadult male varies, from like adult female with few feathers of adult male plumage to like adult male with few feathers of female-like plumage remaining, also tail longer than adult male. Race *sanguineus* differs from nominate in having slightly longer wing and shorter tail, adult male with considerably richer and reddish dorsal plumage, and underparts with less copper-red sheen. Voice. Unconfirmed if male has advertisement vocalization. Calls include harsh and rasping sounds, low harsh hissing, loud clicking repeated several times, and explosive muffled bark repeated at long intervals. A female attending nestling gave soft "wark, wark" on approaching nest; another nest-approaching female repeated a soft sharp "whit", and when disturbed produced soft churring growl as scold; harsh persistent sound like scraping or the tearing of heavy material sometimes uttered by female when disturbed at nest with young.
Habitat. Upper montane and subalpine forest and forest edge, including secondary growth, disturbed vegetation and shrubbery; 2100–3650 m, mainly 2600–3500 m.
Food and Feeding. Only fruits recorded, mostly simple drupes or berries plucked and swallowed whole, without manipulation by bill or feet. Nestling fed exclusively with fruits (odd tiny shelled mollusc incidental). Fruits taken mainly from middle and lower strata of dense forest edges or second growth. Usually forages alone, but several males (up to nine) and female-plumaged individuals may gather in fruiting plants together with other frugivorous species, including other members of present family.
Breeding. Season Aug–Jan in EC highlands; display season undefined, but birds with enlarged gonads in Jun–Nov on Mt Hagen, courting well established in Jun, full sperm production Jul–Sept, and mating before mid-Nov. Polygynous; presumed solitary, promiscuous male attends traditional advertisement-singing perches; female builds and attends nest alone. Male appeared to patrol possible territory c. 200 m in diameter, but territoriality unconfirmed. Nest globular with horizontally ovate entrance hole, externally consisting of green mosses and green fern fronds (which blend with adjacent vegetation) placed on foundation of woody sticks, interior lined exclusively with green-yellow epiphytic orchid stems, and egg-chamber with finer ones; built c. 2–4 m above ground atop decayed mossy tree stump, on side of mossy tree trunk, or within branches of tree and associated vegetation. Clutch probably 1 egg; incubation period more than 19 days; nestling period more than 30 days.
Movements. Few data. Limited information suggests that numbers of individuals above 2600 m on Mt Giluwe increased during dry season, when moving to upper altitudinal limit.
Status and Conservation. Not globally threatened. Restricted-range species: present in Central Papuan Mountains EBA. CITES II. Secretive habits limit meaningful assessment of abundance, but no immediate or long-term global threats apparent. Occurs patchily, in part a result of restricted altitudinal range.
Bibliography. Beehler *et al.* (1986), Clapp (1986), Coates (1990), Diamond (1972), Frith (1996, 1998), Frith & Beehler (1998), Frith & Frith (1993c, 1997b), Frith & Harrison (1989), Gilliard (1969), Gyldenstolpe (1955a), Hoyle (1975), Kwapena (1985), Loke Wan Tho (1957), Mack & Wright (2000), Marshall (1954), Mayr & Rand (1937), Peckover (1990), Sims (1956).

Genus *LOBOPARADISEA* Rothschild, 1896

3. **Yellow-breasted Bird-of-paradise**



Loboparadisea sericea

French: Cnémophile soyeux **German**: Lappenparadiesvogel **Spanish**: Ave-del-paraíso Sedosa
Other common names: Yellow-breasted Cnemophilus/Bird-of-paradise, Wattled/Wattle-billed/Shield-billed Bird-of-paradise

Taxonomy. *Loboparadisea sericea* Rothschild, 1896, western New Guinea.
This genus and *Cnemophilus* sometimes united in a separate family, Cnemophilidae. Two poorly defined subspecies recognized.

On following pages: 4. Paradise Crow (*Lycocorax pyrrhopterus*); 5. Glossy-mantled Manucode (*Manucodia ater*); 6. Jobi Manucode (*Manucodia jobiensis*); 7. Crinkle-collared Manucode (*Manucodia chalybatus*); 8. Curl-crested Manucode (*Manucodia comrii*); 9. Trumpet Manucode (*Manucodia keraudrenii*); 10. Long-tailed Paradigalla (*Paradigalla carunculata*); 11. Short-tailed Paradigalla (*Paradigalla brevicauda*).

Subspecies and Distribution.
L. s. sericea Rothschild, 1896 – mountains of New Guinea from Weyland Mts E, discontinuously, to at least Victor Emanuel Mts, Kubor Range, Mt Karimui and Soliabeda.
L. s. aurora Mayr, 1930 – Herzog Range (E of Watut/Tauri gap) and upper Jimi R, in SE New Guinea.

Descriptive notes. 17 cm; male 50–75 g, female 60–77 g. Basal upper ridge of culmen broadly flattened, gape wide, tail slightly graduated. Male nominate race has bulbous narial wattles (bilaterally bifurcate) and bare skin over mandible bases pale, chalky turquoise-green or yellow; lores and side of face dark brown, crown similar but with coppery-green sheen; nape, mantle and upper back honey-brown with darker feather tips, washed iridescent coppery yellow, lower back and rump pale silky iridescent sulphur-yellow; tail and upperwing and its coverts honey-brown, darker tips on primaries, secondaries and rectrices; malar area and entire underparts silky or glassy sulphur-yellow; thigh feathers dark brown; iris dark brown; bill blackish, mouth dull-coloured (lacking bright pigment); legs blackish. Female is slightly larger than male (uniquely within family), lacks wattles, and has different plumage, dark olive-brown above with cinnamon-brown on exposed wings, and paler, more yellowish-buff, underparts with darker streaking, especially on breast. Juvenile undescribed, possibly briefly grey; first-year immature dark olive-brown above, washed amber on wing and tail, lacking yellow, underparts cinnamon, dark feather edgings on breast forming broad greyish streaking, belly pale greyish; second-year plumage of both sexes like adult female, but darker below and less yellow above; tail of immature male longer than adult's, progressively shorter with age, wattles require at least a year to develop fully, changing from black, to black mottled with turquoise-green, to adult male colour. Race *aurora* male is fractionally larger than nominate, more so in tail length, and upperparts significantly brighter (paler), more brown-yellow, crown far paler and more greenish, less brown, narial wattle pale blue. Voice. Unconfirmed if male has advertisement vocalization. Calls include series of loud, harsh, grating notes slightly upslurred, "sssh sssh sssh", usually 2 notes followed by brief pause and again 2–3 notes, notes becoming slower and stronger as series continues; lower-pitched than notes of *Lophorina superba*.
Habitat. Interior of middle montane forest; 600–2000 m, mainly above 1200 m.
Food and Feeding. Little known. Possibly almost exclusively fruits, simple drupes and berries plucked and swallowed whole; one individual had arthropods in stomach. Forages in canopy, lower canopy and upper middle storey, but also frequents lower strata of forest. Singly or in groups of up to ten individuals in fruiting trees or undergrowth.
Breeding. Males with moderately enlarged gonads in Jun and Aug and greatly enlarged ones May and Oct. Presumed polygynous, with solitary promiscuous males; females build and attend nest alone. Nest said to be an open moss structure built in branches in vegetation; clutch reported as 1 egg by local informant. No other information.
Movements. No information.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Central Papuan Mountains EBA. CITES II. Poorly known. Locally common, but patchily distributed; absent from seemingly suitable forests, perhaps owing to lack of significant food plants. Possibly overlooked because of its secretive behaviour and rugged, rarely visited habitat. Population appears to be fairly small, and declining owing to mining and logging activities. Habitat in most of its range, however, is reasonably secure, and probably safe from large-scale habitat degradation.

Subfamily PARADISAEINAE

Genus *LYCOCORAX* Bonaparte, 1853

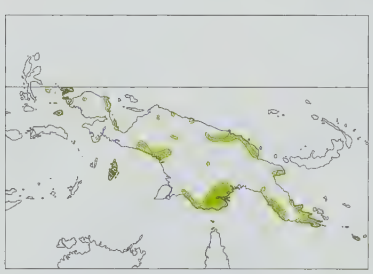
4. Paradise Crow

Lycocorax pyrrhopterus

French: Paradisier corvin **German**: Krähenparadiesvogel **Spanish**: Ave-del-paraíso Corvina
Other common names: Brown-winged Bird-of-paradise, Brown-winged/Obi/Morty Island Paradise-crow, Silky Crow

Taxonomy. *C[orvus] pyrrhopterus* Bonaparte, 1850, Gilolo [= Halmahera].
Originally described as a crow (Corvidae). Distinctive race *obiensis* possibly a separate species; study required. Three subspecies recognized.
Subspecies and Distribution.
L. p. morotensis Schlegel, 1863 – Morotai and Rau, in N Moluccas.
L. p. pyrrhopterus (Bonaparte, 1850) – Halmahera, Kasiruta and Bacan.
L. p. obiensis Bernstein, 1864 – Bisa and Obi (S of Halmahera).
Descriptive notes. 42 cm; male 242–370 g, female 218–316 g. Nominate race has entire head slightly glossy blackish dusky-brown, darkest on crown; mantle to uppertail-coverts paler and greyer with dull blue-grey gloss or sheen (with slight green cast); upperwing brown, darker on coverts and tertials than the dark cinnamon-brown flight-feathers, variably white concealed bases of primaries (obvious in flight); tail glossy blackish-brown, rectrices with fine hair-like central points; underparts as mantle but paler, and with blue-green gloss, browner on belly, vent and undertail-coverts; iris blood-red, small area of bare grey skin behind eye; bill shiny black; legs black. Sexes alike in plumage, female on average smaller than male. Juvenile has crown, middle of back and dorsal surface of tail as adult, rest of plumage brownish with only slightest of blue-black gloss, downy underparts matt brownish; immature duller-coloured, less blackish below than adult, possibly with paler brown wings. Race *obiensis* is like nominate but darker, more glossy blue-green, more blue-black on crown and tail, and with only trace of white on concealed bases of primaries; *morotensis* is

largest race, much like nominate but paler, more brownish, above, slightly darker below, with concealed bases of primaries extensively white. Voice. Several distinct vocalizations, some advertisement and others contact or alarm notes. Geographical variation, e.g. on Obi (race *obiensis*) a "wuhk" or "wunk" note or loud "who-up" often answered by loud "hwhoo"; on Halmahera (nominate) a short hoarse dog-like bark, "woo-up", second note rising and often followed by harsh rasping "krek" or "rek" (which may also be given alone), and loud "wu-wnk", "kreck rek" or "krek kek". On various islands a soft "rrr" call like that of a coucal (*Centropus*), harsh rasping "tschak...tschak", low deep "om", repeated single, moderately loud, dry, slightly upslurred guttural barking or croaking "ekk", short frog-like "ech", and repeated loud, deep, resonant, disyllabic "óó-lip" or deeper "óó-lee" of which first syllable deep and descending and second high-pitched and rising.
Habitat. Lowland, hill, and middle montane forests, fairly open agricultural land with scattered scrub and trees, coconut (*Cocos nucifera*) plantations, and orchards; rarely in swamp-forest and in mangroves adjacent to swamp-forest. Sea-level to hills, to at least 800 m on Obi, at least 1500 m on Halmahera and 1700 m on Bacan.
Food and Feeding. Mostly fruits, some arthropods. At least fruits fed to nestlings. Forages mainly in dense upper middle storey and canopy foliage. Usually forages singly or in twos, occasionally in groups of up to five individuals; rarely in mixed-species flocks or with pigeons (Columbidae).
Breeding. Season at least Dec to early Jun, single nestlings in two nests (Mt Gamkonora, on Halmahera) mid-Apr; males with enlarged gonads Jan, Jun, Aug and Oct–Nov and female in Jul. Monogamous. Nest an open bowl-shaped structure, like that of *Manucodia* but bulkier, exterior of lightweight woody curled vine stems, tendrils, dead leaves and/or moss, lined with pale wood chips or flaky bark, egg-chamber lining of coarse springy hair-like tendrils, built into fork of subcanopy branches 4–15 m above ground. Clutch 1 egg. No other information.
Movements. No information.
Status and Conservation. Not globally threatened. Restricted-range species: present in Northern Maluku EBA. CITES II. Locally common on Halmahera; moderately common to common on Obi and Bisa. On Halmahera, average of 0·2 (0·1–0·4) birds/ha in habitats on limestone and other sedimentary rocks, and 0·5 (0·3–0·8) birds/ha in montane habitats; in Sept 1994 and in 1995–1996, average density of 0·4 (0·1–0·9) birds/ha in logged lowland forest on sedimentary rocks.
Bibliography. Bernstein (1864), Coates & Bishop (1997), Frith (1998), Frith & Beehler (1998), Frith & Frith (1997b), Frith & Poulsen (1999), Heinrich (1956), Lambert (1994), Lambert & Young (1989), Linsley (1995), Parker (1963), Poulsen & Lambert (2000), Ripley (1959), White & Bruce (1986).



Genus *MANUCODIA* Boddaert, 1783

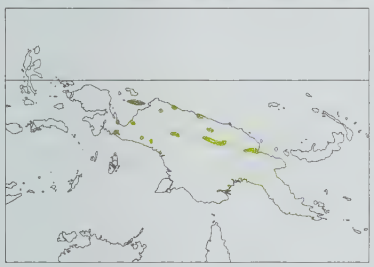
5. Glossy-mantled Manucode

Manucodia ater

French: Paradisier noir **German**: Glanzparadieskrähe **Spanish**: Ave-del-paraíso Negra
Other common names: Glossy/Black Manucode

Taxonomy. *Phonygama ater* Lesson, 1830, Dorey, north-west New Guinea.
Sympatric with *M. jobiensis*, *M. chalybatus* or *M. keraudrenii* at various localities, but no cases of hybridization recorded. Geographical variation largely clinal; species sometimes treated as monotypic. Listed distribution of race *subalter* uncertain, and biogeographically odd; study of geographical variation required. Three subspecies currently recognized.
Subspecies and Distribution.
M. a. ater (Lesson, 1830) – mainland New Guinea from Vogelkop E patchily to Huon Gulf and, in S, to Purari R.
M. a. subalter Rothschild & E. J. O. Hartert, 1929 – West Papuan Is (Gebe, Waigeo, Gam, Batanta, Salawati, Misool), Aru Is, and SE peninsula of New Guinea (E from Kumusi R in N watershed and, in S, from NE Gulf of Papua).
M. a. alter Rothschild & E. J. O. Hartert 1903 – Tagula I, in Louisiade Archipelago (off SE New Guinea).

Descriptive notes. Male 38–42 cm, 170–315 g; female 33–37 cm, 155–252 g. Large paradisaeid with long, graduated tail; base of culmen ridge broadened and flattened to a degree intermediate between those of *M. jobiensis* and *M. chalybatus*. Male nominate race has head and neck blue-black with iridescent blue-green tipping on smooth feathering, also plum-purple sheen in some lights; dense feathers above each eye (not elongated or erectile); smooth-plumaged blue-black mantle, back, rump, upperwing and uppertail with iridescent glosses of blue and of purple to magenta, tail may show subtle blackish barring, rectrices have tiny hair-like central points; iridescent tipping on each feather of chin and throat forms inverted V-shape; breast as upperparts, but more blue-green iridescence increasing on belly, vent and undertail-coverts; iris blood-red with brown inner ring; bill dark grey to black, legs black. Female is on average smaller than male, also with glosses greener, less purple, particularly on underparts. Juvenile is downy and dull brownish-black, this subsequently broken up by glossy feathers of immature plumage (initially more so on upperparts); immature duller than adult, tail on average slightly shorter, iris orange-yellow to yellowish-orange (and probably changing with age), difficult to differentiate from immature *M. chalybatus*. Race *subalter* is larger than nominate, male differs also in having more purple and violet colours (oil-green colour rare); *alter* is considerably larger than other two races, bill length of adult male exclusively so, and male flanks and belly more violet than nominate. Voice. Male gives mournful, high-pitched drawn-out advertisement call (tone having quality of electical feedback); also subdued "korrrrr-korrrrr" or soft "kwek", and hoarse "kek-



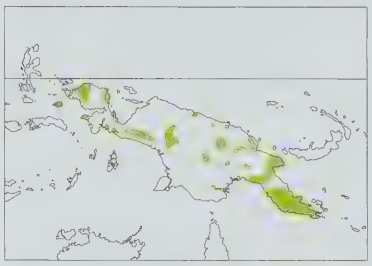
kek-kek" and soft screeching. A deep "chug", "chook" or "ack, ack, ack" given by individuals alarmed near nest; "tuck tuck" during feeding or flying.
Habitat. Lowland rainforest, swamp-forest, forest edge, riverine and monsoon forests, woodlands, denser savanna woodlands, savanna, mangroves, gardens, and associated secondary growth; usually in primary forest and mature secondary forest, only occasionally edges of gardens with remnant trees. Sea-level to low hills, less commonly to 1100 m.
Food and Feeding. Mostly fruits, especially figs (*Ficus*), possibly also flowers (perhaps nectar); also some animals, including insects and worms (Oligochaeta). Nestlings diet regurgitated fruits. Forages mostly in canopy and in subcanopy, also in low dense vegetation. Usually encountered singly or in pairs, occasionally in small feeding associations with conspecifics and/or other frugivorous birds; commonly joins mixed-species flocks of black-plumaged and/or brown-plumaged species; chases foraging competitors from fruiting trees.
Breeding. Season at least Aug–Mar; males with fairly enlarged gonads in Feb–May and much-enlarged ones Jun–Jan, egg-laying Jan, Mar and Aug–Oct, and nestling c. 1 day old in late Sept; one display recorded in Jan. Monogamous pair-bonding; apparently non-territorial. Display on tree branches involving a chase, and then static, male slightly spreading and shaking wings and tail and erecting body plumage. Nest a deep firm cup of slender semi-woody to woody dead and dry vine tendrils or stems, sometimes with few green ones, coiled and interwoven into neat cohesive whole, inner layer of dead leaves and a quantity of dead, dry, rotten wood, with cup lining of blackish semi-woody supple stems bent around inside cup; suspended in forked branch 4–12 m above ground in small tree in tall open rainforest, at or near rainforest/open woodland or savanna edge, in savanna, beside rainforest clearing or in mangrove. Clutch 1–3 eggs; incubation c. 15–17 days; chicks brooded and fed by both parents, both also swallow chicks' faeces, duration of nestling period uncertain, more than 19 days.
Movements. Presumably resident.
Status and Conservation. Not globally threatened. CITES II. Common but inconspicuous; possibly sparsely distributed throughout fragmented range. Common and widespread in Aru Is. Appears not to be at any immediate risk. Survey required of isolated island race *alter* in view of known logging and forest-clearance activity going on in Louisiade Archipelago.
Bibliography. Beehler *et al.* (1986), Bell, H.L. (1982c, 1984a), Bergman (1961), Coates (1990), David & Gosselin (2002b), Diamond (1987b), Frith (1994b), Frith & Beehler (1998), Frith & Frith (1997b), Gilliard (1950, 1956b, 1969), Gilliard & LeCroy (1966), Mayr & Rand (1937), van Oort (1909), Ramsay (1883b), Rand (1938c), Rand & Gilliard (1967), Rothschild & Hartert (1929), Wahlberg (1992).

6. Jobi Manucode

Manucodia jobiensis

French: Paradisier de Jobi **German**: Jobiparadieskrähe **Spanish**: Ave-del-paraíso de la Jobi
Other common names: Allied Manucode

Taxonomy. *Manucodia jobiensis* Salvadori, 1876, Wonapi, Yapen Island (Jobi), New Guinea.
Sympatric with *M. ater*, *M. chalybatus* or *M. keraudrenii* at various localities, but no cases of hybridization recorded. Birds from Rubi (Geelvink Bay) described as race *rubiensis*, but considered inseparable from those in rest of range. Monotypic.
Distribution. Yapen I and W & N mainland New Guinea from Rubi (W Geelvink Bay) E discontinuously in lowlands to mouth of Ramu R and, in S, from area of Mimika R to Setekwa R.



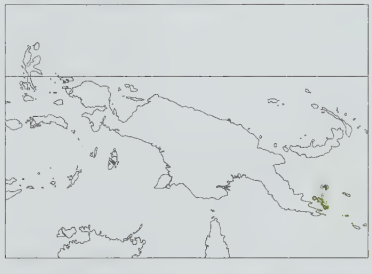
Descriptive notes. Male 34 cm, 212–257 g; female 31 cm, 150–205 g. Large paradisaeid with slightly graduated tail; base of culmen slightly broadened and flattened (far less so than in congeners except *M. keraudrenii*). Has blue-black head and neck with iridescent blue-green tipping on smooth feathering, plum-purple gloss in some lights; nape, neck, chin and throat distinctly barred (iridescent tips contrast with dark matt feather portions); mantle, back, rump and uppertail-coverts blue with iridescent violet-purple gloss and magenta sheen, all barred with broad matt black feather tipping; uppertail deep blue-black, uniformly glossed rich violet-purple with magenta sheens, rectrices with tiny hair-like central points; upper breast as mantle but less purple, lower breast, belly and thighs with iridescence progressively even less purple, more green-blue, vent and undertail-coverts matt brownish-black with subtle green-blue gloss; iris blood-red; bill dark grey to black, legs black. Sexes similar, adult female on average smaller and duller than male. Juvenile has downy upperside and underside, crown and throat brownish-black, crown more matt blackish to dull sooty black, upperwing and tail progressively coloured and glossy with age; immature like adult but duller. Voice. Little known. A series of 4–6 slowly delivered hollow "hoo" notes, much as for *M. chalybatus*, said to be advertisement song; also harsh "chig" or "becheg" call notes.
Habitat. Lowland rainforest, swamp-forest, hill forest, and forest edge; sea-level to 500 m, rarely to 750 m.
Food and Feeding. Fruits and arthropods, but relative preference unknown. Forages for arthropods at up to 15 m in middle storey. Joins mixed-species foraging flocks of predominantly black and/or brown birds, including other birds-of-paradise, with or without Rusty Pitohuis (*Pitohui ferrugineus*) and New Guinea Babblers (*Pomatostomus isidorei*).
Breeding. Birds with gonads fairly enlarged in Jun–Aug and Dec–Jan and much enlarged in Feb–Mar, May and Jul across range; single egg late Dec at Mimika R. Solitary display in tree branches. Nest a deep cup of roots, creepers and leaves, one suspended 2·4 m above ground between two horizontal branches. One clutch contained 2 eggs. No other information.
Movements. No information.
Status and Conservation. Not globally threatened. CITES II. Locally common. As this is a little-known species easily confused with *M. chalybatus*, some of the reported records may be open to question.
Bibliography. Beehler *et al.* (1986), van Bemmel (1947b), Frith & Beehler (1998), Frith & Frith (1997b), Gilliard (1969), Madarász (1897), Ogilvie-Grant (1915), Rothschild (1931, 1932).

7. Crinkle-collared Manucode

Manucodia chalybatus

French: Paradisier vert **German**: Grünparadieskrähe **Spanish**: Ave-del-paraíso Metálica
Other common names: Green-breasted/Green/Crinkle-breasted Manucode

Taxonomy. *Paradisea Chalybata* J. R. Forster, 1781, Arfak Mountains, New Guinea.
May form a superspecies with *M. comrii*. Sympatric with *M. ater*, *M. jobiensis* or *M. keraudrenii* at various localities, but no cases of hybridization recorded. Monotypic.
Distribution. West Papuan Is (Misool) and scattered sites throughout mainland New Guinea.



Descriptive notes. Male 36 cm, 164–265 g; female 33 cm, 160–255 g. Large paradisaeid with fairly long, graduated tail. Male has blue-black head, neck and nape, blue-green iridescent feather tips forming inverted V-shapes on chin, throat, neck and nape; blue-black mantle, back, rump, uppertail-coverts and uppertail with iridescence predominantly of violet-purple with magenta and/or blue sheens; indistinct dark barring sometimes apparent on uniformly glossy purple uppertail in some lights; rectrices with tiny hair-like central points; conspicuous darker broad barring on mantle formed by matt black feather tipping; lower throat, neck and upper breast feathering has fringed edging, creating crinkled surface with conspicuously bronzed yellow-green iridescence; blue-black lower breast and remaining underparts with violet-purple gloss and, in some lights, magenta sheen, darker (blackish) feather tipping giving barred appearance that is less conspicuous on matt blackish vent and undertail-coverts; iris deep red, with dark brown inner ring; bill dark grey to black, legs black. Female is on average smaller than male, also duller below, underparts more green-blue, less purple. Juvenile and immature are like adult female, but breast and belly even greener (lacking purple), chin and throat matt blackish, iris greyish-brown to dark brown, difficult to differentiate from young of *M. ater*; subadult similar to adult, but less purple and less barred, iridescent blue-green of throat and breast duller, and belly more blackish. Voice. Advertisement song of male a slow series of up to 8 low, even-pitched, hollow "hoo" notes; presumed female response a softly whistled series of descending notes, "u -o-u-o-u-o-u–o". Call notes transcribed as "tuk", "chenk", "chook" or "thtop"; short, sharp, high-pitched "kok", sharp "tchich", "kick" or "chack", also high-pitched, nasal, mammal-like trill, short whining cries and low pig-like grunting. Displaying male gives deep "ummmh" or hollow "whoo hoouw", "hmmm" or "hmmm–hoo", or may give deep hollow "hoouw" singly or repeated at intervals of many seconds and fading as display subsides. Female gives single "chengk!" note.
Habitat. Hill and lower montane forest throughout New Guinea mainland, also lowland forest on Misool; sea-level to 1700 m, mostly 500–600 m.
Food and Feeding. Mainly fruits, especially figs (*Ficus*); also invertebrates, including insects and spiders (Araneae). Forages mostly in middle to canopy levels, but also lower when seeking invertebrates. Aggressively defends fruiting trees from other frugivorous birds. Commonly joins mixed-species feeding flocks of predominantly black and/or brown birds.
Breeding. Breeding at least Jul–Sept and Jan; display recorded in Apr, Jun, Jul and Sept. Monogamous pair-bonding; non-territorial. Display on tree branches, male chasing female through foliage via numerous perches; with each display call note, male expands breast and mantle feathering as he leans forwards to stretch neck and raise head. Nest of wiry stalks, intermingled with leaves, lined with finer stalks and fibres, suspended between forking branches of tree limb. Clutch 1–2 eggs; both sexes probably provision young, but this unconfirmed. No other information.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. CITES II. Fairly common over much of range; secretive habits make census difficult. Wide-ranging; an individual radio-tracked for a week during Nov on Mt Missim (E New Guinea) covered a range of c. 45 ha.
Bibliography. Anon. (1972), Beehler (1983b), Coates (1990), Cracraft (1992), David & Gosselin (2002b), Diamond (1972, 1987b), Frith & Beehler (1998), Frith & Frith (1997b), Gilliard (1969), Hartert (1910), Mack & Wright (1996), Mayr (1931c), Mayr & Rand (1937), Pratt (1984), Schodde & Hitchcock (1968).

8. Curl-crested Manucode

Manucodia comrii

French: Paradisier d'Entrecasteaux **Spanish**: Ave-del-paraíso de Comrie
German: Kräuselparadieskrähe
Other common names: Curl-breasted Manucode

Taxonomy. *Manucodia comrii* P. L. Sclater, 1876, Huon Gulf; error = Fergusson Island, D'Entrecasteaux Archipelago, New Guinea.
May form a superspecies with *M. chalybatus*. Sympatric with *M. keraudrenii* on islands of Goodenough, Fergusson and Normanby, but hybridization unrecorded. Races poorly differentiated; species perhaps better treated as monotypic. Two subspecies currently recognized.
Subspecies and Distribution.
M. c. trobriandi Mayr, 1936 – Trobriand Group (Kiriwina and Kaileuna), off SE New Guinea.
M. c. comrii P. L. Sclater, 1876 – D'Entrecasteaux Archipelago (Goodenough, Wagifa, Fergusson, Dobu and Normanby), off SE New Guinea.

Descriptive notes. 43 cm; one male 448 g and one female 418 g (nominate). Large paradisaeid with crown feathering distinctively curled and that of neck crinkled; tail fairly long and graduated, terminal third of central pair of feathers twisted to expose underside. Has head, neck, mantle, back and rump deep blue-black, all tipped with iridescent yellowish-green with deep blue and/or violet-purple and magenta sheens; brighter iridescent tips against black feather bases form barring on mantle and back; blue-black upperwing and lesser upperwing-coverts glossed iridescent green-blue, tipped black, and remainder of coverts iridescent violet-purple with strong magenta sheen and feathers edged blue; primaries blackish, purplish-blue sheen on outer webs and tips; blue-black uppertail glossed purple and with strong magenta sheen throughout, rectrices with tiny hair-like central points; breast and remaining underparts dark blue-black, contrasting with iridescent broad purple/magenta feather tips (with some deep blue to green-blue sheens); iris dull red or red-orange; bill dark grey to black, legs black. Sexes alike in plumage, female on average the smaller. Newly fledged juvenile bare-headed, except for fine central crown line of matt black feathers, for weeks after leaving nest, also has extensive bare blue-black facial skin (giving odd appearance), fluffy soft plumage, matt black flank feathers, wing feathers glossed

blue, iris greyish-brown, bill blackish, legs pale yellow; immature like adult, but plumage less glossy, predominantly matt blackish, throat and breast feathers not crinkled and curved, iris paler and more orange-brown, tiny gape pale pink, mouth bright pink. Race *trobriandi* differs from nominate only in having smaller wing and tail. Voice. Range of calls, usually a mournful, low-pitched, rolling "woodloodloodloodloodll", descending slightly; also described as almost pulse-like low even series of rapidly repeated soft and rounded "oo" notes. Low-pitched resonant "ko-ko-ko-ko-ko" may be given at any time of day, as may a less frequent metallic croak; a monotone whistle, louder and then softer, and a very rapid series of notes all at same pitch; also an apparent low "clacking" flock-cohesion call and a repeated exclamatory, nasal, scolding "ench" note. Occasionally sexes duet. A briefer high-pitched, more musical, rapidly descending call may be by female.

Habitat. All wooded habitats, from lowland to upper montane forests, also forest edges, woodland, savanna, beach-crest casuarina (*Casuarina*) woodland, secondary growth with larger trees about forest edges, neglected gardens, and occasionally mangroves. On Goodenough I, ranges up to at least 2000 m.

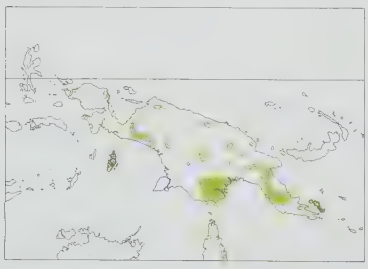
Food and Feeding. Little known. Only fruits recorded, but presumably invertebrates also taken. Forages alone, in pairs, and in small groups; also with *Paradisaea decora* on Fergusson I.

Breeding. Season at least Jun–Nov and Mar; nest-building recorded mid-Nov and egg-laying Mar and Jun–Oct; fledglings in Oct in D'Entrecasteaux Archipelago and on Kiriwina. Recent observation of display in late Sept involved 4–6 individuals perched 2–10 m apart in grove and leaning well forwards with fluttering half-raised wings and cocked and fanned tail, while calling. One nest an open loose structure of vinelets and twigs, and another (Trobriand Is) had a thick base with large thick leaves on outside and many pieces of rotten wood in middle of bottom layer; suspended in fork of tree branch, one nest 7·6 m above ground. Clutch 1–2 eggs. No other information.

Movements. No information.

Status and Conservation. Not globally threatened. Restricted-range species: present in D'Entrecasteaux and Trobriand Islands EBA. CITES II. Fairly common to abundant overall. In D'Entrecasteaux Archipelago abundant on Fergusson and Goodenough. Apparently less plentiful in Trobriand Is, where possibly threatened by habitat loss associated with increasing human population. Occurs in overgrown gardens, which constitutes all habitat on Kiriwina I. This species' feathers were used by Trobriand islanders for ceremonial adornment.

Bibliography. Bell (1970b), Clench (1978), Coates (1990), Frith (1998), Frith & Beehler (1998), Frith & Frith (1997b), Gilliard (1969), Gregory (2007), Jordan (1936), LeCroy & Peckover (2000), LeCroy *et al.* (1984), Peckover (1990), Schram (2000).



9. Trumpet Manucode

Manucodia keraudrenii

French: Paradisier de Keraudren **Spanish**: Ave-del-paraíso Trompetera
German: Trompeterparadieskrähe
Other common names: (Australian) Trumpetbird, (The) Manucode; Hunstein's Manucode (*hunsteini*)

Taxonomy. *Barita Keraudrenii* Lesson and Garnot, 1826, Dorey, north-western New Guinea.
Sometimes placed in a monotypic genus, *Phonygammus*. Sympatric with *M. ater*, *M. jobiensis* or *M. chalybatus* at various localities, but no cases of hybridization recorded. Race *hunsteini* has been considered possibly a separate species. Proposed race *mayri* (described from Wau, in NE New Guinea) synonymized with *purpureoviolaceus*, but may, like many other Huon Peninsula forms, prove to be distinct; further study required. Birds of Mamberamo R area not yet assigned to any subspecies. Nine subspecies currently recognized.

Subspecies and Distribution.
M. k. keraudrenii (Lesson & Garnot, 1826) – W New Guinea (Vogelkop, Onin Peninsula and Weyland Mts).
M. k. aruensis (Cracraft, 1992) – Aru Is.
M. k. jamesii (Sharpe, 1877) – lowlands of S New Guinea from Mimika R to Port Moresby, including islands in N Torres Strait (Boigu and Saibai).
M. k. neumanni (Reichenow, 1918) – N coastal ranges and scarp of Central Range from Bewani, Torricelli Mts and Lordberg E to Schrader Range and Jimi R and Baiyer R watersheds (Sepik–Wahgi Divide), in E New Guinea.
M. k. adelberti (Gilliard & LeCroy, 1967) – Adelbert Mts, in NE New Guinea.
M. k. diamondi (Cracraft, 1992) – S watershed of Eastern Highlands (from near Okapa, possibly including portions of Kratke Range), in E New Guinea.
M. k. purpureoviolaceus (A. B. Meyer, 1885) – uplands of SE New Guinea E from Kuper Range and Wau through Owen Stanley Range (distributional details not well delineated).
M. k. hunsteini (Sharpe, 1882) – D'Entrecasteaux Archipelago (Goodenough, Fergusson and Normanby).
M. k. gouldii G. R. Gray, 1859 – extreme NE Australia (NE Cape York Peninsula, and immediately adjacent Albany I and Mai I).

Descriptive notes. Male 31 cm, 130–240 g; female 28 cm, 130–182 g. Large paradisaeid with elongated feathers of nape and lower neck finely pointed, those above eyes forming conspicuous erectile occipital ear-tufts; fairly long tail slightly graduated. Male nominate race has head, neck and nape blue-black with green-blue iridescence, slight violet-purple sheen on rear crown; smooth-plumaged and iridescent blue mantle, back, rump, uppertail-coverts and uppertail with slightest yellow-green wash and heavy violet-purple sheen; rectrices with tiny hair-like central points at tips; intense iridescent deep violet-purple upperwing with indistinct blue sheen and edging on wing-coverts and tertials; blackish-brown primaries with narrow iridescent blue outer edges; iridescent oily green-blue upper breast, remaining underparts with purplish sheen, vent and undertail-coverts duller and less iridescent; iris red, fine inner ring of dark brown; bill and legs blackish to black; mouth blackish. Female is slightly smaller than male, somewhat duller on underparts, with head and neck hackles on average reduced in length, iris more orange. Juvenile is blackish with slight steely blue-green gloss, but no purple on back, wings or tail, elongate feathers scarcely indicated; immature dull blackish, particularly on head, with only slight bluish-green iridescence on upperparts and breast but duller on wings and belly (younger birds with iridescent sheen on underparts), iris greyish-brown to brownish-red to reddish-orange (redder with increasing age); brighter iridescent plumage and longer ear-tuft feathers gradually acquired with age. Race *jamesii* has throat and breast dark metallic blue, washed greenish, lacking purple of nominate, and with longer occipital tufts; *aruensis* is less green than nominate, differs from previous in being darker and bluer, less green, upperparts (particularly back) suffused purple, lanceolate head feathering more cobalt-blue, occipital tufts much shorter (similar in length to nominate); *neumanni* is like similar-sized nominate, but lower back, rump, tail and upperwing dark blackish-blue, washed iridescent violet-purple (rather than greenish), breast and belly dark metallic blue, occipital tufts on average shorter than all races except *adelberti* (tufts of which comparable in length); *adelberti* differs from nominate in having short occipital tufts and greenish (not blue or purple) upperwing and tail; *purpureoviolaceus* is like nominate but larger, with back, breast and belly iridescent violet-purplish, and occipital tufts far longer; *diamondi* is similar to previous, but distinct in having back, upperwing and tail with strong violet-purple sheen, breast and belly dark metallic blue with little or no violet-purple, and lanceolate head feathering bluish-green (as opposed to greenish-blue) washed violet-purple, occipital tufts slightly longer (thus longer than in all other races); *hunsteini* is larger than all preceding races, with longer occipital tufts that are less blue and more green, and back, rump and uppertail dark bluish-purple (less green); *gouldii* is like nominate, but iridescence more green (less purple), particularly so on upperwing and tail, occipital-tuft feathers more narrowly pointed and much longer, also relative tail length much longer. Voice. Large repertoire, with some sex-specific calls and racial variation. For example, *jamesii* male gives clear "whuu-oh" song, also sheep-like "maaah", displaying male a far-carrying hoarse "chauw, cher au-au-au-auw, chau-auw", other calls (sex unknown) include "chauw" or "chauw-chauw" often accompanied by rolling "chooo-roooo" or long drawn-out "krrrrooooo"; calls of *adelberti* described as forceful rasping "ha...", clear and ringing "who!", display song a whistled far-carrying note like that of peacock (*Pavo*), and a courting male described as giving a "hrarrr" call followed by almost bell-like, musical downslurred, slightly nasal "oo" or "kyeu" like that of a pigeon (Columbidae); "kyoup!", "cawwp!" and "geoaw!" noted for *purpureoviolaceus*; "scowlp", "scowlk" or "kwolk" for *gouldii*. Pair-members commonly call back and forth while foraging. Male nuptial song of upland population *purpureoviolaceus* a hollow, low, reverberating and tremulous single note, "wodldldldldldldl", at even pitch, sometimes preceded by "kaup" note. Presumed male *gouldii* gives repeated "skowlp" notes for periods of c. 30 seconds or more during early breeding season, possibly as nest-site advertisement. Nesting pair in Australia produced a strong, brief, "creaking-door" alarm call, rather like that of cicada (Cicadidae) but deeper.

Habitat. Lowland rainforest, hill forest and middle montane forest; inhabitant of rainforest interior, rarely at forest edge or in second growth. Found at 200–2000 m, mainly 900–1800 m, throughout most of New Guinea range; some New Guinea races primarily lowland-dwelling, others in hill and middle montane forests. In Australia, lowland forests, occasionally in mangroves, and on small offshore islands.

Food and Feeding. Mostly fruits, especially figs (*Ficus*); also invertebrates, including insects, spiders (Araneae), small gastropods. Nestling diet at one nest at least 90% fig pieces. Forages mostly in middle to upper levels of forest. Fruit-foraging birds consist of a pair, or aggregations of up to ten in trees. On lower mountain slopes occurs in mixed-species foraging flocks, including female-plumaged *Paradisaea* and flocks based upon New Guinea Babblers (*Pomatostomus isidorei*) and Rusty Pitohuis (*Pitohui ferrugineus*).

Breeding. Season at least May–Jan over entire range; males with enlarged gonads in Feb–Apr and Jul–Dec and females in Jun and Oct–Nov; displays noted May and Aug, and calls thought indicative of display produced in all months; copulation seen in mid-Nov. Monogamous pair-bonding, some pairs persist for more than one season; non-territorial. Display solitary, in tree branches, involves a chase, frontal lunging display, opening of wings, raising of fanned tail, erection of neck hackles, and loud harsh call. Nest is an open basin-shaped structure of curly vine tendrils, lined with fine creeping fern tendrils, sparser than in those of congeners and lacking larger leaves or pieces of dry wood; suspended 6–27 m above ground in horizontally forking tree branch, around which vine tendrils of nest rim entwined; nesting association with pairs of Black Butcherbirds (*Cracticus quoyi*) recorded in Australia. Clutch 1–2 eggs; incubation performed by both parents, and both also brood and feed the nestlings; no information available on duration of incubation and nestling periods.

Movements. Presumed resident.

Status and Conservation. Not globally threatened. CITES II. Locally fairly common. Distribution in mainland New Guinea patchy as a result of restriction to particular altitudinal zone in certain ranges; some populations isolated in smaller ranges on N coastal New Guinea. Recently found to be uncommon and patchily distributed in Aru Is. Sparse in fragmented and limited habitat in NE Australia. In New Guinea, estimated density (based on transect counts) near Port Moresby 5 birds/10 ha; home range 200 ha or more on Mt Missim (E New Guinea), with high degree of overlap by individuals.

Genus *PARADIGALLA* Lesson, 1835

10. Long-tailed Paradigalla

Paradigalla carunculata

French: Paradisier caronculé **Spanish**: Ave-del-paraíso Carunculada
German: Langschwanzparadigalla
Other common names: Wattled Bird-of-paradise

Taxonomy. *Paradigalla carunculata* Lesson, 1835, Arfak Mountains, New Guinea.
Forms a superspecies with *P. brevicauda*, and was in the past sometimes considered conspecific. Intergeneric hybridization with *Parotia sefilata*, *Lophorina superba* and *Epimachus fastosus* documented. Monotypic.

Distribution. Vogelkop (Arfak Mts), and apparently also Onin Peninsula (Fakfak Mts), in NW New Guinea.

Descriptive notes. Male 37 cm, female 35 cm; one female 170 g. Fairly large paradisaeid with prominent facial wattles, strongly graduated tail; on folded wing, longest secondaries may extend to primary tips. Male has bright yellow to greenish-yellow foreface wattle originating at base of upper mandible, and small swollen sky-blue wattle on lower mandible base, beside which a small

area of orange-red bare skin; velvety jet-black head and neck, oily bluish-green iridescence on head feathering, more greenish-blue on scale-like feathering of crown and nape; velvety jet-black from mantle down to uppertail-coverts, upperwing-coverts, tertials, secondaries and central pair of tail feathers with slight dark purple hue overwashed with rich olive-green iridescent sheen; primaries and outer (shorter) tail feathers dark brownish-black with slight olive-green sheen on outer edges; tail feathers (other than central pair) terminally notched, with tiny hair-like central points; upper breast to undertail-coverts dark brownish-black with coppery-purple iridescent sheen; iris dark brown; bill shiny black; legs blackish. Female is like male but paler, duller and smaller, with mean wing length notably shorter. Juvenile undescribed; immature like adult but duller-plumaged, with shorter tail. VOICE. No information available.

Habitat. Middle montane forest amd forest edge; elevational range poorly defined, probably c. 1400–2100 m.

Food and Feeding. Little known; eats fruits.

Breeding. Virtually unknown. Given that it hybridizes with three other genera, and from what is known of its sole congener *P. brevicauda*, present species assumed polygynous, with male solitary and promiscuous; a "pair" recorded at 1725 m during Jul–Aug 1994 was presumably an adult female with offspring.

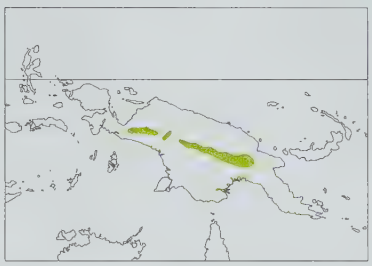
Movements. No information.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in West Papuan Highlands EBA. CITES II. Very poorly known; few records, predominantly of specimens collected in Arfak Mts, where possibly not uncommon. A paradigalla seen in Fakfak Mts (in Onin Peninsula) was presumably of this species. Thought likely to have moderately small and fragmented population; possibly occurs on other mountain ranges in Vogelkop, but no confirmed records. Although probably secure in most of its range, may be suffering local declines owing to forest loss. Within its small range extensive forests still generally undisturbed owing to geographical isolation and low density of human population and traditional lifestyle of latter, although deforestation occurring in hills. Efforts should be made to document distribution and abundance of this little-known species. One large protected area exists in Arfak Mts, and proposal to extend this has been made.

Bibliography. Anon. (2008j), Butchart & Stattersfield (2004), Collar *et al.* (2001), Frith & Beehler (1998), Frith & Frith (1997a, 1997b), Gibbs (1994), Gyldenstolpe (1955a), Hartert (1930), Hartert *et al.* (1936), McCarthy (2006), Stattersfield & Capper (2000).

11. Short-tailed Paradigalla

Paradigalla brevicauda



French: Paradisier à queue courte **Spanish**: Ave-del-paraíso Colicorta
German: Kurzschwanzparadigalla

Other common names: Short-tailed Wattled Bird, Blue-and-yellow Wattled/Short-tailed Bird-of-paradise

Taxonomy. *Paradigalla brevicauda* Rothschild and E. J. O. Hartert, 1911, Mount Goliath, central New Guinea.

Forms a superspecies with *P. carunculata*, and was in the past sometimes considered conspecific. Birds from Utakwa R, at c. 1500 m in Nassau Range (WC New Guinea), described as race *intermedia*, but considered inseparable from birds in rest of species' range. Monotypic.

Distribution. C ranges of New Guinea from Weyland Mts E to Mt Karimui and Bismarck Range.

Descriptive notes. Male 23 cm, 160–184 g; female 22 cm, 155–170 g. Male has bright yellow foreface wattle originating at base of upper mandible, and smaller swollen sky-blue wattle on base of lower mandible; velvety jet-black head, neck and entire upperparts, with oily yellowish-green iridescence on head feathering, more apparent on scale-like crown and nape; mantle and back with slight purple hue overwashed with silk-like olive-green sheen; oily olive-green silk-like sheen on rump, uppertail-coverts, upperwing (mainly as broad leading edges of primaries and secondaries), and central pair of tail feathers (mean length of central pair 3 mm shorter than mean length of remaining rectrices); primaries and remaining tail feathers blackish-brown, rectrices with fine hair-like central points; jet-black breast and remaining underparts suffused with darkest brown and with slightest iridescent sheen of dark coppery purple; iris dark brown; bill black, mouth pale aqua-blue; legs purplish lead-grey. Tail much shorter than that of *P. carunculata*. Female is like male but smaller, with longer tail, also duller, more brownish, the black and iridescence being more subdued. Juvenile is similar to female but uniformly duller (unlike barred young of most Paradisaeinae), lacking iridescence or sheen, and facial wattles pale whitish-yellow; immature of both sexes has tail considerably longer than adult, tail becoming progressively shorter with age. VOICE. Little known. Calls recorded include melodic "hui", also high-pitched mournful whistling of 4 clear ascending notes, the last prolonged and rising in pitch; throaty croak; melodious "hoo ee", and a "churr churr churr" similar to, but quieter than, that of *Lophorina superba*; also a loud rising "zheee".

Habitat. Middle montane forests, including southern beech (*Nothofagus*), secondary growth, also forest edge and edges of gardens; 1400–2580 m, mainly 1600–2400 m.

Food and Feeding. Fruits; also epiphyte-dwelling animals, including insects, spiders (Araneae), worms (Annelida), frogs (Anura), skinks (Scincidae). A single nestling was fed c. 65% animal items, including beetles (Coleoptera) and other arthropods, frogs, skinks. Forages usually in middle and upper strata of forest, but also near ground. Prey taken from trunks, boughs, bark and moss. Encountered singly.

Breeding. Recorded in all months except Mar and Nov in one area; egg-laying Jan, Apr–Jul, Sept–Oct and Dec; one record of nest-building early Sept in Ambua Range. Assumed polygynous, with male promiscuous and solitary; female builds and attends nest alone. Birds giving "zheee" call spaced at intervals of c. 150 m in moss forest in Ambua Range, suggestive of males advertising from songposts. Nest a substantial cup or bowl-shaped structure lacking sticks, exterior of green mosses, fern fronds and small-leaved epiphytic/climbing plants, including orchids (some living), within this entwined woody vine tendrils entirely circling nest rim and outside several supporting branches, inner lining of dry leaves, small egg-cup lining of fine dark wire-like tendrils; placed 5–11 m above ground in branching fork in well-foliaged sapling or larger tree at forest edge or in garden isolated from immediate vegetation; habitual use of nest-site and tree recorded, and one female nested in same immediate area for at least seven years. Clutch 1 egg, same female recorded laying during different seasons; incubation more than 20 days; removed and ate chick's faeces, nestling period at one nest 25 days; female seen to feed immature (of her own size, but with duller plumage, less pure yellow facial wattles) for 108 days, but apparently ceased doing so a week later.

Movements. Presumed resident.

Status and Conservation. Not globally threatened. Restricted-range species: present in Central Papuan Mountains EBA. CITES II. Widespread, but patchily distributed; common in some localities, but uncommon over most of range. Commonly seen but not numerous about Sogolomik, Ok Tedi, Papua New Guinea. An individually marked female in Ambua Range attended six different nests within area of less than 200 m² over period of 29 months.

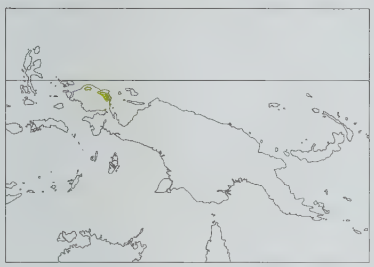
PLATE 22

inches 5

cm 13



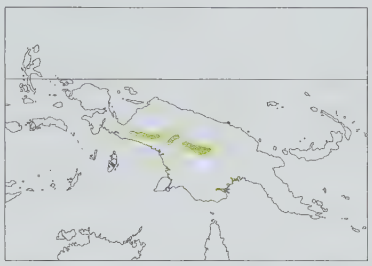
Genus *ASTRAPIA* Vieillot, 1816

12. Arfak Astrapia

Astrapia nigra

French: Paradisier à gorge noire **Spanish**: Ave-del-paraíso de las Arfak
German: Fächerparadieselster
Other common names: Great/Black/Gorget Astrapia, Arfak/Great/Black/Gorget Bird-of-paradise, Long-tailed Astrapia/Bird-of-paradise

Taxonomy. *Paradisea nigra* J. F. Gmelin, 1788, "Oceanic Islands"; error = Arfak Mountains, New Guinea.
Intergeneric hybridization with *Epimachus fastosus* recorded. Monotypic.
Distribution. Vogelkop (Tamrau Mts and Arfak Mts), in NW New Guinea.



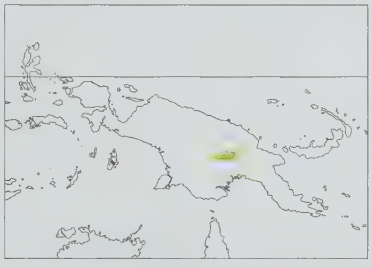
Descriptive notes. Male 60 cm (76 cm with central rectrices included), female 50 cm. Large astrapia with extremely long, markedly graduated tail. Male has velvety jet-black head with blue to purple iridescence, crown and side of face with coppery-bronze wash, especially on larger scale-like nape feathers; obvious "cape" from central nape to mantle consisting of large metallic yellowish-green scale-like feathers with purple-blue to mauve sheen, contrasting with elongate plush velvety jet-black feathers (with dull blue to magenta sheen) on each side; back to uppertail-coverts sooty brownish-black with dark coppery olive-green iridescence; exposed upperwing and uppertail sooty black with violet-purple sheen, blue and/or magenta iridescence; black malar area, chin and throat feathers with velvety iridescent blue with purple and/or magenta wash; elongate dense feathers of upper breast velvety jet-black with dull coppery violet-purple iridescence in some lights, bordered below by broad gorget of iridescent bronzed coppery feathers, and/or lime-green, this extending up side of breast and malar area to beneath eye; remaining underparts dully iridescent dark green, with large and broad scale-like feather tips down sides of lower breast and belly iridescent cyan and/or sky-blue; blackish-brown undertail-coverts; iris dark brown; bill shiny black; legs brownish-black. Female is smaller than male, notably in wing and tail, radically different plumage, with black head and nape glossed iridescent dark blue, iridescent blue of nape grading into upper mantle; rest of plumage drab blackish-brown on upperparts and down to chest, below dusky brown, narrowly barred buff. Juvenile is fluffy, less blackish than immature, dorsal surface of tail as on older female-plumaged birds; immature male like adult female but tail on average longer, after first year little to no paler barring below except lower belly to undertail-coverts; subadult male varies, like adult female but with few feathers of adult male plumage intruding, to like adult male but with few feathers of female-like plumage remaining, length of central pair of rectrices increases progressively with age while that of other rectrices decreases. Voice. Male relatively silent; single record of simple double downslurred hollow "clu-ck".
Habitat. Montane and subalpine forests, presumably to apex of Arfak Mts; 1700–2250 m.
Food and Feeding. Little known. Diet fruits and arthropods, but relative proportions unknown.
Breeding. Female-plumaged individual feeding juvenile of similar appearance in mid-Jul and juveniles at Tanah Merah (Arfak Mts) in Jul–Aug. No other information.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in West Papuan Highlands EBA. CITES II. Most records from Arfak Mts; a single sighting in Tamrau Mts. Said to be common enough, but adult males rarely encountered, in 1872; little recorded since then. In view of its limited range, this species could be, or become, vulnerable. Field studies required.
Bibliography. Frith & Beehler (1998), Frith & Frith (1997b), Hartert (1930), Heads (2002), McCarthy (2006), Sharpe (1891–1898).

13. Splendid Astrapia

Astrapia splendidissima

French: Paradisier splendide **Spanish**: Ave-del-paraíso Espléndida
German: Prachtparadieselster
Other common names: Splendid Bird-of-paradise

Taxonomy. *Astrapia splendidissima* Rothschild, 1895, "Probably Charles-Louis Mountains" = Weyland Mountains, New Guinea.
Possible hybridization with *A. mayeri* in E of range, but no confirmed records of such. Species sometimes treated as monotypic, but race *helios* considered sufficiently distinctive to warrant recognition. E extent of distribution uncertain. Two subspecies recognized.
Subspecies and Distribution.
A. s. splendidissima Rothschild, 1895 – Weyland Mts and Charles Louis Range E to L Paniai (Wissel Lakes), in W New Guinea.
A. s. helios Mayr, 1936 – from E of L Paniai E to Hindenburg Mts and at least to Victor Emanuel Range.
Descriptive notes. Male 39 cm, 120–151 g; female 37 cm, 108–151 g. Medium-sized astrapia with long, markedly graduated tail. Male nominate race has brilliantly iridescent metallic yellowish-green crown, nape and mantle, metallic blue-green chin and throat with blue to purple sheen in suitable lights; velvety black back with rich magenta sheen, matt black rump and uppertail-coverts; dark greyish-brown upperwing, slight purplish-blue iridescence at leading edge (above primary coverts); rectrices blackish-brown, inner four pairs with variable extent of white on bases and shafts, central pair having black broad spatulate tips with slight iridescent magenta gloss, tail feathers with tiny hair-like central points at tips; broad, strongly iridescent coppery-red gorget narrowing as it extends up breast side to side of face to beneath eye; remaining underparts silk-like oily dark green, with some larger plate-like feathers at breast side with strong, paler, lime-green iridescence; matt blackish-brown thighs, vent and undertail-coverts; iris dark brown to blackish-brown; bill



shiny black; legs fleshy lead-grey. Female is smaller than male, radically different plumage, head, nape and throat brownish-black with bluish-green iridescent gloss, drab blackish-brown on upperparts down to chest, below finely barred dusky brown and buff. Juvenile is like female but plumage soft and fluffy, duller and less black above, less rufous in underparts, more grey on chin, throat and upper breast, and tail feathers more pointed; immature like adult female but dark chestnut-brown on crown, sometimes with variable amount of chestnut-rufous in crown; subadult male varies, like adult female but with few feathers of adult male plumage intruding, to like adult male with few feathers of female plumage remaining, initial part of adult plumage acquired is glossy green feathering on crown and throat; male tail becomes progressively shorter with age. Race *helios* is larger than nominate, has extensive, unconcealed white bases on underside of outer primaries (except outermost two), adult male more bluish and less golden-green on crown, neck and dorsal collar, broader spatulate tips on central pair of rectrices, female-plumaged birds slightly darker above. Voice. Male produces nasal insect-like "to-ki", second note rising; similar "teek-teek" given by female-plumaged individual. Other calls include sharp, softly delivered, pathetic "jeet" (in Jayawijaya Mts, in EC part of range); curious clicking "tch tch tch"; frog-like dry "gree" note (at Tembagapura, in W of range); distinctive yelping call; and mechanical/metallic whirring vocalization.
Habitat. Montane and subalpine forests to tree-line, also forest edge and associated secondary growth; 1750–3450 m, mainly 2100–2700 m.
Food and Feeding. Mostly fruits; also animals, including arthropods, frogs, lizards. Forages from canopy down to undergrowth, taking items on moss-covered tree trunks and limbs. Generally solitary, but also in pairs and trios.
Breeding. Nest-building recorded in Mar, juvenile seen in Aug, egg in Oct and nestling in Nov. Observation of four calling adult males perched on exposed branches near tops of tall trees at regular intervals (c. 40 m) around forested edge of natural meadow suggests possibility of lekking behaviour. No other information.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in Central Papuan Mountains EBA. CITES II. Common and widespread in Okbap area of Star Mts (in E of range) at c. 2600–3200 m, whereas only female-plumaged individuals at lower elevations down to c. 2150 m. Little demand for plumes reported in Ilaga Valley and Victor Emanuel Range in 1960s. Not presently under any significant threat.
Bibliography. Cracraft (1992), Junge (1953), Frith (1995b, 1998), Frith & Beehler (1998), Frith & Frith (1997b), Gilliard (1961, 1969), Gilliard & LeCroy (1961), Hartert *et al.* (1936), Rand (1942b), Rothschild (1931), Tolhurst (1989).

14. Ribbon-tailed Astrapia

Astrapia mayeri

French: Paradisier à rubans **Spanish**: Ave-del-paraíso Cuelgacintas
German: Schmalschwanz-Paradieselster
Other common names: Ribbon-tailed Bird-of-paradise, Ribbon Tail

Taxonomy. *Astrapia mayeri* Stonor, 1939, Mount Hagen, New Guinea.
Intrageneric hybridization with *A. stephaniae* recorded; possible hybridization with *A. splendidissima* in W of range, but no confirmed records of such. Monotypic.
Distribution. From Doma Peaks, upper Strickland R, Muller Range and Karius Range E to Porgera/Mt Liwaro highlands, Mt Hagen and Mt Giluwe.

Descriptive notes. Male 32 cm (125 cm with central rectrices), 134–164 g; female 35 cm (53 cm including central rectrices), 102–157 g. Medium-sized astrapia with short, narrow and sharply pointed graduated tail, with central pair of rectrices extraordinarily elongated. Male has entire head, including narial tuft above base of upper mandible, velvety jet-black, intensely iridescent metallic yellowish-green and/or blue and violet-purple and/or magenta in some lights, notably on ear-coverts and on elongate feathers at side of head to nape; velvety jet-black from mantle to uppertail-coverts with iridescent sheen of bronzed olive-green, lesser upperwing-coverts darkest matt brownish-black edged jet-black, greater coverts and alula brownish-black, flight-feathers blackish-brown; uppertail blackish-brown, central feather pair grossly elongated (more than 1 m) into two cotton-white "ribbons" (c. 2 cm broad), each with 3–4 cm at tip blackish-brown, and shaft blackish for terminal quarter; intense metallic yellowish-green throat feathers, tending to slightly scale-like appearance, extending onto upper breast and sharply meeting broad area of velvety jet-black breast feathers with dull iridescent copper-bronze sheen, this bordered below by extensive narrow gorget of iridescent coppery red; remaining underparts iridescent coppery red, broken up by exposed iridescent green bases; vent and undertail-coverts matt brownish-black; iris dark brown; bill blackish, mouth pale greenish-yellow; legs dark leaden blue-grey. Female is smaller than male (no overlap in lengths of wing and central rectrices), radically different plumage, entire head and nape jet-black with iridescent metallic bronzed yellowish-green (more so on older individuals) and/or blue in some lights, blue iridescence more obvious on sides of face and lower throat, with mantle and back velvety blackish and (in some lights, rarely) with dark blue and/or violet-purple to magenta sheen; rest of plumage overall drab blackish-brown, but abdomen rufous to buff-brown with fine blackish barring. Juvenile is like adult female but duller, barred ventral plumage less brown, also soft and fluffy; immature like adult female, but wing and tail (excluding central pair) on average longer; first-year like adult female but iridescence duller, subsequently becoming more like adult female with increasing age; subadult male variable, like adult female with few feathers of adult male plumage intruding, to like adult male but with few

On following pages: 15. Stephanie's Astrapia (*Astrapia stephaniae*); 16. Huon Astrapia (*Astrapia rothschildi*).

female-like feathers remaining, central pair of rectrices shorter than on adult male but remainder of tail significantly longer; with increasing male age central pair of rectrices progressively longer as other rectrices become progressively shorter, one male taken into captivity took at least six years to acquire full adult plumage. Voice. A common call a loud clear "waugh", or "wock, whit-whit" in which first note guttural and immediately repeated second one sharply whistled. Other calls include "kenk!" and scolding "skaw skaw" by adult male; plaintive, nasal, frog-like, single or double "wreden", "kuweep werwer", "reaou reaou" or "wreden weep" by short-tailed immature male; and harsh "hisss-sss-ssh" followed by loud sharp "keaoo-ooo-ooo" by displaying male jumping from branch to branch.

Habitat. Upper montane and subalpine moss forests, forest edge, isolated forest patches, and selectively logged and otherwise disturbed forest; 1800–3450 m, mostly above 2450 m.

Food and Feeding. Mostly fruits, especially of *Schefflera*, also arthropods, spiders (Araneae), frogs (Anura). Forages mostly in upper third of forest, but also lower, down to ground. Probes for animals among mossy or other epiphyte-covered tree boughs, trunks, branches/foliage and pandanus (*Pandanus*) frond bases; uses open-bill-probing in dead branches and accumulated vegetable debris. Usually alone, sometimes two together (one of which may be adult male), or group of 3–7 individuals in female-like plumage.

Breeding. Breeding recorded in all months except Apr; egg-laying May, Jun and Sept–Feb; displays noted Jun, Aug and Dec. Polygynous, with apparently lekking promiscuous males advertisement-singing/displaying from traditional perches; female builds and attends nest alone. In courtship, one or more males jump back and fourth between tree branches, tail ribbons held up and arched and wings drooped, but little else known; display-flight enhances white rectrices and produces significantly louder wing noise than in usual flight. Nest a frail to substantial deep cup of large leaves and pandanus frond pieces, sparsely to densely covered with fresh green-leaved epiphytic orchid stems that are denser around nest-cup circumference and outer rim, sometimes odd piece of small fern frond used externally, egg-cup lined with much finer dead, straw-like, supple leafless orchid stems; placed mostly in near-vertical forking branch 3–18 m above ground in isolated small tree or tree-fern, often in secondary growth; nest-site repeatedly reused. Clutch 1 egg; incubation period 21 days (in captivity, one nest); nestling period 25–29 days.

Movements. Presumed resident.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Central Papuan Mountains EBA. CITES II. Fairly common to locally abundant; female-plumaged individuals far more numerous than adult males. In W of range recently found at new site, Kumul Lodge, where reported as being abundant. Thought likely to have fairly small population within small global range; probably declining owing to continued habitat degradation, but range not yet severely fragmented. Able to survive in degraded forest. Threatened locally by hunting for tail plumes, also by large-scale logging and forest degradation, but not at immediate risk as much of its range is uninhabited or inaccessible. Previous concerns of genetic swamping through hybridization with *A. stephaniae* in extreme E of range now discounted.

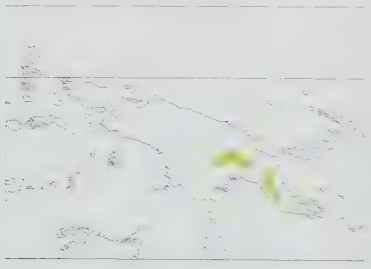
Bibliography. Anon. (2008j), Boehm (1967), Butchart & Stattersfield (2004), Coates (1990), Diamond (1972), Everitt (1973), Frith & Beehler (1998), Frith & Frith (1992a, 1993a, 1993b, 1997b), Gilliard (1969), Kuroda (1943), Kwapena (1985), Mayr & Gilliard (1952), McCarthy (2006), Shaw Mayer & Peckover (1991), Stattersfield & Capper (2000).

15. Stephanie's Astrapia

Astrapia stephaniae

French: Paradisier de Stéphanie **Spanish**: Ave-del-paraiso de Estefania
German: Stephanieparadieselster

Other common names: Princess Stephanie's/Stephanie Bird-of-paradise, Princess Stephanie Astrapia



Taxonomy. *Astrarchia stephaniae* Finsch and A. B. Meyer, 1885, Hufeisengebirge [Horseshoe Mountains = Mount Maguli], south-eastern New Guinea.

Extensive hybridization with *A. mayeri*, in W of range (from Doma Peaks E in narrow zone of altitudinal overlap to Mt Hagen/Mt Giluwe). Races poorly differentiated; additional proposed race *ducalis* (described from Dawong, in Herzog Mts) synonymized with nominate. Two subspecies recognized.

Subspecies and Distribution.

A. s. feminina Neumann, 1922 – Schrader Range, Bismarck Range and Sepik–Wahgi Divide, in E New Guinea.

A. s. stephaniae (Finsch & A. B. Meyer, 1885) – Doma Peaks, Mt Hagen and Mt Giluwe E (including Mt Ialibu, Kubor Range, Mt Karimui, Mt Michael, and Kratke and Herzog Ranges) to SE Owen Stanley Range (Mt Dayman).

Descriptive notes. Male 37 cm (84 cm with central rectrices included), 144–169 g; female 53 cm, 123–159 g. Medium-sized astrapia with large graduated tail, rectrices other than central pair broad and square-ended, central pair extraordinarily elongated. Male nominate race has head velvety jet-black, with cobalt-blue and/or violet-purple and magenta iridescence on crown and extensively on to nape and side of face; upperparts velvety jet-black with strong iridescence of bronzed lime-green; upperwing jet-black, strong iridescent violet-purple and/or magenta sheen on greater coverts, on outer edges of flight-feathers and on tertials; uppertail blackish-brown with slightest coppery sheen, except for greatly elongated velvety jet-black central feather pair with iridescent violet-purple and/or magenta sheen and conspicuous white central feather shafts for basal third of their length; chin to upper breast metallic bluish-green, this extending to upper breast and meeting broad area of velvety jet-black breast feathers with dull iridescent copper-bronze sheen, bordered below by extensive narrow gorget of iridescent coppery red; rest of underparts iridescent coppery red, broken up by exposed iridescent green bases; vent and undertail-coverts dull brownish-black; iris dark brown; bill shiny black, mouth pale green or lime-green; legs purplish leaden grey. Differs from *A. mayeri* mainly in lack of narial tufts, and in having iridescence on head more cobalt-blue and more extensive (to side of face), iridescence on upperparts stronger and paler, upperwing darker, feathers of chin to upper breast more bluish-green and finer, more silky (not tending to scale-like), rectrices other than central pair much larger, broad and square-ended (not shorter, narrow and sharply pointed), and central pair jet-black. Female is smaller than male, radically different in plumage, overall drab blackish-brown on head, upperparts and down to chest, below which rufous to blackish with fine blackish barring; bluish iridescence on head. Juvenile is black above, with variable amount of rich rufous nape feathering that may extend on to rear crown, buff with blackish barring below, plumage soft and fluffy, iris brown-grey; immature like adult female; first-year male may still have some rufous in nape, with iridescence initially on forehead, crown and chin, subsequently entire head, throat and upper breast with iridescence, thereafter more of adult male plumage acquired; subadult male variable, like adult female with few feathers of adult male plumage intruding to like adult male with few female-like feathers remaining; with increasing age, central pair of rectrices progressively longer as other rectrices become progressively shorter. Race *feminina* is like nominate but slightly smaller, wing on average slightly shorter, less contrast between colour of crown nape and that of back, male crown and nape more bluish-black. Voice. Little noted; male not known for loud advertisement. Call of male described as "nge, nge, nge" and, more softly, "ss, ss, ssw, ssw", and that of female as a squeaking note. Also rapid, drawn-out, harsh notes sometimes followed by "hoo-hee-hoo-hee..." (like that of a *Melidectes* honeyeater), given simultaneously by several individuals.

Habitat. Middle montane, upper montane and subalpine forests, including forest edge, selectively logged forest, and other disturbed forest mixed with secondary growth; 1280–3500 m, mainly 1500–2800 m.

Food and Feeding. Mostly fruits, especially of *Schefflera*, also insects, spiders (Araneae), frogs (Anura), skinks (Scincidae). Forages mostly in middle and upper forest strata. Animal prey taken from limbs and moss; employs open-bill probing. Usually forages singly, or in small loose groups of two or three and sometimes up to six individuals; will join mixed-species flocks with *Epimachus meyeri*.

Breeding. Breeding recorded at least May–Dec; egg-laying Jun and Oct–Dec, and fledglings observed Jul (Mt Giluwe) and Nov (Ambua Range); males with moderately to greatly enlarged gonads in all months, more so Mar–Oct, and female gonadal activity Jun–Aug and Oct–Dec; display season Jul–Sept near Jimi R and Nov–Dec on Mt Giluwe (courtship peak during dry season, but males may display all year). Polygynous, lekking promiscuous males sing and display on traditional perches, females build and attend nest alone; communal displays at leks of at least 2–5 males (four leks at nearest-neighbour distance c. 1·5–2 km, on crest or side of steep-sided ridges), each lek of 4–7 trees c. 25 m tall, one or two of which are main display tree(s); when adult males arrive, two or three perch at each end of a display limb to display and swap places from one end of perch to other; males (1–5, average 3) gather at lek shortly after dawn and remain for c. 2 hours. In courtship, male chases a female about branches and displays by hopping back and forth between branches of display tree, or between trees, calling occasionally; one male displaying stimulates others to do so. Few nests found; varies from being a large and bulky structure, mostly of epiphytes, to being a thick shallow structure of large leaves and creepers, lined with root fibres, small leaves and bark debris, said to be like those of *Parotia lawesii* and *Lophorina superba*; two nests were built c. 10 m up in forked tree branch, a third c. 4 m above ground in climbing bamboo. Clutch 1 egg; in captivity, incubation 22 days (in one nest) and nestling period 26–27 days (at two nests).

Movements. No information.

Status and Conservation. Not globally threatened. Restricted-range species: present in Central Papuan Mountains EBA. CITES II. Common in some areas; sparse in others with apparently suitable habitat. Decline noted between early 1960s and 1970s in upper Kaironk valley, possibly a result of plume-hunting. In view of this species' reasonably large range and elevational distribution, there is no reason to believe that it is likely to become at risk in foreseeable future.

Bibliography. 16. Huon Astrapia

Astrapia rothschildi

French: Paradisier de Rothschild **Spanish**: Ave-del-paraiso de Rothschild
German: Blaubrust-Paradieselster

Other common names: Rothschild's Astrapia/Bird-of-paradise, Huon Bird-of-paradise

Taxonomy. *Astrapia rothschildi* Foerster, 1906, Rawlinson Mountains, north-eastern New Guinea. Monotypic.

Distribution. Huon Peninsula (Finisterre Mts, Saruwaged Range, Cromwell Mts, Rawlinson Mts), in NE New Guinea.

Descriptive notes. Male 69 cm, 186–205 g; female 47 cm, 143–200 g. Large astrapia with exceptionally long, broad tail markedly graduated. Male has entirely black head and nape with green-blue iridescence, notably on fine scale-like crown feathers; iridescent dark green hindneck and mantle feathers are plate-like, forming distinctive cowl, exposed bases broadly tipped iridescent magenta, more coppery red against nape; blackish back with olive-green sheen, blackish rump; black upperwing with blue-purple sheen; uppertail velvety black with bluish-purple to pinkish-purple sheens; breast like head, bordered below by strongly iridescent distinct fine coppery-orange gorget; silk-like feathers of lower breast and belly oily dark green, some larger plate-like feathers down breast side strongly iridescent and paler, lime-green; matt brownish-black thighs, vent and undertail-coverts; iris dark brown; bill shiny black; legs fleshy lead-grey. Female is much smaller than male, with wing and tail significantly shorter; plumage radically different, with slightest of dull blue iridescent sheen on head and upper breast, otherwise entirely sooty black except for fine, inconspicuous pale barring on abdomen and undertail-coverts. Juvenile undescribed; immature like adult female but slightly larger, lacking pale nape barring, with abdomen barring much reduced, blue iridescence on head increasing and abdomen barring decreasing with age; subadult male varies, like adult female with few feathers of adult male plumage intruding to like adult male but with few feathers of female-like plumage remaining, with age head becomes increasingly iridescent and barring on underparts becomes obscured by increasing blackish plumage; all rectrices grow progressively longer with increasing male age. Voice. Calls, including muffled scolding "jj, jj" or "jiw, jiw", resemble those of *A. stephaniae*; an adult male gave a 5-note call more melodious than that of a *Parotia* scream, but not the yelp of *A. stephaniae*.

Habitat. Middle montane, upper montane and subalpine forests, at 1460–3010 m. Display trees located on broad crests of ridges, often at edge of windfall clearing.

Food and Feeding. Little known. Diet fruits and animals. Seeks animal prey by biting and tearing at mosses on branches and twigs, and inspecting or probing knotholes. Group of four or five female-plumaged individuals may forage together.

Breeding. Egg-laying at least Oct–Nov; male with moderately enlarged gonads Mar and Oct and female with enlarged gonads Mar and Aug; display recorded only 31st Jan to 7th Feb. Courtship display involves low-intensity erect posture with tail-fanning, and high-intensity inverted posture with various tail movements; between displays males hop back and forth between adjacent perches. Nest a firm shallow cup mostly of vines, rootlets and creepers on conspicuous foundation of large, strong, broad leaves and leaf pieces, leaf skeletons and moss, with odd pieces of moss on outside of structure (mostly on rim); one nest had some fine hair-like rootlets as egg-cup lining. Clutch 1 egg. No other information.

Movements. No information.

Status and Conservation. Not globally threatened. Restricted-range species: present in Adelbert and Huon Ranges EBA. CITES II. A little-known species; common at Ogeranang (Rawlinson Mts), at 1600 m, in 1977. Assumed not to be under any immediate threat, but very few data, and has limited range. Survey required of current distribution, habitats and status.

Bibliography. Crandall (1932), Draffan (1977a), Frith (1971), Frith & Beehler (1998), Frith & Frith (1997b), Heads (2002), Lambley (1990), Mayr (1931c), Schmid (1993).

PLATE 23

inches 4
cm 10

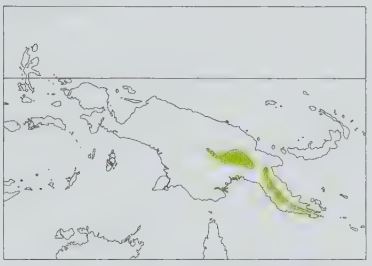
Genus *PAROTIA* Vieillot, 1816

17. Western Parotia

Parotia sefilata

French: Paradisier sifilet **German**: Strahlenparadiesvogel **Spanish**: Ave-del-paraíso de Pennant
Other common names: Arfak Parotia/Six-wired Parotia/Six-wired Bird-of-paradise, Arfak/Greater Six-plumed Bird-of-paradise

Taxonomy. *Paradisea sefilata* J. R. Forster, 1781, Arfak Mountains, New Guinea.
Hybridization with *Paradigalla carunculata* and *Lophorina superba* recorded. Monotypic.
Distribution. Vogelkop (Tamrau Mts, Arfak Mts) and Wandammen Peninsula (Wondiwoi Mts), in NW New Guinea.



Descriptive notes. Male 33 cm, 175–205 g; female 30 cm, 140–185 g. Large parotia with medium-length tail. Male is entirely velvety jet-black, head adorned with erectile triangular frontal crest of elongate finely pointed silver feathers atop forecrown, rest of crown with dark coppery-bronze sheen, broad nuchal bar of intensely iridescent blue scale-like feathers anteriorly and violet-purple to red-purple feathers with magenta hues posteriorly; from behind each eye, amid ear-tuft of elongate narrowly pointed feathers, three long erectile wire-like bare occipital plumes with near-circular spatulate tips of normal feather webs; upperparts, including upperwing and tail, with dull but rich coppery-bronze sheen; chin and throat velvety blackish with slightest iridescence of coppery bronze to rich purple, grading into otherwise discrete breast shield of large intensely iridescent scale-like feathers; remaining underparts jet-black with plum-purple sheen; iris cobalt-blue with pale yellow outer ring; bill shiny black, mouth greenish-yellow; legs purplish lead-grey. Female is smaller than male (almost no overlap in wing length), lacks head plumes and iridescence, head blackish with slight chestnut lustre, broad pale greyish submoustachial stripe flecked blackish-brown, bold blackish malar stripe (sometimes incomplete at rear), very faint superciliary stripe of tiny pale greyish-buff central feather streaks, upperparts, upperwing and tail olive-brown, paler chin, throat and underparts regularly barred blackish. Juvenile is like female, but with rufous-red outer and inner edgings on flight-feathers and upperwing-coverts; immature male like adult female; subadult male variable, like adult female with few adult male feathers intruding to like adult male but with few feathers of female-like plumage remaining; male tail length decreases slightly with age, shape of outer primaries of immature male almost normal, but in earliest subadult plumage outer two primaries modified (as in adult male). Voice. Harsh "gned gned" or "gnaad gnaad", and other notes like those of a cockatoo (*Cacatua*). Adult male at court gives loud squawking notes, but those in female-like plumage only quiet high-pitched mewing sounds.
Habitat. Middle montane forests and adjacent well-established secondary forest with abundant small saplings; 1100–1900 m.
Food and Feeding. Fruits and arthropods; relative preference for each not known. Probes for arthropods in bark and epiphytes on underside of branches. Joins mixed-species foraging flocks.
Breeding. Few data. Male gonadal activity indicates breeding about Jul–Jan; display season early Aug to late Oct. Polygynous, with presumed promiscuous males seasonally maintaining terrestrial courts, but not known if solitary or in exploded lek; female builds and attends nest alone. Male clears leaves and debris from ground court c. 2 m in diameter, with branches up to c. 3–4 m above it, branches often stripped of leaves by males for display perches; courtship involves static and leg-flexing postures with complex movements of flank plumes, pectoral shield, mantle cape, nuchal crest and occipital plumes; display starts on horizontal perch, male hopping sideways back and forth along perch while repeatedly flicking wings half-open and fanning tail, before hopping to court to perform complex dance involving Upright Sleeked Pose, Initial Display Bow and Ballerina Pose phases, similar to those of *P. lawesii*; female solicits by squatting low on perch, with beak agape, and fluttering wings. No information on nest and nest-site, eggs, incubation and nestling care.
Movements. No information.
Status and Conservation. Not globally threatened. Restricted-range species: present in West Papuan Highlands EBA. CITES II. Few recent data. Common in S Arfak Mts (at Ditschi and Siwi), and even more so in Wandammen Peninsula (Wondiwoi), in late 1940s; common in Arfak Mts mid-Aug 1995. Probably not currently at any risk, but limited distribution dictates need for monitoring.
Bibliography. Bergman (1957c, 1958), Crandall (1932), Diamond (1986a), Frith & Beehler (1998), Frith & Frith (1997b), Gyldenstolpe (1955b), Hartert (1930), Heads (2002), Johnas (1932), Mayr & Meyer de Schauensee (1939), McCarthy (2006), Stresemann (1931).

18. Lawes's Parotia

Parotia lawesii

French: Paradisier de Lawes **Spanish**: Ave-del-paraíso de Lawes
German: Blaunacken-Paradiesvogel
Other common names: Lawes's Six-wired Bird-of-paradise, Lawes's Six-plumed Bird-of-paradise; Eastern/Helena's Parotia (*helenae*)

Taxonomy. *Parotia lawesii* E. P. Ramsay, 1885, Astrolabe Mountains, subsequently considered to be Aruma Apa-Maguli Range, Owen Stanley Range, New Guinea.
Intergeneric hybridization with *Paradisaea rudolphi* recorded; no records of hybridization with sympatric *P. carolae*. Race *helenae* sometimes treated as a separate species. Additional proposed races *exhibita* (described from Mt Hagen area) and *fuscior* (Herzog Mts) synonymized with nominate. Two subspecies recognized.
Subspecies and Distribution.
P. l. lawesii E. P. Ramsay, 1885 – highlands of EC New Guinea E to S slopes of SE peninsula.
P. l. helenae De Vis, 1897 – N watershed of peninsular SE New Guinea (from Waria SE to Milne Bay), possibly also S watershed in extreme SE.

Descriptive notes. Male 27 cm, 153–195 g; female 25 cm, 122–169 g. Broad-winged and short-tailed parotia. Male nominate race is velvety jet-black, head adorned with erectile silver narial tuft atop basal half of upper mandible, immediately behind this a frontal crest of coppery-brown feathers, and with narrow nuchal bar of intensely iridescent blue to pink-purple scale-like feathers; behind each eye, from amid ear-tuft of elongate pointed feathers, three long erectile wire-like black occipital plumes with roughly circular spatulate tips; mantle and back with silk-like sheen that appears coppery bronze and/or green in some lights, remaining upperparts, including tail, velvety jet-black with coppery-bronze sheen; primaries paler, more brownish-black, but exposed leading edges dully iridescent green in some lights; velvety jet-black chin and throat with iridescent sheen of purple, this grading into otherwise discrete breast shield of large intensely iridescent scale-like feathers bronzed metallic emerald-green to greenish-yellow and, in some lights, purple-magenta to bluish-violet (jet-black feather bases visible at lower side of shield), remaining underparts jet-black with coppery sheen; iris cobalt-blue with narrow pale cream-yellow outer ring (but bird can alter colour, from mostly blue to mostly yellow); bill shiny black, mouth lime-yellow to lime-green; legs purplish lead-grey. Female is smaller than male, lacking head plumes and iridescence, has distinctive brownish-black head with contrasting paler submoustachial stripe, dark malar stripe, upperparts mostly chestnut-brown, underparts regularly barred blackish, bill brownish-black. Juvenile undescribed; immature male like adult female but iris duller, more greyish to brownish; subadult male variable, like adult female with few adult male feathers intruding to like adult male but with few female-like feathers remaining, adult head plumage acquired first, when wings and tail similar to those of adult, and breast shield has coppery sheen, rather than clearer green of fully plumaged male; male tail length decreases slightly in length with age. Race *helenae* differs from nominate in having narial tuft of adult male bronzed brown, not silvery white, and female dorsal plumage slightly less russet. Voice. Possible advertisement a loud, raucous, growling, metallic and rasping or grating "graannh-graannh" or unpleasant "kraanh kraanh", sounding anguished and often questioning, the note given up to six times. A call heard on Mt Missim was "whennh", like that of *Cicinnurus magnificus*. Race *helenae* in Mambare valley (above Kanga, at 1000 m) heard to give double harsh "kschack kschack". Males give nasal twittering at courts; prior to display a faint short "sip".
Habitat. Middle montane forest, including primary mixed oak forest, disturbed forest, also secondary growth and large to small remnant forest patches within areas of extensive village gardens; 500–2300 m, mostly 1200–1900 m.
Food and Feeding. Mostly fruits; also some animals, i.e. arthropods and skinks (Scincidae). Leaves eaten in captivity. Takes animal prey from epiphytes, dry tree limbs and foliage 20–30 m above ground. One individual in female-like plumage foraged for arthropods in a mixed-species flock of which *Paradisaea raggiana* also a member.
Breeding. Season at least Jun–Jan; egg-laying early Dec (one nest), a nest with chick 5–6 days old in late Nov, males with gonads moderately enlarged Jan–Jul and much enlarged Aug–Dec, females with moderately enlarged oocytes Aug–Dec. Polygynous, with promiscuous males seasonally maintaining terrestrial courts dispersed as exploded leks, female builds and attends nest alone. Courts of 25 males were 5–350 m (average 77 m) apart, males of closer ones (15 m) being in visual and/or auditory (20–70 m) contact, each court maintained by single adult (infrequently, a male may have two immediately adjacent courts), male advertisement-sings from court perches or canopy above, court size variable, 0·5–20 m²; male cleans court of leaves and debris and decorates it with sloughed snakeskin, mammal dung, chalk, fur, feathers and bone (may steal decorations from neighbouring courts), decorations not used in display but removed by females throughout nesting season; some females show fidelity to particular male, returning to same individual to mate year after year; neighbouring males disrupt each other's courtship; courtship involves static and leg-flexing postures with complex movements of flank plumes, pectoral shield, mantle cape, nuchal crest and occipital plumes; male performs Bounce Display on court perch as female approaches (analogous to Hopping-on-the-spot Display of *P. carolae*); ground display a complex dance involving Upright Sleeked Pose, Initial Display Bow, Ballerina Pose, and Back–forward Dance phases, male typically lunges across court to a female prior to copulation; complete sequence consists of danced ritualized steps and body movements accompanied by intricate feather manipulations. Nest like that of *Manucodia*, one described as an open shallow structure of fern tendrils and creeping-fern stems worked together with a few green fern fronds on outside, lined with fine tendrils, another was large and bulky but shallow; placed c. 5–12 m above ground in canopy foliage or vine tangle. Clutch 1 egg; no information on incubation and nestling periods. An adult-plumaged male recaptured at point of original capture more than 8 years later, and thus more than 15 years old.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in Central Papuan Mountains EBA. CITES II. Common in Tari Valley and fairly common in Owen Stanley Mts. On Mt Missim, 28 courts of 25 males were in area of c. 4 km² and three other males called regularly but apparently lacked a court. Although this species inhabits forest at elevations settled by humans, it appears not to be under any current threat.
Bibliography. Anon. (1989), Beehler (1983b, 1989a), Beehler & Pruett-Jones (1983), Coates (1990), Coates *et al.* (1970), Crandall (1931), Diamond (1972), Frith, C.B. & Beehler (1998), Frith, C.B. & Frith (1981, 1996a, 1997b), Harrison & Frith (1970), Mack & Wright (1996), Majnep & Bulmer (1977), Mayr & Rand (1937), McCarthy (2006), Pratt & Stiles (1985), Pruett-Jones (1985), Pruett-Jones & Pruett-Jones (1988b, 1990), Salvadori (1896), Schodde & McKean (1972, 1973b), Scholes (2008b, 2008c).

19. Wahnes's Parotia

Parotia wahnesi

French: Paradisier de Wahnes **Spanish**: Ave-del-paraíso de Wahnes
German: Wahnesparadiesvogel
Other common names: Wahnes's Six-wired Bird-of-paradise/Parotia, Wahnes's Six-plumed Bird-of-paradise, Huon Parotia

Taxonomy. *Parotia wahnesi* Rothschild, 1906, Rawlinson Mountains, New Guinea.
Monotypic.

On following pages: 20. Carola's Parotia (*Parotia carolae*); 21. Foja Parotia (*Parotia berlepschi*); 22. King of Saxony Bird-of-paradise (*Pteridophora alberti*).

Distribution. Adelbert Range and Huon Peninsula (Finisterre Range, Saruwaged Range, Cromwell Mts, Rawlinson Mts), in NE New Guinea.

Descriptive notes. Male 43 cm, 170–172 g; female 36 cm, 144–154 g. Large parotia with long, wedge-shaped tail often cocked slightly upward or to the side. Male is entirely velvety jet-black, head decorated with distinctively large erectile narial tuft of elongate coppery bronzed feathers and narrow nuchal bar of intensely iridescent blue to pink-purple scale-like feathers; behind each eye, from amid ear-tuft of elongate narrowly pointed feathers, three long erectile wire-like bare occipital plume shafts with spatulate tips of normal black feather web; mantle to uppertail with slight plum-purple sheen; velvety black chin and throat with slight purple iridescence, this grading into otherwise discrete breast shield of large scale-like feathers intensely iridescent bronzed emerald-green to green-yellow and, in some lights, purple, magenta to bluish-violet (jet-black feather bases visible on lower side of shield), remaining underparts jet-black with plum-purple sheen; iris cobalt-blue, comparatively broad pale greenish-cream outer ring; bill shiny black; legs purplish lead-grey. Female is smaller than male (no overlap in wing length), lacking head plumes and iridescence; cryptically coloured brown above, with brownish-blackish head, off-white superciliary stripe originating from behind eye, and broad submoustachial stripe flecked blackish-grey, bordered below by comparatively narrow blackish malar stripe, chin and throat whitish-grey, flecked and barred brownish-black, grading to remaining underparts of brown-cinnamon, uniformly barred brownish-black. Juvenile undescribed; immature male like adult female, but iris as adult male; first-year plumage has pointed rectrices and lacks indentation on ninth primary (present on adult); male tail length slightly decreases with age. VOICE. Male calls at court include harsh raspy "yeah-yeah" or "yack-yack", or a "khh kaakkk" with quality like that of a cockatoo (*Cacatua*), possibly as advertisement. Similar harsh screeching transcribed as sharp and dry "wetch" or "snatch" given in twos or as part of longer, more complex song based on them; also nasal twittering, and single loud nasal "garr" note. Scream of adult male described as essentially like that of *P. lawesii*, but slightly higher-pitched, quieter and given more often. Thin and soft cheeping notes and rolling trill-like calls given by male descending to court from perches above. Whistling wing noise produced as birds fly about their court, and ticking sound produced as wings flicked during perched display.

Habitat. Middle montane forests; 1300–1600 m in Adelbert Range and 1100–1700 m in Huon Peninsula. Display courts tend to be adjacent to or within windfall gaps, and thus beneath a hole in canopy; two were c. 5 m apart in thick shrubbery beneath small canopy gap on broadly rounded ridge at 1590 m in mixed primary montane forest.

Food and Feeding. Little known. Fruits and insects recorded as eaten, but relative preferences not known; leaf-eating recorded in captivity. Forages actively in subcanopy. Seeks insects by probing in moss and epiphytes.

Breeding. Season at least Nov–Feb, but data few; display period centred on dry season, waning court attendance noted in Jan. Polygynous, promiscuous males seasonally maintaining terrestrial display court on flat parts of gently sloping hillside or flat ridgetop, courts solitary but within auditory range of others, thus possibly as exploded lek; female builds and attends nest alone. Male cleans court of leaves and debris beneath at least one horizontal perch, leaves removed from saplings within court; courtship involves static and leg-flexing postures, with complex movements of flank plumes, pectoral shield, mantle cape, nuchal crest and occipital plumes; basic display pattern similar to that of *P. lawesii* but with some variation, display differs mainly in that it is preceded by little court-clearing, narial tufts opened but no crest to extend forwards to cover them, occipital plumes are thrown forwards before bird stands erect, and it uses tail and wings when crouched; male performs a Horizontal Perch Pivot as enticement followed by Horizontal Perch Sidle and Ballerina Dance; as with congeners, courtship highly complex, involving eleven diagnosable behaviour patterns, including some of up to 46 elements, within highly structured framework. In captivity, clutch 2 eggs, laid on consecutive days. No other information.

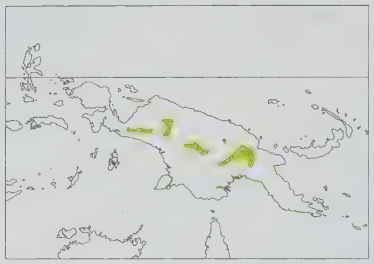
Movements. Presumed resident

Status and Conservation. VULNERABLE. Restricted-range species: present in Adelbert and Huon Ranges EBA. CITES II. Very poorly known. Uncommon to rare in Adelbert Range; locally common in Cromwell Mts. Estimated global population in range c. 2500–10,000 individuals. Declining as a result of increasing human population, leading to habitat loss. Most recent records from Satop (Cromwell Mts), where three individuals observed during three days in 1994; much scarcer than *Astrapia rothschildi* (16 seen in same three-day period). Although human population in region relatively small, it is expanding rapidly, resulting in increasing clearance of forest within this species' elevational range, which is the same as that preferred by local people for settlement and agriculture. Comprehesive survey required.

Bibliography. Anon. (2008j), Butchart & Stattersfield (2004), Coates (1990), Crandall (1940), Frith & Beehler (1998), Frith & Frith (1979, 1997b), Gilliard (1969), Heads (2002), Mackay, M.D. (1990), Mayr (1931c), Schodde & Mason (1974), Scholes (2008a), Stattersfield & Capper (2000), Stresemann (1924).

20. Carola's Parotia

Parotia carolae



French: Paradisier de Carola **German**: Carolaparadiesvogel **Spanish**: Ave-del-paraíso de Carola
Other common names: Queen Carola's Six-wired Bird-of-paradise, Queen Carola's Parotia

Taxonomy. *Parotia carolae* A. B. Meyer, 1894, "Amberno River" [Mamberamo River]; error = Weyland Mountains, New Guinea.

Forms a superspecies with *P. berlepschi*, previously treated as conspecific. Intergeneric hybridization with *Lophorina superba* recorded; females of the two exhibit parallel geographical variation, one explanation being that smaller *L. superba* mimics larger and more aggressive present species. Five subspecies recognized.

Subspecies and Distribution.

P. c. carolae A. B. Meyer, 1894 – Weyland Mts E to Wissel Lakes (Paniai) region, in W New Guinea.
P. c. meeki Rothschild, 1910 – Snow Mts, from E of Wissel Lakes and S of Doorman Mts (N scarp facing Mamberamo R), E to C New Guinea (around W edge of Victor Emanuel Range).
P. c. chalcothorax Stresemann, 1934 – Doorman Mts, just S of Idenburg R (Taritatu R), in W New Guinea.
P. c. chrysenia Stresemann, 1934 – N scarp of C Cordillera, including Lordberg, Hunstein Mts and probably Schrader Range, also N scarp of Bismarck Range, in E New Guinea.
P. c. clelandiae Gilliard, 1961 – from C New Guinea SE probably to S watershed of Eastern Highlands (E at least to Crater Mt).

Descriptive notes. Male 26 cm, 205 g (one *clelandiae*); female 25 cm, 110–163 g. Distinctive short-tailed parotia. Male nominate race has velvety jet-black head with coppery-bronze sheen, short erectile blackish-bronzed frontal crest tipped silver-white, jet-black elongate and vertically raised loral and foreface feathering from nostril to above eye; eye broadly encircled by iridescent coppery-gold feathering; feathering on slightly concave crown similar to that around eye, and immediately behind this a narrow nuchal bar of highly iridescent scale-like feathers that appear blue-green to purple and/or magenta; behind each eye, from amid ear-tuft of elongate narrowly pointed feathers, three long erectile wire-like occipital plumes with relatively small spatulate tips; mantle to uppertail velvety jet-black with coppery-bronze sheen, including upperwing the same except for primaries and coverts, which brownish-black; chin dusky olive-brown, smudged blackish, with paler tips of elongate "whiskers" surrounded by malar area and throat of buff with golden sheen; lower central throat more whitish, flecked cinnamon, with fine long whiskers on each side, grading into otherwise discrete breast shield of large scale-like feathers with intense iridescence of bronzed yellow-green and/or magenta to pink (jet-black feather bases visible on lower side of shield); remaining central underparts, to undertail-coverts, blackish-brown with iridescent lustrous coppery sheen, becoming browner to dark reddish-brown adjacent to extensive patch of cotton-white elongate and inwardly curving flank plumes; iris sulphur-yellow; bill black, mouth colour apparently pale green; legs blackish-grey. Female is smaller than male (notably in wing length) but with tail longer; lacks head plumes and iridescence; plumage very different, brownish to grey-brown head with broad supercilium, moustachial and submoustachial stripes dirty white, flecked olive-brown, some paler flecks extending onto anterior ear-coverts, malar area olive-brown, upperparts and tail brown, upperwing with ochraceous chestnut area on exposed parts of flight-feathers and outer greater coverts, chin faintly barred greyish-brown, throat paler, underparts buff with blackish-brown barring; iris pale grey or cream to yellow (difference possibly age-related), but confirmation required. Juvenile undescribed; immature male like adult female, but iris pale grey; subadult male variable, like adult female but with few feathers of adult male plumage intruding, initially on head, to like adult male with few feathers of female-like plumage remaining; male tail length decreases considerably with age. Race *meeki* is like nominate in size and appearance, but bill slightly larger, and chin and side of throat blackish; *chalcothorax* is like nominate, but occipital plumes significantly longer, upperparts with bright coppery sheen, underparts more coppery, and long loral feathering more brownish (less intensely black); *clelandiae* is like nominate, but upperparts darker, more jet-black (less brown), and on average larger, bill slightly shorter, and with longer occipital plumes (almost no overlap in length with nominate); *chrysenia* has tail longer than all other races, occipital plumes longer than all except *chalcothorax*, said to differ from nominate in having long black loral feathering with coppery sheen (like eyering but darker), but several specimens lack this (their lores being pure black). Females vary subtly with race, notably in extent of pale facial stripes and in overall colour saturation; further study required. VOICE. Loud advertisement song "scree scree scree, oo-wit, oo-wi-oo", first 3 notes short and grating, last two phrases powerfully whistled and low-pitched, first of which (of 2 notes) rising and second (3 notes) a repetition of the first and reminiscent of human wolf-whistle; also characteristic of male is upward-inflected "kwoi", given singly or up to four times (typically two times); also grating "chack", bell-like squeaking call, and loud, grating "cor cor cor". Variety of other notes, including short chips, squeaks and chortles, a bleating whistle, a metallic note suggestive of *P. lawesii*, and some quiet musical notes. Duetting by males common; calls of other bird species and of micro-hylid frogs possibly mimicked. Adult male produces clacking sound with wings.

Habitat. Primary and secondary middle montane forests, also regrowth and abandoned gardens; 1100–2000 m, mainly 1450–1800 m.

Food and Feeding. Fruits and animals, but relative preferences unknown; leaf-eating recorded in captivity. Forages mainly in upper and middle storeys of forest; groups of adult males and individuals in female-like plumage recorded in fruiting trees and elsewhere. Seeks insects by probing.

Breeding. Few data; female gonadal activity indicates breeding in at least Sept–Oct; display season in E New Guinea Jun, Jul and Oct (dry season) in Jimi R area and Oct–Dec in Herowana area. Polygynous, promiscuous males seasonally maintaining terrestrial courts, dispersed to form exploded leks; female builds and attends nest alone. Courtship involves static and leg-flexing postures, with complex movements of flank plumes, pectoral shield, mantle cape, nuchal crest and occipital plumes, both on court perches and on court floor (recent detailed field research revealed courtship of this species to be as complex as that of any other avian species, involving 58 distinct elements); male performs a Hopping-on-the-spot-like display on a court perch as female approaches (analogous to Bounce Display of *P. lawesii* and *P. wahnesi*), as well as alternate "sideways-facing" displays; basic pattern on ground initially like that of *P. lawesii* up to Initial Display Bow; courtship elements include Ballerina Display, and some feature the white area of flank plumes and fine detail of elaborate head plumage not found in other adult male pariotias. No information on nest, nest-site, eggs, incubation and nestling periods, and other aspects of breeding.

Movements. Presumed resident.

Status and Conservation. Not globally threatened. CITES II. Fairly common and widepsread; reasonably common on S slopes of Bismarck Range. Adult males thought to be outnumbered by female-plumaged birds (by ratio of 1:3) in Ok Tedi area of C New Guinea. No evidence of any current threat, nor of any likelihood that this species will become at risk in immediate future.

(1968), Frith, C.B. & Beehler (1998), Frith, C.B. & Coles (1976), Frith, C.B. & Frith (1996b, 1997b), Gilliard & LeCroy (1961), Gyldenstolpe (1955a), Healey (1976, 1980), Junge (1953), Mayr (1962d), McCarthy (2006), Mees (1964a), Rothschild (1931), Scholes (2006, 2008b).

21. Foja Parotia

Parotia berlepschi

French: Paradisier de Berlepsch **Spanish**: Ave-del-paraíso de Berlepsch
German: Berlepschparadiesvogel
Other common names: Berlepsch's Six-wired Bird-of-paradise, Berlepsch's/Kleinschmidt's Parotia

Taxonomy. *Parotia berlepschi* O. Kleinschmidt, 1897, New Guinea.

Forms a superspecies with *P. carolae*, and previously treated as conspecific. Monotypic.

Distribution. Foja Mts, in W New Guinea.

Descriptive notes. c. 25 cm. Male has blackish head and body, with nape, upper neck and mantle heavily bronzed; short erectile frontal crest tipped silver-white, elongate and vertically raised loral

and foreface feathering from nostril to above eye tipped whitish at rear (above eye), eye narrowly encircled by dark iridescent golden-brown feathering; crown with dark golden yellowish-brown iridescence, and similar but darker sheen on ear-coverts, nape and hindneck; behind each eye, from amid ear-tuft of elongate narrowly pointed feathers, three long erectile wire-like occipital plumes (12 cm long) with small spatulate tips; chin, cheek and throat black (slight reddish-brown iridescence in some lights), lower central throat slightly paler, grading into otherwise discrete breast shield of scale-like feathers with iridescence of bronzed yellow-green; rest of central underparts blackish-brown, inwardly curving flank plumes black, brown and white; iris cerulean grey-blue; bill dark grey; legs blackish. Differs from similar *P. carolae* mainly in having slightly shorter bill with upper mandible more decurved, cheeks and chin to throat black, nape and hindneck with golden-brown sheen, elongate loral feathering without whitish terminal tips and less inwardly curled, occipital plumes slightly longer, iris blue (not yellow). Female is smaller than male, lacks occipital plumes and iridescence, has brown upperparts, brownish head and upperparts with broad supercilium, moustachial and submoustachial stripes white, lightly flecked olive-brown, some paler flecks extending onto anterior ear-coverts, malar area olive-brown, chin faintly barred greyish-brown, throat whitish with tiny brown markings, rufous area on exposed parts of flight-feathers and outer greater coverts, and finely dark-barred whitish underparts. Immature male has slightly more extensive whitish on elongate loral feathering, tail longer than adult male. VOICE. Little information. Primary contact song said possibly to be distinct from that of both *P. carolae* and *P. lawesii*; as these exhibit considerable vocal variation, fieldwork and confirmation required.

Habitat. Montane wet forest, at c. 1100–2000 m.

Food and Feeding. No information.

Breeding. No information.

Movements. Presumably resident.

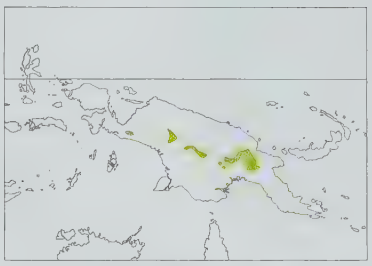
Status and Conservation. Not assessed. CITES II. Until recently was treated as a race of more widespread *P. carolae*. Was for a long time known only from a handful of specimens, and virtually unknown in the field; female observed in Foja Mts in 1985. No further observations until, in Dec 2005, an international team of eleven scientists (from USA, Australia and Indonesia) rediscovered this parotia, among other little-known and new species, in Foja Mts. Habitat within its very small range is currently secure, and area is mostly uninhabited by humans. In view of this species' remote, isolated and highly restricted range within W New Guinea, it would be potentially at risk were any change in status of its presently undisturbed habitat to occur. Extensive further fieldwork and surveys are required.

Bibliography. Beehler (2008), Beehler *et al.* (2007), Kleinschmidt (1897), Rothschild (1908).

Genus *PTERIDOPHORA* A. B. Meyer, 1894

22. **King of Saxony Bird-of-paradise**

Pteridophora alberti



French: Paradisier du Prince Albert **German**: Wimpelträger **Spanish**: Ave-del-paraíso de Alberto
Other common names: Enamelled Bird-of-paradise, The Enamelled Bird

Taxonomy. *Pteridophora alberti* A. B. Meyer, 1894, mountains on Ambernoh River [Mamberamo River] = apparently Weyland Mountains, New Guinea.

Birds from Schraderberg (in Sepik Mts) described as race *buergersi* and birds from S slope of Mt Hagen as *hallstromi*, but both considered inadequately differentiated from those in rest of species' range. Treated as monotypic.

Distribution. C Cordillera of New Guinea from Weyland Mts E, discontinuously (including Snow Mts, Star Mts, Victor Emanuel Range, Mt Bosavi, Mt Hagen, Mt Giluwe, Ambua Range, Kubor Range, Schrader Mts and Bismarck Range), to Kratke Range.

Descriptive notes. Male 22 cm, 80–95 g; female 20 cm, 68–88 g. Male has head, mantle and back velvety black with iridescent sheen of bronzed green, notably on elongated "cape" feathers of mantle; behind each eye, from amid an ear-tuft of elongate feathers, a uniquely modified occipital

plume (up to 50 cm long) of bare central feather shaft with 40–50 plastic-looking "flags" decorating outer side only, the upper surface of each "flag" an enamel-looking glossy sky-blue to true blue and the underside dark brown; rump, uppertail-coverts and uppertail matt black, washed dark brown, upperwing similar but exposed bases and broad leading edges of secondaries and all except outermost two primaries cinnamon; chin and throat as upper head, but large and sparse scale-like feathers at centre and lower border of black throat narrowly tipped iridescent green-blue to purple (suggesting a faint breast shield); remaining underparts dark yolk-yellow, brighter on breast, paler and duller on vent and undertail-coverts, with creamy feathering in flanks; iris dark brown; bill black, mouth pale to rich aqua-green; legs dark brown-grey. Female is smaller than male, lacks occipital plumes, has radically different plumage, most of head and entire upperparts grey to sooty grey, darker and browner on lower back, with chin, throat and neck sides buffy grey with broad dark brownish-grey barring (scalloped appearance), and breast to vent whitish, heavily marked with open, shallow, blackish-brown chevrons, undertail-coverts contrastingly ochraceous. Juvenile undescribed; immature male resembles adult female, but upperparts paler, more uniformly brownish-grey to grey (less scalloped), underparts whiter (less dark barring and spotting), iris red-brown; subadult male variable, like adult female with few feathers of adult male plumage intruding to like adult male with few female-like feathers remaining, first sign of adult plumage is black nasal-tuft feathering and darker primaries with orange (not grey) concealed bases, followed by more black head plumage and some yellow in breast; male tail length decreases slightly with age. VOICE. Adult male gives unique advertisement song, a dry rattling jumble of insect-like notes poured out at rapid pace and suggestive of bad radio static, which briefly turns into a twittering at climax. Adult male courtship vocalizations consist of a subsong of hissing sounds within which soft high-pitched clucks, chatters, mews and squeaks are produced; some vocal avian mimicry may be incorporated. Young male repeats monotonous jeering 4–5 notes, the series rising slightly in pitch, each note harsh, rolling and downslurred, "chweer chweer chweer chweer". Immature male (in female-like plumage) also gives distinctive scolding note and is noisier than adult male.

Habitat. Middle to upper montane forest and forest edge, also lightly disturbed areas of forest around hunting lodges and tracks; 1400–2850 m, mainly 1800–2500 m.

Food and Feeding. Mostly fruits (drupes, notably those of *Timonius belensis*); also insects and spiders (Araneae). Forages mostly alone, at all levels down to shrubbery near ground. Seeks invertebrates by tearing and probing at mosses and lichens.

Breeding. Breeding possible in all months, peak about Jul–Feb; one nest found, constructed in Dec, egg-laying early Jan (Tari Gap, in EC New Guinea); display at least Sept–Apr. Polygynous, solitary promiscuous male advertisement-singing from several traditional emergent perches; female builds and attends nest alone. Male's song perches regularly dispersed, on Mt Hagen apparent territory of adult male in mid-Apr c. 137 m in diameter, male calling from emergent trees 30–37 m tall, but territorality remains to be confirmed; display perches in forest substage (2–15 m high), three groups of 3–7 males reported as displaying at inter-group distances of c. 8–16 km and suggestive of exploded leks (confirmation required, as other observers report solitary males throughout extensive habitat); courtship involves initial canopy advertisement-singing and display from perches in emergent trees, during which male performs simple displays with mouth gaping and movement of occipital plumes, then descends to understorey vine perch to perform Understorey Bouncing Display with leg-flexing (and continuous subsong), wing-shivering and erection of mantle cape, breast shield and head feathering, and occipital plumes raised to c. 45° and held widely apart; copulation follows. Only one nest found, a shallow open cup of loosely accumulated fine stems of epiphytic orchid and fresh green "comb-tooth" fern fronds, egg-cup interior sparsely lined with fine epiphytic orchid stems or tendrils, placed 11 m above ground in large trifurcate upright branch fork of *Timonius belensis* tree; contained 1 egg, incubation period more than 22 days; no information on nestling period.

Movements. Presumably resident.

Status and Conservation. Not globally threatened. Restricted-range species: present in Central Papuan Mountains EBA. CITES II. Widespread, and often common. Common at 2745 m and moderately common at 2105–2560 m in Okbap area, in Star Mts; common in Tari Gap; uncommon on Mt Hagen. Three males called from display trees within 1·6 km of each other; c. 1 bird/4·5 ha at Tsuwenkai, in Bismarck Range. Some areas of extensive and apparently suitable habitat appear to lack adult males, while in others a number of males sing from perches dispersed within auditory contact of one another. Appears not likely to be at any risk in the near future.

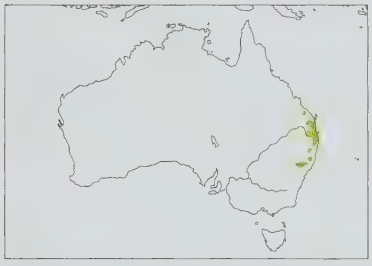
Genus *PTILORIS* Swainson, 1825

23. Magnificent Riflebird

Ptiloris magnificus

French: Paradisier gorge-d'acier **Spanish**: Ave-del-paraíso Goliazul
German: Prachtparadiesvogel
Other common names: Albert Rifle-Bird, Prince Albert's Riflebird; Growling/Eastern Riflebird (*intercedens*)

Taxonomy. *Falcinellus magnificus* Vieillot, 1819, Dorey, Vogelkop, New Guinea.
Sometimes thought to form a superspecies with *P. victoriae*, and has been considered conspecific. Intergeneric hybridization with *Lophorina superba*, *Seleucidis melanoleucus* and *Paradisaea minor* recorded. Race *intercedens* sometimes treated as separate species. Three subspecies currently recognized.
Subspecies and Distribution.
P. m. magnificus (Vieillot, 1819) – W & C New Guinea from Vogelkop E to Wewak area in N and, in S, to Purari R.
P. m. intercedens Sharpe, 1882 – E New Guinea SE from about Wanuma (Adelbert Mts).
P. m. alberti Elliot, 1871 – Albany I and patchily on adjacent Cape York Peninsula (S to Weipa area on W coast and to Rocky R area of McIlwraith Range on E), in NE Australia.



Descriptive notes. Male 34 cm, 143–230 g; female 28 cm, 94–185 g. Fairly large paradisaeid with long, decurved bill and short, rather square-ended graduated tail. Male nominate race has velvety jet-black head decorated from lores to nape with scale-like metallic green-blue feathers washed purple and magenta; sides of face, chin and throat dully iridescent violet-purple and/or (rarely) olive-green; mantle to uppertail-coverts, lesser wing-coverts and tertials velvety jet-black with strong iridescence of violet-purple with magenta wash (and, rarely, blues and/or olive-green sheen visible), greater coverts, alula and exposed flight-feathers iridescent dark blue; uppertail velvety jet-black, iridescent deep blue sheen on basal outer edges of webs, but shorter central feather pair highly iridescent metallic dark blue-green to green-blue with violet-purple and/or magenta sheens; narrow area on central throat broadening to upper breast decorated with extensive delta-shaped breast shield of scale-like intensely iridescent green-ish-blue feathers, in some lights washed with violet-purple and/or magenta sheens; lower shield edge bordered by narrow band of velvety jet-black feathers with violet-purple sheen, and below this even narrower band of iridescent bronzed yellow-green; remaining underparts, including elongate filamental flank plumes (extending past tail), matt brownish-black, overwashed with dully iridescent maroon to carmine and/or (rarely) olive-green, particularly against breastband; vent and undertail-coverts, also tips of longer flank plumes, matt blackish; iris dark brown; bill black, gape pale yellow, mouth pale lemon-yellow to lime-green; legs dark leaden grey to blackish. Female is smaller than male, with slightly shorter bill (unlike congeners) and, especially, shorter wing (no overlap between sexes); plumage radically different, cryptically brown and rufous above, with broad supercilium and malar stripe dirty white, finely flecked variably buff to brown, chin whitish to greyish-white, throat flecked and spotted blackish-grey, these marks grading to fine barring on breast and then to broader and paler barring on greyish-white remaining of underparts. Juvenile has plumage soft, more downy, dark bars on breast and belly sooty brown and wider apart, crown and upperparts paler and more rufous; immature male like adult female; subadult variable, like adult female with few feathers of adult male plumage intruding to like adult male with few feathers of female-like plumage remaining; with increasing age male acquires progressively shorter tail, central retrices decreasing in length at greater rate than rest. Races differ only minimally, mainly in biometrics: *alberti* is like nominate, but base of culmen slightly less feathered, bill more curved, shorter wing, tarsus and tail, male with only faint maroon sheen below, relatively shorter central pair of rectrices, female browner (less rufous-tinged) above and lacks speckling on upper throat; *intercedens* is like nominate, but bill on average shorter, base of culmen with more feathering, flank plumes shorter (not extending beyond tail). Voice. Races differ in advertisement vocalizations of male: nominate race (W & C New Guinea) and *alberti* (NE Australia) a powerful clear upslurred but variable "woiiieet-woit"; notes of nominate in Kumawa Mts, West Papua, are lower, upward-inflected, clear, hollow ones delivered more as hoots; notes of *intercedens* (SE New Guinea) described variously as "hrraah-hraoou", first syllable rising and last part of second one falling, deep guttural growled "crrraiy-crrrow" or "uráúow-urauow", and above Wasu (in Huon Peninsula) typical double growl-like notes but of harsher, rasping quality and with second note inflected upwards or downwards. Australian *alberti* calls geographically variable: at Cape York 2 identical upward-inflected clear whistled notes, the first sometimes flatter and softer, or the two sometimes repeated as a song series; at Claudie R (Iron Range) first note is lower and briefer and is continuous with second in being fluidly connected by downward inflection prior to sharp end (sounding like a person whistling to attract another); at Rocky R (Silver Plains) call like that at Cape York and nominate race of New Guinea. Louder calls carry up to c. 1 km.
Habitat. Lowland forest, hill forest and middle montane forest, also monsoon forest, swamp-forest, and gallery forest and forest edge; occasionally in mangroves and timber plantations. Sea-level mainly to 700 m, occasionally or locally to 1450 m.
Food and Feeding. Fruits (mostly capsules) and animals, latter including wide variety of insects, spiders (Araneae) and myriapods; overall a greater proportion of arthropods eaten, but relative proportions vary seasonally. Forages mostly in main canopy for fruits, but gleans/probes in lower canopy and subcanopy for animals. Forages alone, occasionally with small groups of loosely associated individuals at fruiting trees; joins (female-plumaged birds possibly more so than adult males) mixed-species foraging flocks containing pitohuis (*Pitohui*) and other paradisaeid species.
Breeding. Season variable across range, at least Jun–Feb, females with enlarged oocytes Feb, Jun, Jul and Oct–Nov and some males with moderately to greatly enlarged gonads during all months (but smallest Feb–Mar); egg-laying early Sept to mid-Feb but also early Jun in SE New Guinea (Moroka area), and nestlings (one nest) Nov and presumed female attending dependent young late Sept in NE Australia; display late wet season to throughout dry season, Apr–Sept near Port Moresby (SE New Guinea). Polygynous, solitary promiscuous male advertisement-singing/displaying from several traditional perches; female builds and attends nest alone. Males regularly dispersed through forest (c. 500 m apart at Ok Tedi, in C New Guinea), but territoriality unconfirmed. Male displays with initially static sleeked postures, then raising fully opened wings high to each side, with head and neck swung between them, followed by vigorously animated hopping along horizontal display bough (unlike *P. victoriae*, not atop a vertical stump) while in this pose; courtship mostly in lower understorey to subcanopy. Nest composed of large dead leaves and vine tendrils loosely put together, sometimes epiphytic ferns fronds included, lined with fine leaf midribs and fibres; recorded sites used in Australia include base of living fronds of pandanus (*Pandanus*) tree crown, atop basket-fern epiphytes on tree trunk, and atop broken-off trunk with new regrowth, variously 0·5–16 m above ground. Clutch 1–2 eggs, mostly 2; no information on incubation and nestling periods.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. CITES II. Mostly common where found; uncommon at 300–1200 m in S Cyclops Mts in Jul, with calling males sparse. In 2002, within Crater Mountain Wildlife Management Area (E New Guinea), estimates at 432–650 m were 14·1 individuals/km² in primary forest, 5·7/km² in old gardens and 5·2/km² in new gardens, and figures at 651–935 m were 14·9 in primary forest, 5·8 in old gardens and none in new gardens. Near Port Moresby (SE New Guinea) 6 birds/10 ha counted; in 100 ha near Kakoro (E New Guinea) minimum of 7 adult males, at mean nearest-neighbour distance of 175 m (range 140–275) m; in Ok Tedi area males called c. 500 m apart; and near Kiunga (C New Guinea) calling adult males were common c. 100–200 m apart, in slightly rolling topography, in both low swampy forest and poorer, more elevated forest. In Australia, one observer considered female-plumaged individuals to number 15 or 20 for every adult-plumaged male. This species is tolerant of selectively logged forest, and thought not likely to be at any risk in near future. In Australia, an adult male killed and eaten by a Rufous Owl (*Ninox rufa*) at Iron Range, in Cape York Peninsula.

24. Paradise Riflebird

Ptiloris paradiseus

French: Paradisier festonné **German**: Schildparadiesvogel **Spanish**: Ave-del-paraíso Festoneada

Taxonomy. *Ptiloris paradiseus* Swainson, 1825, no locality = northern New South Wales, Australia.
Monotypic.
Distribution. E coastal Australia, from SE Queensland (Calliope Range, S of Rockhampton) S on Great Dividing Range, also some lowlands to E, to NE New South Wales (S to just N of Newcastle).

Descriptive notes. Male 30 cm, 134–155 g; female 29 cm, 86–112 g. Fairly large paradisaeid with long, decurved bill and short, barely graduated tail. Male has head (except crown) and upperparts, including upperwing and tail (except central pair of feathers), velvety jet-black with rich silk-like iridescent sheens of purple/magenta, mantle with green sheen; entire crown of scale-like feathers intensely iridescent greenish-blue to bluish-green, washed rich purple, notably on nape; central pair of rectrices short and highly metallic bluish-green to greenish-blue; velvety jet-black chin to lower breast, with central throat to upper breast adorned with extensive, roughly triangular breast shield of scale-like feathers intensely metallic greenish-blue, washed purple, broad feathering below breast shield to undertail-coverts with silk-like iridescent oil-green broken by extensive jet-black feather bases (conspicuously visible at upper and lower border of this area); iris dark brown; bill shiny black, gape pale yellow, mouth bright yellow or lime-yellow; legs black. Female is smaller than male, with shorter wing (almost no overlap between sexes) but larger bill; plumage radically different, cryptically brown and grey-brown above with rufous panel on outer wing, often greyer on head and usually darker on sides of crown and lores, with broad whitish superciliary stripe, whitish submoustachial area, chin and throat, becoming buff on upper breast to pale cinnamon on remaining underparts, which are strongly marked with blackish-brown deep chevrons, deteriorating to barring on flanks and undertail-coverts; legs blue-grey to dark grey. Juvenile undescribed; immature like adult female; subadult male variable, like adult female with few feathers of adult male plumage intruding to like adult male with few feathers of female-like plumage remaining; unlike congeners, male acquires slightly longer tail with increasing age, but central pair of rectrices becomes slightly shorter with age. Voice. Advertisement call of male an explosive "yaassss" (structurally similar to advertisement of *P. victoriae*), repeated once; can be heard from at least 800 m. Immature male calls inferior to those of adult.
Habitat. Subtropical and temperate rainforests; also wet sclerophyll forest adjacent to rainforest and dry sclerophyll forest to 1 km and more from rainforest, particularly during winter. Most numerous above 500 m, rarely below 200 m except in winter, when down to sea-level.
Food and Feeding. Fruits and animals, latter including wide variety of insects and spiders (Araneae); arthropods probably dominate diet, but relative proportions vary seasonally. Forages mostly high up in forest. Usually alone, but aggregations of up to six or seven individuals visit fruiting trees, sometimes with bowerbirds (Ptilonorhynchidae).
Breeding. Season Aug–Feb, peak in Sept–Jan, a presumed female with fledgling(s) mid-Feb and another mid-Mar; display at least Aug–Dec, period of least calling Mar–Aug, with significant increase in Sept and most vocal Oct–Feb. Polygynous, solitary promiscuous male advertisement-singing/displaying from several traditional arboreal perches; female builds and attends nest alone. Display sites of males regularly dispersed in forest; each site contains several regularly used exposed bare canopy or subcanopy limbs or branches, and male probably territorial at least with

On following pages: 25. Victoria's Riflebird (*Ptiloris victoriae*); 26. Superb Bird-of-paradise (*Lophorina superba*).

regard to these. Detailed understanding of sequence of display to mating lacking, but courtship involves a static posture, dance, leg sway, movements of wings and pectoral shield, and mouth gaping; much as for *P. victoriae*, but perhaps with wings held more horizontal and less vertical. Nest larger and bulkier than that of *P. victoriae*, a shallow bowl of vine stems, lined with finer vines, fibres and rootlets, rim typically decorated with fresh green fronds of climbing ferns (*Polypodium*), sometimes also lengths of sloughed snakeskin, some large dead leaves incorporated into base; frequently built in dense tangle of vines (including *Calamus*) 5–40 m above ground, also in many other sites; same nest tree reused habitually. Clutch 1–2 eggs, mostly 2; incubation period not documented, possibly 18–19 days; nestling period at one nest at least 21 days.

Movements. Presumably resident. Some short-distance movement; during austral winter, some move from subtropical and temperate rainforests and adjacent wet sclerophyll forest into dry sclerophyll forest up to 1 km and more from rainforest. Some descend to lower elevations, down to sea-level, in winter months.

Status and Conservation. Not globally threatened. Restricted-range species: present in Eastern Australia EBA. CITES II. Common in upland forests in N of range; less abundant in remaining habitat in S. Has lost much habitat through forest clearance, with consequent diminution of range. Rare or absent in rainforest patches of 2·5 ha or smaller in NE New South Wales, but reportedly extinct in remnants as large as 60 ha in Big Scrub. Six individuals recorded in 112 ha of subtropical rainforest and 13 in 102 ha of wet sclerophyll forest near Dorrigo (New South Wales). Because of lowland clearance, now predominantly in hill forests of Great Dividing Range.

25. Victoria's Riflebird

Ptiloris victoriae

French: Paradisier de Victoria **Spanish**: Ave-del-paraíso de Victoria
German: Victoriaparadiesvogel
Other common names: Queen Victoria('s) Riflebird, Victorian/Lesser Riflebird

Taxonomy. *Ptiloris Victoriae* Gould, 1850, Barnard Island, north Queensland, Australia.
Sometimes thought to form a superspecies with *P. magnificus*, and has been considered conspecific. Monotypic.

Distribution. Atherton Region of NE Queensland (from Big Tableland, S of Cooktown, S to Mt Elliot, and some offshore islands), in NE Australia.

Descriptive notes. Male 25 cm, 91–119 g; female 23 cm, 77–96 g. Fairly large paradisaeid with fairly long, decurved bill and short tail. Male is mostly velvety jet-black with rich silk-like purple/magenta sheens above, crown feathers scale-like and intensely iridescent greenish-blue to blue-green, washed rich purple, especially on nape, mantle with green sheen, central pair of rectrices short and metallic bluish-green to greenish-blue; velvety jet-black chin to lower breast, central throat to uppermost breast with roughly triangular breast shield of intensely metallic purple-washed greenish-blue scale-like feathers, belly to undertail-coverts olive-grey to oily olive-green, typically with more bronze-yellow reflections than in *P. paradiseus*, and some black feather bases visible posteriorly; iris dark brown; bill shiny black, gape pale yellow, mouth bright yellow or lime-yellow; legs black. Differs from similar *P. paradiseus* mainly in smaller size, narrower and smaller breast shield, and often more bronze-yellow lower underparts, with lack of visible black feather bases on anterior part of abdomen. Female is smaller than male, with shorter wing (almost no overlap between sexes) but larger bill; plumage very different, grey to grey-brown above, with rufous panel on outer wing, broad whitish superciliary stripe, whitish submoustachial area and chin, becoming buff on throat and upper breast, and rich cinnamon on remaining underparts, with small blackish chevron marks (except on lowermost areas), becoming more bar-like on sides, undertail-coverts paler; legs blue-grey to dark grey. Juvenile is like female, but underparts indistinctly barred, not spotted, brownish, bill pale bluish-grey, smudged dark grey, legs pale bluish-grey; immature male like female, gaining increasingly stronger and broader blackish flank barring until first sign of adult male plumage attained; subadult male variable, like adult female with few feathers of adult male plumage intruding to like adult male with few feathers of female-like plumage remaining; central rectrices decrease slightly in length with age. VOICE. Male advertisement call an explosive loud "ssssssshh" or "yaaaass", in S of range typically immediately repeated, but in N (on Atherton Tableland) usually a single note; often responds immediately to advertisement of other males. Aggressive call to conspecifics a sharp repeated "kek". A parent gave repeated soft low "kuk" on nest rim, followed by a "bubbling" form of such notes when flying from nest and from nearby perches.

Habitat. Lowland to hill rainforests, also adjacent wet sclerophyll woodland dominated by eucalypts (*Eucalyptus*) and swamp-woodland dominated by paperbarks (*Melaleuca*); also landward edge of mangrove communities and gardens. Sea-level to 1200 m.

Food and Feeding. Fruits (mostly capsules); insects, including cockroaches (Blattodea) and cicadas (Cicadidae), and spiders (Araneae), centipedes (Chilopoda) and millipedes (Diplopoda); also flower nectar. Probably more arthropods than fruits overall, but relative proportions vary seasonally. Nestlings fed with animal items (up to 80–90%) and fruits. Forages mostly in canopy, also close to and on forest floor. Takes arthropods by gleaning and probing. Up to four or more individuals may gather at a single fruit resource during about May–Jul (outside display season).

Breeding. Season at least Aug–Feb; egg-laying late Aug to early Jan, and female with fledged young observed late Nov and Jan–Mar; males with moderately to greatly enlarged gonads Jan, Apr, Jul and Sept–Oct and females Oct–Dec; display season Jul–Dec, post-moult displays (particularly by young males) during Mar–Apr. Polygynous, solitary promiscuous male advertisement-singing/displaying from traditional arboreal perch; female builds and attends nest alone. Adult male sedentary and territorial with regard to traditional display site during breeding season, display perches consisting of top of broken-off vertical tree or tree-fern stump several metres to many metres tall (higher and larger, bare, living or dead tree boughs occasionally used); courtship displays involve a static posture, dance, leg sway, wing-clap, wing movements and movements of pectoral shield, and mouth gaping; display elements include a Circular Wings and Gape and an Alternate Wings Clap; females attracted by advertisement calls which are accompanied by conspicuous wide gaping to expose bright yellow mouth. Nest has outer structure of *Pyrrosia* ferns (some with associated mossy growth), within this a substantial cup-shaped structure of dead leaves, with shallow egg-cup lining of fine woody tapering stems of vine flower inflorescences, many nests with sloughed snakeskin on outer rim; built 1·5–20 m above ground, often atop broken-off tree trunk with prolific new foliage, in vine-covered tree or in centre of tree-fern crown, sometimes in pandanus (*Pandanus*), fan palm (*Licuala*) or cordyline (*Cordyline*); nest-site habitually reused. Clutch 1–3 eggs, mostly 2; incubation period 18–19 days; female ceases brooding of chicks when latter 8 days old, feeding rates higher for brood of two than for one, nestling period 13–15 days; one fledgling was fed 74 days after leaving nest. A wild male lived for more than 15 years.

Movements. Mostly sedentary; during winter months some adult males move out of rainforest into adjacent wet sclerophyll woodland, typically frequenting ecotone to W of Great Dividing Range rainforests.

Status and Conservation. Not globally threatened. Restricted-range species: present in Queensland Wet Tropics EBA. CITES II. Common throughout small range; reported as more abundant on Bloomfield R during Jul–Jan than at other times, but this may reflect relative vocalization levels and hence conspicuousness. Adult males estimated to occupy area of c. 2 ha or more. Range has contracted owing to habitat loss; for example, much rainforest on Atherton Tableland has been destroyed. Can be a pest in soft-fruit orchards and is sometimes persecuted as a result. Despite this, the species appears not to be facing any significant threat.

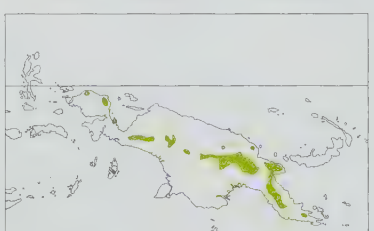
Genus *LOPHORINA* Vieillot, 1816



26. Superb Bird-of-paradise

Lophorina superba

French: Paradisier superbe **German**: Kragenparadiesvogel **Spanish**: Ave-del-paraíso Soberbia
Other common names: Lesser Superb Bird-of-paradise

Taxonomy. *Paradisea Superba* J. R. Forster, 1781, Arfak Mountains, New Guinea.
Intergeneric hybridization with *Paradigalla carunculata*, *Parotia sefilata*, *Parotia carolae*, *Ptiloris magnificus*, *Epimachus fastosus* and *Cicinnurus magnificus* recorded. Proposed race *connectens* (Dawong, in Herzog Mts), treated as synonym of *latipennis*. Proposed race *sphinx*, described on basis of one immature male (like *minor* but considerably larger, with more reddish-brown on upperparts, eyestripe less extensive, forehead and neck lacking white flecks), is of unknown origin, but possibly from mountains of far SE New Guinea; validity unproven. Form named as "*pseudoparotia*" (based on single specimen from Hunstein Mts, in middle Sepik Mts) has been shown to be hybrid of present species and *Parotia carolae*. Five subspecies currently recognized.

Subspecies and Distribution.
L. s. superba (J. R. Forster, 1781) – Vogelkop (Tamrau Mts and Arfak Mts), in NW New Guinea.
L. s. niedda Mayr, 1930 – Mt Wondiwoi (in Wandammen Peninsula), in NW New Guinea.
L. s. feminina Ogilvie-Grant, 1915 – C Cordillera from Weyland Mts E to C New Guinea (Hindenburg Mts and Victor Emanuel Mts).
L. s. latipennis Rothschild, 1907 – E & NE New Guinea in Central Highlands and Eastern Highlands (E to Herzog Mts, Kuper Range and Ekuti Range), also Adelbert Mts and mountains of Huon Peninsula.
L. s. minor E. P. Ramsay, 1885 – mountains of SE New Guinea (E probably from SE of Wau).

Descriptive notes. Male 26 cm, 60–105 g; female 25 cm, 54–85 g. Male nominate race has scale-like crown feathers iridescent metallic green-blue with purple to magenta sheens, rest of head velvety jet-black with dark coppery-green sheen, tuft of elongate erectile feathers above and behind each nostril, feathers at base of latter, those on lores and elongate forward-pointing chin feathers with purple to magenta iridescence; nape feathers grossly elongated and modified to form vast erectile nuchal "cape", its outer spatulate to fan-shaped feathers resulting in a symmetrical shape when raised, these velvety jet-black feathers and those of mantle with dull dark olive-green iridescence; back and rump black, uppertail-coverts as mantle; upperwing-coverts and tertials velvety matt black, flight-feathers blackish-brown, primaries with narrow olive-brown leading edges; uppertail similar to remiges but velvety jet-black, longest central pair of feathers with violet-purple iridescence; throat velvety black with dark olive-green sheen grading to purple iridescence, all with magenta washes, feathers scale-like and greatly elongated laterally, forming shallow, "winged" delta-shaped shield of intensely iridescent metallic greenish-blue with bluish-green to violet-purple sheens; underparts slightly glossy black, with trace of dark olive-green and purple sheens on belly; iris dark brown; bill black, mouth lemon-yellow to lime-green; legs blackish. Female is markedly smaller than male, particularly in wing length (almost no overlap between sexes); plumage radically different, head and nape blackish-brown with short line of tiny whitish spots as postocular stripe, similar submoustachial stripe immediately beneath gape, upperparts cryptically coloured brown and rufous, chin and throat whitish-grey, grading to pale buff on upper breast and to darker buff on flanks, thighs and undertail-coverts, all uniformly narrowly barred brownish-black; similar to females of some parotias and *Ptiloris magnificus*. Juvenile is like female, but plumage soft and fluffy, with darker crown, rear and side of neck barred ochraceous; immature male like adult female, but mean lengths of wing and tail longer; subadult male variable, like adult female with few feathers of adult male plumage intruding, initially outer primaries becoming black, to like adult male with few feathers of female-like plumage remaining; tail length of male increases slightly with age (varies with race). Race *niedda* is like nominate in appearance and proportionate measurements, but female darker and more ochraceous on underparts; *feminina* has proportionately much longer wing in relation to tail than do others, female similar to *latipennis* but broad superciliary stripes join narrowly across nape; *latipennis* is smaller and lighter than nominate, mean tail length as proportion of mean wing length smaller, female differs from nominate in having head dark brown, broad whitish superciliary stripe, white streaking on forehead, crown and nape, upperparts variably olive-tinged brown,

chin and throat whitish; *minor* has mean wing length shorter than all others, tail shorter than all except *feminina*, female blacker than preceding race, head and throat more blackish-brown, superciliary stripe reduced to small postocular streak, little or no pale nape marking, upperparts rich dark chestnut. Voice. Advertisement of male a loud, metallic, nasal series of 4–7 (sometimes many) "shre" or "scheee" notes, initial ones softer and more slowly delivered, then each becoming louder and faster until slowing toward end. In Kubor Range, song described as harsh, grating "au-aa-aa-aah" screech starting softly and building in volume, to fade at end; continuously repeated notes of Vogelkop males said to resemble "mjat-mjat". Display occasionally preceded by clockwork-like hiss. During courtship, male produces loud, sharp "click tick-tick" or "tick" (singly or continuously repeated) by sudden movement of wings; sharp ticking may be produced also in flight.

Habitat. Middle to upper montane forests, disturbed forest, and forest patches among gardens and other cleared areas; 1000–2300m, mostly 1650–1900 m. Male territories centred on ridge crests, with preference for steeply sloping spurs or flanks of large ridges for song perches.

Food and Feeding. Fruits (mostly capsules) and variety of arthropods; proportions vary seasonally, from nearly all arthropods to almost entirely fruits. Typically forages at all levels, by hopping about small trees and tree limbs which are covered with moss and other epiphytic growth. Probes and tears into moss and other growth for arthropods; occasionally sallies for fruits. Usually solitary and slow-moving, but joins mixed-species foraging flocks, including other birds-of-paradise, in fruiting trees.

Breeding. Breeds in any month across range; nest-building recorded in Apr, egg-laying Jan, Mar, Jun and Nov, and female feeding fully developed begging juvenile Feb–Mar in C New Guinea (Mt Bosavi); display observed during Aug–Jan. Polygynous, solitary promiscuous male advertisement-singing from traditional high exposed perch(es); female builds and attends nest alone. Males territorial, within auditory contact of rivals, display on low perch, tree trunk or flat ground to high perch; territories of three males non-overlapping but abutting, average size 1·5 ha, average of 140 m between males (which were at all times in vocal or visual contact); territory of individually marked adult male on Mt Bosavi estimated at 150 m in diameter, but territory near Kompiam R considered significantly smaller. Courtship involves static display, and an animated dance with wing-flicking and leg-flexing, erection of nuchal cape, pectoral shield and forecrown feathers, and gaping; Initial Display activity followed by high-intensity phases. One nest was a loosely made rough cup, mostly of dark springy rootlets and fibres with a few large dead leaves and with small *Polypodium*-type fern fronds and strands of a *Selaginella*-like creeping plant incorporated, another a deep substantial cup of leaves with vine-like tendrils, quite possibly epiphytic orchid stems, and some living *Pyrrosia* fern stems with fronds on outside and rim; built at 1·5 m or higher in crown of palm or structurally palm-like plant. Clutch 1–2 eggs; in captivity, incubation period 18–19 days and nestling period once 18 days.

Movements. Presumably resident.

Status and Conservation. Not globally threatened. CITES II. Locally common. Commonest bird-of-paradise within its altitudinal range (c. 1060–2135 m) in Eastern Highlands. Common in riverine forests bordering Wahgi R (1524 m) and in Kubor foothills to 2226 m; not uncommon in tall middle montane forest edges but not found above c. 1800 m in Victor Emanuel Mts and Hindenburg Mts. More abundant at lower elevations of range (where individuals predominantly in female-like plumage) during non-breeding season. At Tsuwenkai (in Bismarck Range), estimated density 1 male/2·3 ha (1/2·7 ha in primary forest, 1/1·8 ha at forest edge). Marked change in composition of population noted with altitude: at 1220–1280 m only a single immature male; at 1341–1448 m two female-like birds; at 1448–1643 m numerous female-plumaged birds, and an adult male calling at 1560 m; at 1643–1817 m adult males common and females only up to 1738 m, and above this few birds seen were all adult male. Very common in Feb–Mar in middle and upper canopy in Adelbert Mts, where adult males dominated at 1500–1600 m and female-plumaged individuals much more common at 1200 m.

Bibliography. PLATE 25

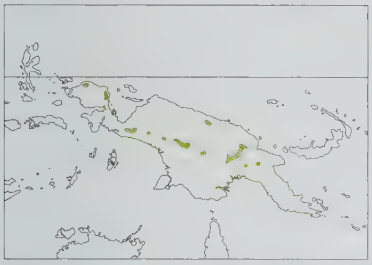
inches 5

cm 13



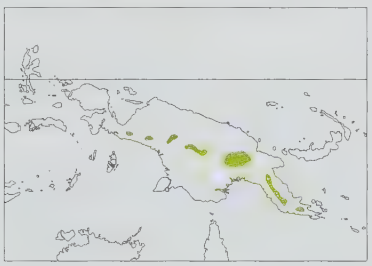
Genus *EPIMACHUS* Cuvier, 1816

27. **Black Sicklebill**

Epimachus fastosus

French: Paradisier fastueux **Spanish**: Ave-del-paraíso Fastuosa
German: Breitschwanz-Paradieshopf
Other common names: Greater Sicklebill, Black Sickle-billed/Black Saber-tailed Bird-of-paradise, Greater Sicklebilled Bird-of-paradise

Taxonomy. *Promerops fastuosus* [sic] Hermann, 1783, Arfak Mountains, New Guinea.
Intergeneric hybridization with *Paradigalla carunculata*, *Astrapia nigra* and *Lophorina superba* recorded. Proposed race *stresemanni* (described from Schraderberg, in Sepik Mts) synonymized with *atratus*. Species name often listed as "*fastuosus*", the spelling first used in the scientific description; however, this spelling was explicitly corrected by original author on later page of same work. Three subspecies recognized.
Subspecies and Distribution.
E. f. fastosus (Hermann, 1783) – Vogelkop (Tamrau Mts and Arfak Mts), in NW New Guinea.
E. f. atratus (Rothschild & E. J. O. Hartert, 1911) – mountains of Wandammen Peninsula, and C Cordillera E to Kratke Range, in E New Guinea.
E. f. ultimus Diamond, 1969 – Bewani Mts (Menawa) and Torricelli Mts (Mt Somoro), in N New Guinea.



Descriptive notes. Male 63 cm (110 cm including central rectrices), 250–318 g; female 55 cm, 160–255 g. Large paradisaeid with long, sickle-shaped bill and greatly elongated central tail feathers. Male nominate race has entire head black, scale-like feathers showing iridescence of metallic green-blues with purple and/or magenta washes; chin tuft and throat blackish with only slightest magenta sheen; velvety black above, mantle to uppertail-coverts with violet-purple and/or magenta iridescence, large scale-like central back feathers with highly metallic blue-green iridescence, upperwing with variable blue to violet-purple and/or magenta sheens; primaries blackish-brown; uppertail blackish-brown with iridescent purple except central feather pair, which iridescent metallic blue-purple to violet-purple and/or magenta; upper breast brownish-black, grading to slightly paler browner on lower breast and to sepia on elongate filamental flank plumes, vent and undertail-coverts (black of underparts may show plum-purple sheen); greatly enlarged axehead-shaped pectoral plumes black with metallic dark magenta iridescence, and shorter overlying ones broadly tipped iridescent metallic blue, purple and/or violet; elongate modified feathers on each side of belly and vent with highly iridescent metallic deep purple-blue to violet-purple broad tips, tapering distally; iris bright blood-red; bill black, mouth bright yellow; legs blackish-grey. Female is markedly smaller than male, particularly in tail, has brown iris and radically different plumage, with no iridescence; cryptically coloured in various shades of dark brown dorsally, more reddish-brown on forehead, crown, nape, greater coverts and flight-feathers; face, chin and throat to upper breast dark brown, rest of underparts pale buff with dark brown barring, bars on breast becoming increasingly broad down on to lower breast and belly, with even broader barring on flanks, vent and undertail-coverts. Juvenile is like adult female, but crown and upperparts more rust-red, plumage soft and downy below, browner on chin and throat, underparts more buff; immature male like adult female, but tail on average longer and primaries more tapered and pointed; subadult male variable, ranges from like adult female with few adult male feathers intruding to much like adult male with few female-like feathers remaining, lacks specialized tail feathers of adult male, acquires progressively longer tail with age, central feather pair more than doubling in length. Race *atratus* differs from nominate in darker ventral plumage of adult male; *ultimus* has bill shorter than other races, male differs from nominate in being more black, less brown, on underparts, female in having tail longer and more olive, less rufous. Voice. Advertisement calls of males regionally variable, but best known is loud ringing, upslurred whip-like "qwink qwink!", which may be repeated or given as series of single notes, and audible beyond 1 km; transcribed also as e.g. "whik whik"/"kwik kwik"/"bwink bwink", or "blick blick"/"blit blit", or "buk buk"/"bek kek". Other, uncommonly given calls include guttural notes and honking, a growled deep "grr-grrk grr k-wick!" or "guck-er-ruk bl-whit!". Loud whistled "whick" by adult male in display; also a quiet rattle (sounding like distant machine gun) during horizontal display posture. Adult male in Arfak Mts (nominate race) started display with loud "du dug....du dug" song, and repeated this later during display.
Habitat. Middle montane forest, occasionally at forest edge, mostly in primary forest; more rarely in adjacent second growth and garden edges. At 1280–2550 m, mainly in narrow elevational zone of 1800–2150 m; predominatly at lower elevation than *E. meyeri*.
Food and Feeding. Fruits and animals in about equal proportion; animal food includes insects and small vertebrates. Forages primarily in middle and upper forest stages, often by bounding from perch to perch; also descends to ground.
Breeding. Breeds at least Nov–Feb (wet season); males with enlarged gonads Apr–Sept, a female with large eggs in oviduct early Feb (Baiyer Valley), juvenile seen mid-Feb on Mt Goliath (WC New Guinea) and juvenile early Nov at Mt Giluwe (E New Guinea); display Sept, Oct and Feb–Apr, peak activity near Crater Mt (E New Guinea) in late Sept. Polygynous, solitary promiscuous male advertisement-singing/displaying from traditional perches; female builds and attends nest alone. Each adult male frequents home range with singing/display perches typically high in forest, rarely to ground level. Courtship display performed atop broken-off vertical tree trunk, involves static posture, leg-flexing while leaning to horizontal and swaying with erect pectoral, flank and tail plumes, and possibly mouth gaping, mostly in pre-dawn twilight; some upright display postures similar to those of *E. meyeri* (see page 439), but will also stretch forwards to assume near-horizontal position and sway side to side while giving quiet rattle call (like soft knocking on empty box); one observed to adopt head-down crouched posture, tail cocked at more than 45°, as mouth widely gaped at a female below; one male dived c. 30 m downwards to within metres of forest-floor shrubs, then turned upwards and sailed back up on spread wings to original perch. A nest found on Mt Giluwe was of orchid stems, with vines and moss on base, placed on forked tree branch 10 m above ground. No other information.
Movements. No information.
Status and Conservation. VULNERABLE. CITES II. Mostly uncommon or rare; apparently locally common but at low density above 1800 m on Mt Bosavi; thought to be common in Tamrau Mts, probably locally common in Arfak Mts. Estimated population in range c. 2500–10,000 individuals, and declining as a result of exploitation. Much of this species' favoured elevational zone is heavily settled by humans, and many potentially suitable areas have been cleared; uncommon on Mt Giluwe, where habitat had been degraded by logging and agriculture; does not generally favour secondary forest. This species is hunted both for its tail feathers and for food. Skins becoming increasingly valuable, hunters targeting adult males; hunting pressure increasing as shotguns become more widely available and as human populations increase within species' altitudinal range. Following heavy hunting with firearms around the Ok Tedi copper mine, decline in bird numbers was so dramatic that it was thought that this species may have approached a "minimum survival level"; shooting there continued until at least as recently as 1994. Prior to designation of Crater Mt as a Wildlife Management Area, the people of Ubaigubi considered this species vitually extinct there owing to hunting for traditional purposes. Forest in its favoured altitudinal range is under considerable pressure from large and increasing human population, which continues to clear large areas for agriculture.
Bibliography. Anon. (2008j), Bell (1969a), Butchart & Stattersfield (2004), Coates (1990), Cracraft (1992), Diamond (1969, 1972), Frith & Bechler (1998), Frith & Frith (1997b), Gilliard (1969), Gilliard & LeCroy (1961), Hartert (1930), Junge (1953), Kwapena (1985), Majnep & Bulmer (1977), McCarthy (2006), Peckover & Filewood (1976), Ripley (1957), Rothschild (1931), Stattersfield & Capper (2000).

28. **Brown Sicklebill**

Epimachus meyeri

French: Paradisier de Meyer **Spanish**: Ave-del-paraíso de Meyer
German: Schmalschwanz-Paradieshopf
Other common names: Meyer's Sicklebill, Brown/Meyer's Sickle-billed Bird-of-paradise, Grey Saber-tailed Bird-of-paradise

Taxonomy. *Epimachus Meyeri* Finsch and A. B. Meyer, 1885, Hufeisengebirge [Horseshoe Mountains = Mount Maguli], south-eastern New Guinea.
Intergeneric hybridization unrecorded in wild, but species crossed with *Astrapia mayeri* in captivity. Proposed race *megarhynchus* (described from Gebroeders Mts, in Weyland Range) synonymized with *albicans*. Three subspecies recognized.
Subspecies and Distribution.
E. m. albicans (van Oort, 1915) – C Cordillera of New Guinea from Weyland Mts E to Hindenburg Mts and Victor Emanuel Mts.
E. m. bloodi Mayr & Gilliard, 1951 – mountains of E New Guinea from at least Mt Hagen and Mt Giluwe (probably from Doma Peaks/Tari region) E to Kratke Range just W of Watut/Tauri Gap.
E. m. meyeri Finsch & A. B. Meyer, 1885 – mountains of SE New Guinea E from Mt Missim (E of Watut/Tauri Gap) and Ekuti Range.

Descriptive notes. Male 49 cm (96 cm including central rectrices), 144–310 g; female 52 cm, 140–202 g. Large paradisaeid with long, sickle-shaped bill and long, graduated tail with greatly elongated sabre-shaped central rectrices. Male nominate race has entire head black, in certain lights scale-like feathers of crown and face showing metallic green-blue iridescence with purple and/or magenta washes, chin, throat and entire neck black with iridescent magenta feather tipping; black above, mantle and back with green-blue and/or magenta sheens, modified large scale-like central back feathers highly iridescent metallic blue-green, rump with purple or plum gloss; velvety black upperwing with variable blue-green, blue to purple or plum gloss or sheen; brownish-black uppertail with blue iridescent sheen on outer webs, elongated central feather pair iridescent metallic green-blue and/or magenta; dark brown breast, increasingly washed with plum-purple at side; greatly enlarged axehead-shaped pectoral plumes black with metallic dark magenta iridescence, shorter overlying ones broadly tipped iridescent metallic blue, purple and/or violet; elongate modified feathers on each side of breast, belly and vent with highly iridescent metallic purple and/or magenta broad (but tapering) tips, sparse filamental flank plumes variable fawn-brown with paler, straw-coloured, central shafts; vent and undertail-coverts olive-brown; iris pale chalk-blue; bill black, mouth bright yellow; legs dark greyish to blackish. Female is markedly smaller than male, particularly in tail, has plumage radically different, lacking iridescence; cryptically coloured in various dark browns dorsally, but more reddish-brown on forehead, crown and nape, darker brown upperwing with raw umber edging to remiges and greater coverts; face blackish, chin and throat dark sooty-brown, finely flecked dull buff, underparts greyish-white to light buff with regular blackish-brown barring throughout, slightly paler barring towards rear. Juvenile is like adult female, but crown and mantle brighter and more rust-coloured, general plumage soft and fluffy, especially on abdomen; immature male like adult female, but tail longer; subadult male variable, from much like adult female with few feathers of adult male plumage intruding to like adult male but with few female-like feathers remaining, young male first acquires darker crown than adult female and blackish feathering around eyes, lores, bill, chin and upper throat, followed by adult head plumage and then, with subsequent moults, an increasing proportion of adult plumage; male acquires progressively longer tail with age, central feather pair more than doubling in length. Race *bloodi* is similar to nominate but is considerably smaller, with male flank plumes paler, rather more dirty whitish; *albicans* is also similar to nominate but is slightly smaller, with male flank plumes whitish. Voice. Advertisement song of male sounds like a burst of automatic machine-gun fire, with slight geographical variations, in SE of range "tat-at, tat-at, tat-at" but in Central Highlands "tat-at-at-at, tat-at-at-at-at-at"; audible at distance of up to 2 km. A foraging or contact call is rendered as a nasal "nreh!" or a rising "wahn"; other vocalizations and mechanical sounds (drumming, snapping, cracking) have been noted, but are not yet adequately described. Notes produced by individuals in female-like plumage are chicken-like and a barking "ugh!".

On following pages: 29. Buff-tailed Sicklebill (*Drepanornis albertisi*); 30. Pale-billed Sicklebill (*Drepanornis bruijnii*).

Habitat. Middle and upper montane forests, including moss forest, also disturbed forest, secondary growth and forest edge; 1500–3200 m, mainly 1900–2900 m.
Food and Feeding. Fruits (mainly drupes), also arthropods and small vertebrates, in fairly equal proportions. Fruits and arthropods fed to nestlings. Forages from ground to canopy, mostly in middle stages of forest interior. Probes into and tears epiphytic plant growth, mostly using bill to locate animals within debris between bases of pandanus (*Pandanus*) fronds. Often solitary, but not uncommonly forages in company of conspecifics or other birds-of-paradise (especially *Astrapia*). Adult male appears to forage within a home range from which it excludes other adult males, but permitting individuals in female-type plumage to feed there.
Breeding. At least Apr–Jan; males with gonads moderately enlarged in Jan–Feb, Apr and Jun and much enlarged in Jul–Dec, female with oocytes moderately enlarged in Mar, Jul and Dec and much enlarged in Jan; in Wau area of SE New Guinea, recently fledged juvenile at Bulldog Road mid-Dec and another on Mt Kaindi early Mar; display at least Feb, May–Aug and mid-Dec on Mt Hagen, also Sept–Dec in Tari Gap. Polygynous, solitary promiscuous male advertisement-singing/displaying from one or more traditional perches; female builds and attends nest alone. Male maintains large territory containing display perches (usually near-horizontal or gently sloping branches) in forest canopy, upper middle stage or substage near centre of territory, perches sometimes regularly dispersed along ridges; counter-singing at territorial boundaries possibly maintains male dispersion, but most singing performed at display sites defended against rival males. Main courtship displays include static posture, leg-flex to lean and sway, incorporating movements of pectoral, flank and tail plumes, and gaping; three phases recorded, respectively the Pumping, Leaning and Upright postures. Nest a shallow bowl of stringy living mosses, fern fronds, leaves, grasses and/or slender vines, lined with slender brownish rootlets, orchid and fern stems, dried fern tips, small leaves and many skeletonized leaf fragments, placed c. 4–12 m above ground in crown of pandanus or tree-fern or in small tree. Clutch 1 egg; no information on incubation and nestling periods.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in Central Papuan Mountains EBA. CITES II. Common to abundant over much, if not most, of range; uncommon or absent in some apparently suitable habitats. In 350 ha on Mt Missim, at least ten adult males resident, with nearest-neighbour distance 270–440 m (mean 332 m). Adult males rare in Baliem and Ilaga Valley areas (W New Guinea) in mid-1950s and 1960 owing to traditional hunting; in Kaironk Valley (Schrader Range, in E New Guinea), species was much less in evidence in 1970s than in 1960s. Lives in altitudinal range above that where most clearing of forest for human habitation and agriculture occurs; probably in no immediate danger.
Bibliography. Genus *DREPANORNIS* P. L. Sclater, 1873

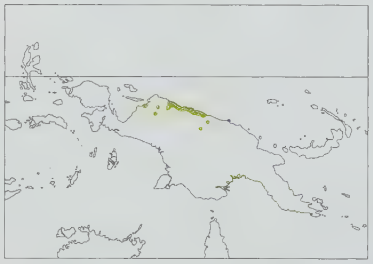
29. **Buff-tailed Sicklebill**

Drepanornis albertisi

French: Paradisier d'Albertis **Spanish**: Ave-del-paraíso de Albertis
German: Gelbschwanz-Paradieshopf
Other common names: Black-billed/Red/Short-tailed Sicklebill, Black-billed/D'Albertis's Bird-of-paradise

Taxonomy. *Drepanephorus albertisi* P. L. Sclater, 1873, Hatam, Arfak Mountains, New Guinea.
Genus sometimes subsumed in *Epimachus*. Possibly forms a superspecies with *D. bruijnii*. Birds from Huon Peninsula sometimes recognized as race *geisleri*; further study required. Proposed race *inversus* (described from Mt. Kunupi, in Weyland Mts) synonymized with *cervinicauda*. Two subspecies recognized.
Subspecies and Distribution.
D. a. albertisi (P. L. Sclater, 1873) – non-Cordilleran ranges of New Guinea, including mountains of Vogelkop, Wandammen Peninsula and Huon Peninsula, and presumably also Fakfak Mts, Kumawa Mts and Foja Mts.
D. a. cervinicauda P. L. Sclater, 1884 – C Cordillera of New Guinea from Weyland Mts E, very patchily, to Lordberg and Tari area and mountains of SE New Guinea.



Descriptive notes. Male 35 cm, 103–125 g; female 33 cm, 92–138 g. Fairly large paradisaeid with very long, sickle-shaped bill and medium-length tail. Male nominate race has head variably cinnamon-brown, browner on crown, where feathers tipped iridescent coppery purple; lores, chin and throat blackish, strongly tainted iridescent leaf-green; elongate forecrown feathers form "horn" above front edge of each eye, with some shorter feathers tipped iridescent purple-blue and longer ones magenta; bare facial skin dark maroon-grey; upperparts and upperwing cinnamon-brown, rump and uppertail-coverts paler, tertials and primaries with broad cinnamon leading edges; uppertail pale cinnamon; sooty-brown to sooty-grey upper breast separated from lower breast and flank plumes of same colour by band of feathers broadly tipped iridescent violet-purple with magenta wash; loosely structured pectoral plumes iridescent bronze with magenta wash, and similarly structured elongate flank plumes broadly tipped purple; central belly, vent and undertail-coverts white; iris dark brown; bill shiny black, mouth pale green or pale yellow; legs brownish to greyish or blackish. Female is similar to male in size and weight, lacks iridescent feathering, but otherwise similar above to adult male but darker and more amber on tail; chin and throat cinnamon-brown with fine pale, buffy central feather shafts, underparts barred dark brown throughout except on lower breast, where feather barring forms chevrons. Juvenile undescribed; immature like adult female, but with longer tail than both adult sexes; subadult male varies, from similar to adult female with few feathers of adult male plumage intruding to much like adult male but with few feathers of female-like plumage remaining; adult male plumage exhibited patchily for at least one breeding season, horns over eyes usually acquired at same time as iridescent green throat, iridescent purple-tipped flank plumes and extensive central breast patch of olive-brown, barred female-like plumage remaining above and below latter; male tail length decreases slightly with age. Race *cervinicauda* is smaller than nominate, with proportionately shorter tail, paler uppertail-coverts and tail, underparts of birds in female-type plumage pale buff with paler brown barring. Voice. Male advertisement song a high, powerfully whistled, musical "dyu dyu dyu dyu dyu dyu dyu...", increasing in speed and rising (sometimes falling) in pitch; contact a plaintive "wrenh"; display call a variable elaboration of advertisement song but higher, more insistent, faster, ending with sibilant "tish-tish-tish-tish-tish-tish-tish-tish" or "ki-ki-ki-ki-ki-ki-ki". One male preceded displays by whistling "to to to to to to to to" followed by harsh but softer note. Vocalization on Fakfak Mts a series of downslurred whistles slightly decelerating and rather slowly delivered, distinct from that on Arfak Mts, which is a much more rapidly delivered trill like that of a Whimbrel (*Numenius phaeopus*).
Habitat. Middle montane forests, infrequently logged areas and forest edge; 600–2250 m, mainly 1100–1900 m.
Food and Feeding. Primarily insectivorous, taking various arthropods, but also fruits (mostly capsules). Forages mostly in middle and upper levels of forest. Gleans, prises, and probes bark, dead wood, limb surfaces, mosses, dead leafy debris and knotholes for prey; uses bill as forceps to pick up items or to remove fruit from capsular husks; entire bill or either upper or lower mandible used for probing holes. At least individuals in female-type plumage join mixed-species foraging flocks.
Breeding. Breeds at least Sept–Dec, and birds with enlarged gonads noted Feb–Oct over entire range, but little studied; a begging juvenile following its mother at end Nov; display season at Mt Missim (E New Guinea) May–Nov, virtually silent in intervening months, and mating mostly Oct–Nov or shortly before or after in EC New Guinea. Polygynous, solitary promiscuous male advertisement-singing/displaying from one or more traditional perches; female builds and attends nest alone. Adult male territorial, occupying and defending large display/foraging all-purpose territory all year, adjacent males in auditory contact from high posts, displays at habitual site involving several perching areas, descending to saplings to court females; display calls typically given in lower forest, to within a metre of ground; an individually marked male's territory was c. 14 ha (mean nearest-neighbour distance between display sites of five males 450 m, at dispersed posts in 200 ha of forest), his display site, used for at least four years, a small area in old-growth forest near centre of his home range. Courtship display involves static and inverted postures and movements of pectoral, flank and head plumes, and possibly gaping. Only nest known was a thin, rather flat structure with slight egg-cup depression, foundation of pale reddish-brown wiry grasses, lining of black wiry roots, placed in fork of thin branch between horizontal bough and trunk. Clutch 1 or 2 eggs; no information on incubation and nestling periods. Male ringed when in adult plumage lived for at least a further 9 years, and thus reached more than 15 years of age.
Movements. Presumably resident. A female was silent while moving about her 43-ha range during period of eight days.
Status and Conservation. Not globally threatened. CITES II. Nowhere abundant; may be absent from apparently suitable areas of habitat, especially in C parts of New Guinea. Although thought not to be at any immediate risk, this species probably merits monitoring.
Bibliography. Beehler (1983a, 1987a), Beehler & Pruett-Jones (1983), Diamond (1972, 1985, 1987b), Frith & Beehler (1998), Frith & Frith (1997b), Gibbs (1994), Gilliard (1969), Hartert *et al.* (1936), Mayr (1931c), Opit (1975), Schodde (1976), Sharpe (1891–1898).

30. **Pale-billed Sicklebill**

Drepanornis bruijnii

French: Paradisier à bec blanc **Spanish**: Ave-del-paraíso Piquiblanca
German: Braunschwanz-Paradieshopf
Other common names: White-billed/Lowland Sicklebill, White-billed/Bruijn's Bird-of-paradise, White-billed Sicklebill(ed) Bird-of-paradise

Taxonomy. *Drepanornis Bruijnii* Oustalet, 1880, coast of Geelvink Bay between 136°30' and 137° of longitude, New Guinea.
Genus sometimes subsumed in *Epimachus*. Possibly forms a superspecies with *D. albertisi*. Monotypic.
Distribution. N New Guinea from E side of Geelvink Bay E through Meervlakte (Lakeplain) and presumably Idenburg (Taritatu) basin and N coastal lowlands to Vanimo area and NW reaches of Sepik R drainage (Utai).

Descriptive notes. Male 35 cm, 160–164 g; female 34 cm, 184–207 g. Fairly large paradisaeid with very long, sickle-shaped pale bill and medium-length tail. Male has forehead, crown and anterior loral area variable dark brown, elongate feathers above eye forming erectile tuft that is iridescent blue-purple and/or red-purple in certain lights; chin, throat and ear-coverts darker, velvety blackish-brown, with leaf-green iridescence; extensive bare facial skin lead-grey with slight purple hue, small roughly circular patch of strongly iridescent blue to purple fine scale-like feathers below eye and over base of lower mandible; mantle and upper back dull brown, becoming cinnamon-brown on lower back, rump and uppertail-coverts; upperwing brown, with narrow richer and slightly paler cinnamon leading edges of greater coverts, tertials and secondaries, and paler edges to primaries; uppertail cinnamon-brown; upper breast dark olive-brown, extensive tips of longer feathers (including elongate feathers covering bases of pectoral plumes) iridescent olive-green; pectoral plumes dark greyish-brown, shorter row broadly tipped strong iridescent coppery red, these overlying longer ones that are finely tipped iridescent purple and/or blue; grey feathers of side of lower breast with iridescent leaf-green broad tipping, beyond these a line of jet-black feathers finely tipped with iridescent purple and/or blue; remaining parts of breast and belly dark warm grey with dark lavender wash, thighs, vent and undertail-coverts paler, more greyish-brown; iris dark brown; bill ivory-whitish; legs purplish-brown. Female is similar in size to male but lighter in weight, lacks iridescent feathering; like adult male above but paler, more buff; different below, chin to upper breast buff, becoming darker on lower breast and paler cinnamon on belly, vent and undertail-coverts; chin and throat finely flecked blackish-brown, otherwise regularly barred blackish-brown below. Juvenile undescribed; immature male like adult female, but tail longer than adult of both sexes; subadult male variable, from similar to adult female with few feathers of adult male plumage intruding to like adult male with few feathers of female-like plumage remaining, acquires dark throat feathers and pectoral plumes first, with partial warm grey of underparts only and much barring retained, and gains more grey

dorsal feathering as barring diminishes with subsequent moults; male tail length decreases slightly with age. Voice. Male advertisement call a variable series of hoarse or hollow whistled plaintive musical notes, each rising or falling in pitch, sometimes preceded or followed by one or more low musical gurgles or coughs, e.g. "wik-kew kwéér kwéér kwer, kor kor kor", moderately high-pitched and carrying considerable distance. During foraging a quiet interrogative "whehn", similar to that of several other members of family.

Habitat. Lowland rainforest, including disturbed areas, and original and selectively logged forest on limestone hills; sea-level to 180 m.

Food and Feeding. Fruits (mainly drupes) and arthropods. Appears to be more frugivorous than *D. albertisi*. Forages mostly in canopy, but descending to substage to join mixed-species foraging flocks, including other paradisaeids and pitohuis (*Pitohui*).

Breeding. Gonadal enlargement at Holtekong (Hollekang), near Jayapura, suggests nesting in Nov; display at least in Aug. Polygynous, solitary promiscuous male advertisement-singing from one or more traditional perches; female builds and attends nest alone. Adult male territorial, exclusively occupying and defending large area used for both display and foraging (some sharing of foraging range at least as part of mixed flocks); patrols territory daily, singing at different points and counter-singing and counter-displaying to neighbouring rival males. Display involves at least a static posture with movements of pectoral and flank plumes, fanned tail, and gaping, but incompletely known; in one posture male perches upright, with short upper pectoral plumes erected vertically, longer lower feathers erected into wide skirt, and tail fanned, holding this pose with little movement for up to ten seconds and conspicuously rattling bill. No other information.

Movements. Presumed resident.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in North Papuan Lowlands EBA. CITES II. Poorly known. May be widespread and locally quite common, even in selectively logged forest, within its geographically rather small range. Four singing males heard from a single vantage point on one roadside. Home range of a male near Puwani R (in E of range) over 7 days was c. 15 ha. Population thought probably to be declining owing to habitat loss and degradation, as lowland forest throughout its range are under pressure for development and commercial trade in timber.

Genus *CICINNURUS* Vieillot, 1816

31. **Magnificent Bird-of-paradise**

Cicinnurus magnificus

French: Paradisier magnifique **Spanish**: Ave-del-paraíso Magnífica
German: Sichelschwanz-Paradiesvogel

Taxonomy. *Paradisea Magnifica* J. R. Forster, 1781, Arfak Mountains, New Guinea.
Present species and *C. respublica* sometimes separated from *C. regius* in genus *Diphyllodes*. Hybridization with *C. regius* and, intergenerically, with *Paradisaea minor* recorded. Proposed race *intermedius* (described from upper Setekwa R, in Snow Mts) synonymized with *chrysopterus*. Three subspecies recognized.
Subspecies and Distribution.
C. m. magnificus (J. R. Forster, 1781) – West Papuan Is (Salawati) and NW New Guinea (N & E Vogelkop, Wandammen Peninsula and Onin Peninsula).
C. m. chrysopterus (Elliot, 1873) – Yapen I (in Geelvink Bay) and W & C New Guinea E to mountains of Jimi R and Sepik–Wahgi Divide, also Adelbert Range.
C. m. hunsteini (A. B. Meyer, 1885) – E & SE New Guinea from upper Fly R region (E along S scarp of C Cordillera), Wahgi region and Huon Peninsula.

Descriptive notes. Male 19 cm (26 cm inclusive of central rectrices), 75–119 g; female 19 cm, 52–60 g. Male nominate race has upper head and nape feathers short and stubbly, olive-brown with scalloped darker feather tipping on central crown, reddish-brown on side of crown and on ear-coverts; iridescent dark green small spot of loral feathering, jet-black semicircle of feathers above eye; indistinct narrow area of bare pale blue skin behind eye; grossly elongate square-ended hindneck feathers form sulphur-yellow cape refracting white light (as does spun glass), several elongate feathers at side of cape olive-brown to reddish-brown, tipped blackish; back feathers from beneath cape form semicircle of dark carmine, bordered jet-black with white iridescence; reddish to dark brownish-olive lower back and rump, former with white iridescence; uppertail-coverts dark brownish-olive, washed reddish-brown, with dark green iridescence; lesser upperwing-coverts olive-brown, washed reddish-brown, remainder of upperwing dark brownish-olive, with fine buff leading edges on all except outermost primaries, broader on secondaries, modified tertials of frill-edged buff feathers washed orange-yellow, with white iridescence; uppertail dark brownish-olive, central feather pair modified into fine "sickles" (which cross near "normal" tail tip) with narrow web on outer edge only, iridescent metallic green-blue above and olive-brown below; chin and upper throat brownish-black with dark green iridescent sheen; lower throat to lower breast feathers forming extensive breast shield of glossy dark green, elongate lower feathers extending onto belly; line of broadly elongated scale-like feathers extending down ventral mid-line intensely iridescent turquoise, interspersed with dark green barring; feathers of lower and outer breast shield narrowly tipped iridescent turquoise to cobalt-blue; entire shield can produce rich purple and/or magenta iridescence; blackish-brown belly to undertail-coverts with slightest wash of violet-purple in certain lights; iris dark brown; bill chalky pale grey blue, upper ridge of culmen not sharply keeled to knife edge (unlike congeners), mouth pale green; legs blue. Female is slightly smaller than male, notably in weight, but tail (excluding central rectrices) longer; plumage radically different, cryptically drab-coloured olive-brown to reddish-brown above, richer on face and darkest on lores, wings somewhat brighter than mantle, thin line of pale blue skin behind eye (as on male), chin olive-brown and throat dirty white, flecked brown, underparts pale, uniformly barred dark brown; bare parts as for male, but bill duller. Juvenile undescribed; immature male like adult female, but bill blackish-brown, older birds with orange on secondaries and wing-coverts, mouth of younger birds (less than two years or so) orange; older birds in female-type plumage develop narrow, pointed and increasingly longer central rectrices prior to acquiring wire-like sickles of adult; subadult male variable, like adult female with few feathers of adult male plumage intruding, initially on head, to like adult male with few feathers of female-like plumage remaining, full adult plumage not acquired until at least six years; with age, male acquires progressively shorter outer rectrices while simultaneously gaining longer central pair. Race *chrysopterus* is nearly identical to nominate in both sexes, but secondary coverts and outer edges of flight-feathers more orange, less yellow, and crown darker; *hunsteini* is like nominate but paler on head and back, with brighter orange on secondary coverts and outer edge of flight-feathers, all measurements (both sexes) fractionally smaller than for other races. Voice. Court advertisement song of male a strident "ca cru cru cru", or loud clear "car" or "cre" repeated a number of times, or hoarse or squeeling "caaat ca ca ca". Male at court also produces a series of plaintive, downslurred churrs, single metallic downslurred "kyong" note, loud, sharp "kyerng!", scolding "ksss-kss-ks-ks-ks–kss"; low spitting and clucking notes or scolds when disturbed. In low-intensity courtship male gives low enticing "eek" or "eeeor" notes or "cheeeung"; during Dancing Display a peculiar, low, rhythmic, hard, clicking, buzzing song with higher and lower notes. Female and immature male utter 1–3 harsh, downslurred, quiet "chew" notes, or shortened soft form of adult male call. Adult male may produce audible clacking or rattling sound in flight.
Habitat. Hill forest to lower montane forest, rarely in lowland rainforest; from near sea-level (where hilly) to 1780 m, mainly to 1400 m. Courts are on steep slopes, notably in treefall or landslip areas beneath a gap in forest canopy.
Food and Feeding. Fruits and animals, latter including wide variety of insects, also spiders (Araneae); possibly also flowers or nectar. Nestlings fed at least with fruits. Forages solitarily in all forest strata, mostly in middle and lower levels; adult males more in understorey and commonly join mixed-species foraging flocks.
Breeding. Season at least Jul–Dec, but probably in all months over its range; males with much-enlarged gonads Mar–Nov, and females in breeding condition Feb–Mar and May–Nov; displays performed possibly throughout year, but mostly Jul–Feb. Polygynous, solitary promiscuous male clearing traditional terrestrial court; female builds and attends nest alone. Court several to many square metres in extent, contains vertical saplings, court-owners spending much time on stems of these, which they defoliate and wear smooth by use, court may be maintained for at least three consecutive years; male non-territorial, but maintains home range around court which overlaps with those of one or more other adult males, mean nearest distance between five males at courts on Mt Missim (SE New Guinea) 209 m; males maintain auditory contact by calling while moving about home ranges; females have home ranges overlapping extensively. Courtship displays involve static and leaning postures, and dancing up and down sapling stems, with complex ritualized progression of movements of nuchal cape, pectoral shield and central rectrices, and gaping; four distinctive phases are Back Display, Breast Display, Cape Display, Dancing Display. Nest mostly of mosses, dry leaves, weeds and/or mammal fur, lined with plant fibres and rootlets, placed c. 1–4 m above ground in pandanus (*Pandanus*) crown or other dense foliage. Clutch 1–2 eggs, mostly 2; in captivity, incubation (of one egg) 18–19 days, nestling period (brood of two) 17 and 18 days.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. CITES II. Widespread, and common. In 2002, within Crater Mountain Wildlife Management Area (E New Guinea), estimates at 432–650 m were 17·9 individuals/km² in primary forest, 3·4/km² in old gardens and 5·4/km² in new gardens, and figures at 651–935 m were 11·6 in primary forest, 31·6 in old gardens and 8·1 in new gardens. Considered not to be at any risk in immediate future. Highland men wear central tail wires of adult males in their hair.
Bibliography. Beehler (1983a), Beehler & Pruett-Jones (1983), Campbell (1977), Coates (1990), Cracraft (1992), Diamond (1972), Everitt (1965, 1973), Frith (1998), Frith & Beehler (1998), Frith & Frith (1997b), Gilliard (1969), Gyldenstolpe (1955a), Hartert (1930), Marsden *et al.* (2006), Mayr & Rand (1937), McCarthy (2006), Meyer (1892), Pratt & Stiles (1983), Rand (1940a, 1940b), Schodde (1976), Thair & Thair (1977).

32. **Wilson's Bird-of-paradise**

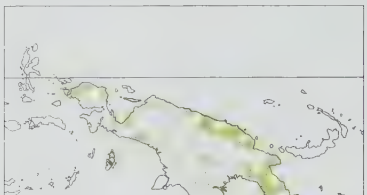
Cicinnurus respublica

French: Paradisier républicain **Spanish**: Ave-del-paraíso Republicana
German: Nacktkopf-Paradiesvogel
Other common names: Waigeu/Waigeo Bird-of-paradise, Bare-headed Little King Bird-of-paradise

Taxonomy. *Lophorina respublica* Bonaparte, 1850, Waigeo, off north-west New Guinea.
Present species and *C. magnificus* sometimes separated from *C. regius* in genus *Diphyllodes*. Monotypic.
Distribution. West Papuan Is (Waigeo and Batanta), off NW New Guinea.

Descriptive notes. Male 16 cm (21 cm inclusive of central rectrices), 53–67 g; female 16 cm, 52–60 g. Male has tuft of velvety black feathering about bill base, and largely unfeathered crown and nape, the bright turquoise-blue exposed skin with criss-crossing lines of velvety black fine feathering and copper-bronze iridescent sheens; semicircular cape of brilliant yellow on upper mantle contrasts with crimson rest of mantle, latter bordered by broad black line; upperwing with blackish-brown lesser coverts broadly edged paler brown, darker brown greater coverts and alula with fine dark crimson edging, dark crimson tertials tipped black, brownish-black secondaries with dark crimson leading edges (not reaching tips), and dark brown primaries with finest of crimson leading edges; rump, uppertail-coverts and uppertail blackish-brown, modified central tail "sickles" iridescent violet-purple with magenta sheens; chin and upper throat velvety black with coppery-bronze to purple gloss; mid-throat to belly occupied by extensive breast shield of smooth, oily and glossy emerald-green plumage (appearing blue-purple to red-purple in some lights), tiny central spots of several central throat feathers iridescent turquoise-blue, and broadest outermost feathers of lower shield broadly tipped iridescent turquoise-green; remaining underparts sepia-brown with violet to purple sheen; iris dark brown; bill blackish, upper ridge of culmen sharply keeled to knife edge (as in *C. regius* and *Semioptera*), gape narrowly pale yellow (often concealed), mouth bright yellow to green; legs violaceous cobalt-blue to blue-grey. Female is similar in size to male, but tail longer (excluding central feathers), has crown and nape naked but bare skin darker, more lilac-blue, and less extensive; otherwise radically different, cryptically drab-coloured dark olive-brown to reddish-brown above, rustier on uppertail-coverts, tail warm brown, upperwing dull brown, remiges with narrow rusty margins, primaries duller and greyer to tips, chin pale buff, finely flecked greyish, underparts dilute buff, finely and uniformly barred brown-black; legs duller than adult male's. Juvenile undescribed; immature male like adult female, except that rectrices pointed at tips; subadult male variable, like adult female but few feathers of adult male plumage intruding, initially about head and breast, to like adult male but with few feathers of female-like plumage; with age, male acquires progressively shorter rectrices while simultaneously gaining progressively longer central pair. Voice. Advertisement vocalizations of male include repeated clear powerful, whistled "cheew", "chau", "chow" or "twou" note; this call may be given as series of sharper, metallic frog-like wooden clicks, sometimes followed by 3 clearer and sharper clicks. Other calls include sharp explosive single "keeetch", repeated soft, high-pitched "teel" whistle; also stronger, louder "too-too-too-too-too-too-wit", last note sharply raised in pitch to give whip-crack ending, and in even louder form as "too-too-too-too-too-too-zeet". Scold notes harsh and churring. During display, male gives complex squeaky twitterings in subsong punctuated with guttural burring notes. Adult male in flight around court produces rapidly repeated loud sharp clear dry "tick".
Habitat. Primarily hill forest, more rarely also lowland rainforest and middle montane forest; ranges from hills, at 300 m, to perhaps summits of larger islands (c. 1000–1200 m).
Food and Feeding. Fruits and arthropods; possibly joins mixed-species foraging flocks. No other information.
Breeding. Males with enlarged gonads in May–Jun and Oct, and females with moderately enlarged oocytes in Jun; display season undefined. Polygynous, solitary promiscuous male clearing traditional terrestrial court; female builds and attends nest alone. Court c. 0·5–1 m in diameter, usually in dense forest, preferably in small well-lit clearing around fallen tree, landslide or in close vicinity; male keeps court clean of litter, and removes leaves from sapling display stems growing within court. Display involves static and leaning postures and dance, with movements of nuchal cape, pectoral shield, head and central rectrices, and gaping; male initially responds to female-plumaged visitor with "frozen" posture on base of vertical sapling; several other postures and movements

On following pages: 33. King Bird-of-paradise (*Cicinnurus regius*); 34. Standardwing Bird-of-paradise (*Semioptera wallacii*); 35 Twelve-wired Bird-of-paradise (*Seleucidis melanoleucus*).



have been observed, and some elements similar to those of *C. magnificus*, but complete successful courtship apparently undocumented. No other information.
Movements. No information.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in West Papuan Lowlands EBA. CITES II. Very poorly known. Population probably fairly small and thought likely to be declining as a result of habitat loss. Was present in fair numbers on Waigeo and fairly common on Batanta I (noted as much more abundant than on Waigeo) during Sept–Oct 1948. Moderately common in tall, mature secondary forest, selectively logged forets and primary lowland and hill forest (c. 60–700 m) on N slopes of Batanta in Feb 1986. Selective logging reported in N Waigeo, where much forest in SE corner was destroyed by fire in 1982; concerns expressed over a cobalt-mining concession on the island. On Batanta (where sole protected area covers just 100 km²), logging activities have caused major habitat degradation and much lowland habitat has been lost to swidden agriculture, but this species seems to be moderately common in logged forest and is probably secure at higher elevations. In addition to slow decline through habitat loss, it is hunted for skins in some areas.
Bibliography. Anon. (2008j), Attenborough (1996), Butchart & Stattersfield (2004), Collar *et al.* (2001), Frith (1974, 1998), Frith & Beehler (1998), Frith & Frith (1997b), Greenway (1966), Gyldenstolpe (1955b), Rothschild (1932), Stattersfield & Capper (2000), Winterbottom (1928).

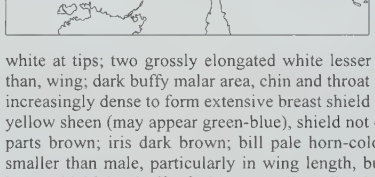
33. **King Bird-of-paradise**

Cicinnurus regius

French: Paradisier royal **German**: Königsparadiesvogel **Spanish**: Ave-del-paraíso Real
Other common names: Little King Bird-of-paradise

Taxonomy. *Paradisea regia* Linnaeus, 1758, Aru Islands, New Guinea.
Hybridization with *C. magnificus* recorded. Proposed races *rex* (described from Sorong district, in Vogelkop) and *gymnorhynchus* (from near Finschhafen, on NE coast of Huon Peninsula) synonymized with nominate, and *cryptorhynchus* (from Taua, on lower Mamberamo R) and *similis* (from Stephansort, in Astrolabe Bay) treated as synonyms of *coccineifrons*. Two subspecies recognized.
Subspecies and Distribution.
C. r. regius (Linnaeus, 1758) – West Papuan Is (Salawati, Misool), Aru Is, and scattered localities in mainland New Guinea except N portion.
C. r. coccineifrons Rothschild, 1896 – N New Guinea from E coast of Geelvink Bay E to E Ramu R.

Descriptive notes. Male 16 cm (31 cm inclusive of central rectrices), 43–65 g; female 19 cm, 38–58 g. Very small paradisaeid with upper ridge of culmen sharply keeled to knife edge (as in *C. respublica* and *Semioptera*). Male nominate race has crimson head, chin, breast and upperparts, more orange on forecrown and tuft of elongate plush feathering over culmen base, discrete spot of black feathering above central eye showing iridescent dark green; elongate mantle "cape" feathers, back, rump, tertials and some upperwing-coverts crimson to carmine with intense white iridescence, uppertail-coverts duller, more orange (less glossy crimson); upperwing predominantly glossy crimson, flight-feathers and some coverts variably brown; uppertail dark brownish-olive with brown-orange outer feather edges, elongated central feather pair reduced to fine bare red-brown central shafts with remarkable terminal spiral discs, latter (formed of inner feather web) iridescent metallic dark green with bronzed-yellow sheen; lowermost crimson throat feathers finely tipped pale buff where they meet narrow breast shield of iridescent dark green (can appear jet-black to burnished green-yellow in some lights); on each side of shield several elongate erectile fan-shaped olive-brown pectoral plumes, these pinkish-buff immediately prior to a broad iridescent tip of metallic bright green; remaining underparts white; iris pale brown to dark brown or greyish-brown; bill ivory-yellow, mouth pale aqua-green; legs violaceous cobalt-blue to blue-grey. Female is similar in size to male, but tail (excluding central rectrices) longer; plumage radically different, in cryptically drab-coloured olive-brown above, with rusty margins on greater coverts, remiges and tail feathers, often with paler, buffier area above eye, variably buff on breast, flanks and lower belly, and entire underside finely and uniformly barred dark brown; bill and legs duller than adult male's. Newly fledged juvenile (11 days) has upper head brown, tinged russet, with light superciliary stripe with dark spot above, upperparts and tail grey-brown, wing feathers darker brown, greater coverts and outer primaries red-brown, chin grey-tinged brownish-yellow with fine streaks and points, underparts light grey with dark barring, iris grey-brown, bill-horn coloured, legs paler blue than female; immature male like adult, younger (darker-billed) individuals having much orange-rufous on wing-coverts and outer edges of flight-feathers, and orange-rufous wash on upper breast and (more so) to side of it, but steadily losing this as acquiring increasingly paler bill and then the red of adult plumage, rectrices pointed at tips; subadult male variable, like adult female with few feathers of adult male plumage intruding to like adult male with few feathers of female-like plumage remaining; with age, male acquires progressively shorter outer rectrices while simultaneously gaining progressively longer central pair. Race *coccineifrons* is very like nominate, differs only in having central pair of rectrices and bill slightly longer. Voice. Advertisment calls of males are varied, more typical ones being transcribed as a descending "whei-wher-wha" and ringing, falling, "wher-whei-wha"; a descending "queu-queu-queu"; a deep "kraaa-kraaa-kraaa"; a rising series of loud, throaty, "cho-chow-chaw-chaw-chaw-chaw-chai" notes; a nasal and plaintive series of "ca", "wa" or "wau" notes rising slightly in pitch; a lower-pitched, trilled, slowly delivered "rahn rahn rahn rahn"; a high, plaintive and nasal "ki-kyer"; a high insistent "ki kyer kyer kyer kyer kyer kyer kyer kyer kyer" rapidly delivered and dropping in pitch and speed toward the end. Some calls reminiscent of typical *Paradisaea*, whereas others like *C. magnificus*. A foraging call given by all birds is a plaintive "weeo-weeo" with each note downslurred and descending. During courtship adult males produce subdued chittering of rhythmic twittering, churring, buzzing and grating notes continuously.
Habitat. Lowland rainforest, monsoon forest, gallery forest and forest edge, including disturbed areas and tall secondary forest; from sea-level to 950 m, mainly no higher than 300–400 m.
Food and Feeding. Fruits and arthropods; no information on relative proportions of each. Forages at various levels of forest; joins mixed-species foraging flocks that may include *C. magnificus* and *Paradisaea* species.
Breeding. Breeds at least Mar–Oct, but probably in all months over range; two separate females with newly fledged young in May; males with much-enlarged gonads in Jan–Nov (mainly Apr–Oct), a female with enlarged oocytes in late Mar; display in Oct–Jan in SE of range (Port Moresby area). Polygynous, solitary to communal promiscuous males defoliating a traditional arboreal court; female builds and attends nest alone. Court in thick subcanopy vines of shaded forest interior; adult males dispersed predominantly in twos c. 45–90 m apart, but occasional group of four may gather to form lek; some males 150 m to more than 530 m apart, apparently forming mating system intermediate between non-territorial one and exploded lek; adult males vocalize persistently throughout day. Courtship involves a dance, and inverted and flight postures, with movements of wings, pectoral fans, relictual flank plumes and central rectrices, and gaping; display phases include Wing-cupping, Dancing, Tail Swinging, Horizontal Open Wings Display, an Inverted Phase of the Open Wings Display, and a Pendulum Display. One nest described, in Aru Is, in tree hole 2 m above ground, entrance c. 38 mm in diameter and cavity depth c. 46 cm, filled to within "a few inches" of entrance perch with palm fibres. Clutch 1–2 eggs; incubation in captivity (from first egg) 17 days, chicks left nest (possibly prematurely) at 14 days of age; female performed distraction display when almost fledged young examined by keeper.
Movements. Presumably resident.
Status and Conservation. Not globally threatened. CITES II. Locally fairly common; widespread, but patchily distributed. Calculated as representing c. 1% of avifauna at Soliabeda (near Purari R, at 610 m), in SE New Guinea. In 2002, within Crater Mountain Wildlife Management Area (E New Guinea), estimates at 432–650 m were 64·6 individuals/km² in primary forest, 31·9/km² in old gardens and 28·9/km² in new gardens, and figures at 651–935 m were 5·4 in primary forest, 27·2 in old gardens and 15·9 in new gardens; in forest near Port Moresby, estimated density of 6 individuals/10 ha. Total of 22 adult males located during eleven days in 100 ha of mature forest at Kakoro (SE range), but only nine in 150 ha of similar habitat during six days at Nomad R (in EC New Guinea).
Bibliography. Anon. (2000b), Beehler & Pruett-Jones (1983), Bell (1982a, 1982c, 1983), Berggy (1978), Bergman (1956, 1957b, 1968), Coates (1990), Cracraft (1992), Diamond (1972), Dupond (1937), Frith & Beehler (1998), Frith & Frith (1997b), Frost (1930), Gilliard (1969), Hoppmann & Magnus (2009), Marsden *et al.* (2006), McCarthy (2006), Mees (1964a, 1965, 1982), Ogilvie-Grant (1915), Rand (1938c).



Genus *SEMIOPTERA* G. R. Gray, 1859

34. **Standardwing Bird-of-paradise**

Semioptera wallacii

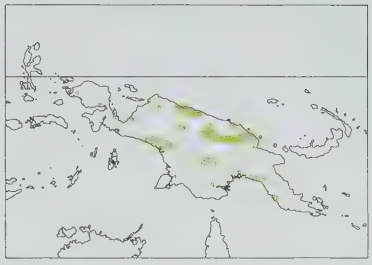
French: Paradisier de Wallace **Spanish**: Ave-del-paraíso de Wallace
German: Bänderparadiesvogel
Other common names: (Wallace's) Standardwing

Taxonomy. *Paradisea* (*Semeioptera*) *Wallacei* [sic] G. R. Gray 1859, near Labuha Village, Bacan, off south-west Halmahera.
Birds on Kasiruta presumed to belong to nominate race, but confirmation needed. Original spellings of genus and species names were "*Semeioptera Wallacei*", but these spellings have both been formally rejected by ICZN and the current spellings formally protected. Two subspecies recognized.
Subspecies and Distribution.
S. w. halmaherae Salvadori, 1881 – Halmahera, in N Moluccas.
S. w. wallacii (G. R. Gray, 1859) – Kasiruta and Bacan, off SW Halmahera.

Descriptive notes. Male 26 cm, 152–174 g; female 23 cm, 126–143 g. Distinctive paradisaeid with short tail, and upper ridge of culmen sharply keeled. Male nominate race has conspicuous tuft atop upper mandible base and lores buff, grading into somewhat flattened crown of dully iridescent lavender-grey with lilac sheen, paler on side of face; mantle and back olive-brown to earth-brown, rump and uppertail-coverts mid-brown, uppertail greyish with whitish feather shafts, central pair of rectrices shortest; upperwing-coverts, tertials and secondaries mid-brown to greyish, alula and primary bases drab grey, fading to off-white at tips; two grossly elongated white lesser coverts form "standards" as long as, or longer than, wing; dark buffy malar area, chin and throat with iridescent bronzed yellow-green feathering increasingly dense to form extensive breast shield of iridescent emerald-green with bronzed green-yellow sheen (may appear green-blue), shield not clearly defined and not scale-like; rest of underparts brown; iris dark brown; bill pale horn-colour; legs yellow-orange. Female is on average smaller than male, particularly in wing length, but central tail longer; lacks wing standards and breast shield, has buff tuft above nostril smaller than in adult male, and crown has only slightest of discernible lilac sheen. Juvenile undescribed; immature male like adult female, but on average slightly longer tail; subadult male varies, from like adult female with few feathers of adult male plumage intruding to like adult male with few feathers of female-like plumage remaining, wing and tail length on average intermediate between those of adult and immature males; with age, male acquires progressively shorter tail, central feather pair decreasing considerably in length. Race *halmaherae* is similar to nominate, but crown and nape (sometimes also mantle) with pinkish coppery-purple iridescence, tail longer but other measurements fractionally smaller. Voice. Four distinctive vocalisations: advertisement call of 6–7 upslurred loud clear strident "wark" notes (sometimes a single note); aerial-display call of loud, raucous and nasal upslurred barks; musical chatter and twittering associated with high-intensity display; and, most common vocalization, a series of loud, upslurred, nasal "wark" notes by foraging adult males or by individuals moving about canopy away from lek, which would thus appear to be a contact call. Lekking males give variable harsh loud churring "waughh" notes, repeated several to many times, also a repeated clearer "wau-wau-wau..."; individuals click mandibles in unison at lek; some calls audible at c. 300 m or more. Distinctive wing-rustling in flight.
Habitat. Rainforests in lowland and hills, to at least 1000 m (mostly above 250 m) on Halmahera and to above 1150 m on Bacan; rarely, in mature secondary woodland. Best-known lek, on Halmahera, situated in tropical rainforest at ridge crest of range of low hills, on slight knoll on N-facing slope c. 50 m above and from a large, ephemerally flooded, boulder-strewn creek.
Food and Feeding. Fruits and arthropods; no data on relative proportions of each, but possibly more fruits. Nestling fed at least with fruits. Frequents dense foliage of lower canopy and subcanopy, foraging on fruits in groups of 3–4 individuals, including adult males; sometimes joins mixed-species foraging flocks.

Breeding. Breeds at least May–Sept; males with much-enlarged gonads in Apr–Oct and a female similarly in Sept; one nest with egg in early May and nestling 9th Jun (left nest in same month); display from early dry season (about Apr) to onset of wet season (about Dec). Polygynous, lekking promiscuous adult males on traditional display perches in a few adjacent trees; female builds and attends nest alone. Display perches thin, near-vertical branches or twigs, 25–30 m above ground in lower crown of tall forest canopy trees, removes foliage from perches; on Halmahera lek typically of 5–7 adult males, but up to 30–40 birds (including young males in female-like plumage) reported. Display involves limb-hopping, with static postures, and flight displays with movements of wings, pectoral shield and wing standards; phases include communal Convergence Display, in which one or several males charge along or about branches, and this may develop into Wing Pose, Wing Standard Display followed by Aerial Display (adult males), perched Static Display and copulation; perch displays like those of *Paradisaea*, but aerial display flight unique, involving vertical leap from extended legs, nearly vertical ascent flight with beating of fully open wings, at peak of flight wings held fully extended and bill turned downwards, then downward "float" while conspicuously white primaries rapidly vibrated. Only known nest an open cup, base of dried leaves, placed 10 m above ground between foliage of a large epiphytic orchid and trunk of palm immediately beneath its canopy; contained 1 egg. No other information.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in Northern Maluku EBA. CITES II. Generally common on both Halmahera and Bacan. On Halmahera, not located in remaining lowland forests around Sidangoli and N along coast to Gilolo and at foot of Mt Gamkanora, on W coast of N peninsula, and apparently rare in Tobelo area (on E coast); absent from apparently suitable coastal forest on E shores of E peninsula. On Bacan, recently found to be moderately common in primary and logged forest at 70–1150 m, but scarce in flat areas of logged forest close to Ra R. Systematic surveys in 1994 resulted in average of 0·2–0·3 birds/ha on limestone and non-calcareous sedimentary rock, but few on igneous rock and in montane areas. Similarly systematic surveys during 1994–1995 on Halmahera calculated average relative abundance in primary lowland forest as 0·4–0·8 birds/ha (higher number for volcanic substrate). In 1976–1978, forest remaining on Halmahera and Bacan estimated to be c. 19,000 km², of which less than 10% on limestone. Recent logging, agricultural expansion and clearance have resulted in almost complete destruction of lowland forests and considerable damage to hill forest, representing a serious threat to future survival of many animal species. Careful monitoring required.

(1990b, 1995), Bishop (1984, 1992b), Coates & Bishop (1997), Friedmann (1934), Frith (1992), Frith & Beehler (1998), Frith & Frith (1997b), Frith & Poulsen (1999), Goodfellow (1927), Graves (1995), Lambert (1994), LeCroy (1983, 1988), LeCroy & Bock (1989), McAlpine (1979), Mlikovský (1989), Poulsen & Lambert (2000), Steinheimer (2005), Stephan (1967), Wallace (1869).



Genus *SELEUCIDIS* Lesson, 1835

35. **Twelve-wired Bird-of-paradise**

Seleucidis melanoleucus

French: Paradisier multifil **German**: Fadenparadieshopf **Spanish**: Ave-del-paraíso Filamentosa
Other common names: Twelve-wired Paradise Bird

Taxonomy. *Paradisea melanoleuca* Daudin, 1800, "Waigiou"; error = Salawati or the Vogelkop, New Guinea.
Intergeneric hybridization with *Ptiloris magnificus* and *Paradisaea minor* recorded. Two subspecies recognized.
Subspecies and Distribution.
S. m. melanoleucus (Daudin, 1800) – West Papuan Is (Salawati) and W & S New Guinea from Vogelkop E in N watershed to Mamberamo R and, in S watershed, to Port Moresby area and possibly to Milne Bay.
S. m. auripennis Schlüter, 1911 – N New Guinea from Mamberamo R to Ramu R.
Descriptive notes. Male 33 cm, 170–217 g; female 35 cm, 160–188 g. Male nominate race has entire head velvety black with iridescent coppery olive-green sheen, entire crown with purple iridescence; upperparts, including lesser upperwing-coverts, velvety black with iridescent oily sheen of coppery olive-green (washed purple in some lights); greater wing-coverts, alula, tertials, secondaries and uppertail iridescent violet-purple and/or magenta, primaries black; chin, throat and

entire breast velvety black with slight coppery yellowish-green iridescent sheen; large feathers bordering lower breast broadly tipped iridescent emerald-green, with violet-purple adjacent bases, forming gorget that extends up each side of breast; elongate and dense breast feathers form extensive breast "cushion"; remaining underparts, including grossly elongated, inwardly curving filamentous flank feathers, brilliant yellow; white central shaft of six flank plumes on each side grossly elongated beyond webs into black "wires" that, after recurving upwards, are again white; iris bright blood-red; black postocular stripe of bare skin; long, slightly decurved bill shiny black, mouth aqua-green; legs (including bare thighs) pink. Female is smaller than male, but with tail much longer; plumage radically different, cryptically drab-coloured, upper head and upper mantle sooty black with dull iridescent purple sheen, remaining mantle and entire upperparts chestnut-brown, paler on exposed primaries; malar area, throat and upper breast greyish-white, flecked, spotted and then uniformly barred blackish, as are remaining underparts; black postocular stripe of bare skin; bright pink tarsus. Juvenile undescribed; immature male like adult female (tail longer than adult male), also sometimes paler, washed with sandy orange-yellow and/or with brown base of lower mandible, iris pale brown, turning yellow with age; subadult male variable, from like adult female but with few feathers of adult male plumage intruding to like adult male with few remaining feathers of female-like plumage; with age, iris changes from yellow to almost red, and male progressively acquires grossly shorter tail. Race *auripennis* is smaller than nominate, notably in bill length, female underparts darker, more brownish, and more heavily barred than nominate. Voice. Male has two advertisement calls (accompanied by raising of open wings to expose yellow flanks): a throaty, nasal, resonant, mournful and downslurred "harnhr hahn" or "hahng"; and a series of 3–8 "hahr–haw haw haw" (note transcribed also as "ca'h", "wah", "wau", "wauk" or "oww"), first note highest-pitched and followed by brief pause, and final 2–7 in rapid succession. When a female visitor arrives, males give higher, insistent, whining, nasal "twang hahng-hahng-hahng-hahng-hahng", the notes falling in pitch, and a series of *Paradisaea*-like upslurred "koi-koi koi koi koi".
Habitat. Flat lowland rainforest, notably swamp-forest permanently or seasonally flooded and supporting pandanus (*Pandanus*) and sago palms (*Metroxylon*). Present up to 180 m.
Food and Feeding. Fruits, notably pandanus; also animals, mostly arthropods, but also small vertebrates (frogs, lizards); also flower nectar. Relative proportions of fruit and animals in diet estimated to be 50:50. Will forage acrobatically, hanging upside-down, to probe holes in tree branches. Joins mixed-species foraging flocks, including those with other birds-of-paradise and pitohuis (*Pitohui*).
Breeding. Breeds Jan to late Oct/early Nov in SE (near Port Moresby); males with enlarged gonads in Jan–Feb and Jun–Dec, peak gonadal activity Aug–Dec, females with enlarged oocytes Aug–Sept; display at least Jul–Jan. Polygynous, solitary adult male displaying at traditional perches; female builds and attends nest alone. Adult male frequents and vocally advertises one or several adjacent vertical, leafless and typically dead tree stumps protruding from forest canopy, three vocal males mapped at each of Nomad R and Kakoro (in E New Guinea) were at mean nearest-neighbour distance of 730 m; display perches, defended from other males, c. 0·5–1 km apart. Display involves perch dance, bill-fencing with female, postures involving movements of wings, flank plumes and wires, pectoral shield and thighs, and gaping, and a tactile phase (Wire-wipe Display) in which male swipes female across face with his flank wires. Nest a shallow egg-cup of (once supple) vine or tree inflorescence stems inside bulky deep structure of pandanus bark and vines on sparse foundation of sticks and leaves, lined with rootlets and plant fibres; built up to 14 m above ground in pandanus or sago palm. Clutch 1 egg, rarely 2; in captivity, incubation period 20 days, nestling left nest at 3 weeks of age.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. CITES II. Inadequately known, in part because of largely impenetrable habitat. Appears in general to vary from being locally uncommon to common; common on uplifted karst hill forest at 180 m in West Sepik Province (N New Guinea). In view of its extensive range and preferred habitat, this species is unlikely to be at any risk. Precise limits in SE of range uncertain, and species may occur E to Milne Bay if adequate coastal plains permit.

Genus *PARADISAEA* Linnaeus, 1758

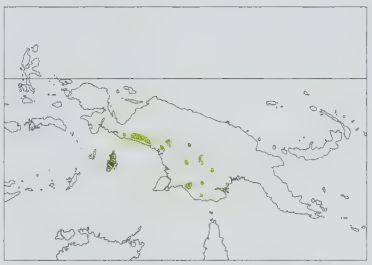
36. **Lesser Bird-of-paradise**

Paradisaea minor

French: Paradisier petit-émeraude **Spanish**: Ave-del-paraíso Esmeralda Chica
German: Kleiner Paradiesvogel
Other common names: Little Emerald Bird-of-paradise

Taxonomy. *Paradisea minor* Shaw, 1809, Dorey, Vogelkop, New Guinea.
Genus name sometimes spelt *Paradisea* (see page 46). Has been suggested to form a superspecies with *P. apoda*, *P. raggiana*, *P. decora* and *P. rubra*. Hybridization with *P. raggiana* and *P. guilielmi* and also, intergenerically, with *Ptiloris magnificus*, *Cicinnurus magnificus* and *Seleucidis melanoleucus* recorded. Proposed race *pulchra* (described from Misool, in West Papuan Is) synonymized with nominate. Three subspecies recognized.
Subspecies and Distribution.
P. m. minor Shaw, 1809 – West Papuan Is (Misool) and W New Guinea E in N watershed to West Papua–Papua New Guinea border and, in S watershed, to Etna Bay.
P. m. jobiensis Rothschild, 1897 – Yapen I, in Geelvink Bay (NW New Guinea).
P. m. finschi A. B. Meyer, 1885 – N New Guinea from just E of border E to Gogol and upper Ramu R.

Descriptive notes. 32 cm (excluding tail wires); male 183–300 g, female 141–210 g. Male nominate race has lores, forehead, ear-coverts, malar area, chin and throat finely feathered iridescent yellowish emerald-green, nostril covered by feathers; rest of head pale orangy yellow, glossed iridescent silver, this extending onto nape and mantle and blending into mid-brown of back and upperwing; remaining upperparts, including upperwing and tail, paler brown, washed maroon on back, rump and uppertail-coverts, wing with extensive orangy-yellow shoulder bar and outer edges of greater coverts; central pair of rectrices grossly elongated, only basally webbed and coloured as tail, distally reduced to fine brown wires; breast darker maroon-brown, becoming paler on belly, thighs and undertail-coverts, central tail-coverts soft, fluffy and much elongated; grossly elongated filamental flank plumes bright yellow at bases, streaked maroon, fading distally to dirty white and to slightest of beige hue; iris yellow; bill chalky bluish-grey, mouth pinkish-flesh; legs purplish grey-brown. Female is smaller than male, exclusively so in wing length, with central rectrices shorter, narrower and more pointed than rest; entire head dark brown, grading to paler buff on nape and mantle, remaining upperparts variably mid-brown to dark brown; dark brown throat, white rest of underparts with pinkish light brown wash, especially on flanks and undertail-coverts, thighs brown. Juvenile undescribed; immature male like adult female; subadult variable, like adult female with few feathers of adult male plumage intruding, and with central rectrices longer, narrower and more pointed than rest, to like adult male with few feathers of female-like plumage remaining; in captivity, transition from female-like to adult male plumage started at age 4 and continued for further 4–5 years, individual thus 8–9 years old when first in full adult male plumage; male acquires progressively longer central rectrices. Race *jobiensis* is larger than others, especially in tarsus length, has flank-plume colour same as nominate; *finschi* is on average similar in size to nominate, but flank plumes proportionately slightly shorter and of brighter orangy yellow; yellow shoulder less extensive than in other races. Voice. Advertisement song of lekking males is a series of high-pitched clear sharp "wak" notes (alternatively transcribed as "wok", "whi", "uwhi", "wha" or "waiy"), and "wik wong–wau wau", similar to songs of congeners; similar but more excited, higher-pitched and more quickly delivered convergence call usually started by a few softer introductory notes; calls show much variation in pitch, tone and speed between or within series of notes, especially by excited and counter-singing males.
Habitat. Lowland and hill forest, swamp-forest, forest edge and second growth; adaptable to human-altered environments. Sea-level to c. 1550 m. Adult and subadult males restricted to forest and advanced second growth, whereas birds in female-type plumage have broader habitat acceptance; upper altitudinal limit of adult and subadult males lower than that of female-plumaged birds. Leks reported from much-disturbed, secondary mid-mountain forest, and in a single lofty tree or two immediately adjacent trees in forest interior.
Food and Feeding. Mostly fruits, also arthropods. Forages mainly in canopy; also lower when seeking arthropods. May join mixed-species foraging flocks with other birds-of-paradise and flocks of New Guinea Babbler (*Pomatostomus isidorei*).
Breeding. Season at least Jul–Feb; males with enlarged gonads in most months, but more so Feb–Aug, and females with enlarged oocytes in Jul–Sept, Nov and Feb (mostly Aug). Polygynous, lekking promiscuous males at traditional tree perches; female builds and attends nest alone. Males defoliate lek area, up to twelve adult males in single lek tree, most copulations performed by centrally located individual male; traditional leks persist in one tree, or a few adjacent ones, for many years, possibly up to a century. Display occurs as males gather at a lek because one or more females nearby; courtship involves three fundamental display phases, i.e. Convergence Display, Static Display and Copulatory Sequence dance phase, with some additional postures and movements, the Convergence Display including upright Wing Pose (as for *P. apoda*). Two nests known, both a bulky open cup made from twigs, sticks, vines and dead leaves, lined with black wire-like fibres or rootlets, one placed 6 m above ground in branch fork of slender tree in forest near native garden, the other "very high" in thick foliage in a garden and fallow zone. Clutch 1–2 eggs, mostly 1; in captivity, incubation period 18 days, three single-nestling broods left nest 18 or 19 days after hatching.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. CITES II. Common and widespread. Very common in S Adelbert Mts in Mar–Apr 1959, and moderately common in forests from base to c. 1070 m on Cyclops Mts in Jul 1990; one of commonest birds on Yapen I, in lowland, hill and mountain forests, in Mar 1997. Despite generations of hunting of adult males by local people, this species appears not to have suffered any serious decline in its populations.



Bibliography. Aruah & Yaga (1992), Beehler (1983c), Coates (1990), Cooper (1995), David *et al.* (2009), Frith (1998), Frith & Beehler (1998), Frith & Frith (1997b), Gilliard (1969), Gilliard & LeCroy (1961), Gyldenstolpe (1955b), Healey (1978a), Hoogerwerf (1971), Hundgen *et al.* (1990), Laska *et al.* (1992), LeCroy (1981b), Majnep & Bulmer (1977), Mayr (1941), McCarthy (2006), Mees (1965), Menegaux (1913), Rand & Gilliard (1967).

37. **Greater Bird-of-paradise**

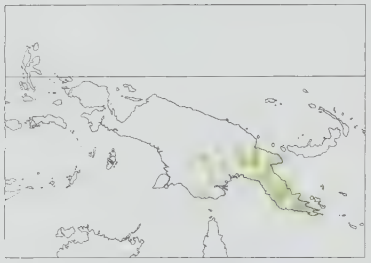
Paradisaea apoda

French: Paradisier grand-émeraude **Spanish**: Ave-del-paraíso Esmeralda Grande
German: Großer Paradiesvogel
Other common names: Great Bird-of-paradise

Taxonomy. *Paradisaea apoda* Linnaeus, 1758, India; error = Aru Islands, New Guinea.
Genus name sometimes spelt *Paradisea* (see page 46). Has been suggested to form a superspecies with *P. minor*, *P. raggiana*, *P. decora* and *P. rubra*. Hybridization with *P. raggiana* recorded; mixed leks including hybrid males found in S New Guinea. Race *novaeguineae* has been considered undiagnosable by some authors, who treat present species as monotypic. Two subspecies currently recognized.
Subspecies and Distribution.
P. a. novaeguineae D'Albertis & Salvadori, 1879 – mainland S New Guinea from Timika E to Fly/Strickland watershed.
P. a. apoda Linnaeus, 1758 – Aru Is.

Descriptive notes. Male 43 cm (excluding central tail wires); female 35 cm, 170–173 g. Male nominate race has lores, forehead, ear-coverts, malar area, chin and throat iridescent yellowish emerald-green, nostril covered by feathers; rest of head, including nape and hindneck, pale orangy yellow, glossed iridescent silver; entire upperparts, including upperwing and tail, maroon-brown, washed darker brown on mantle, back and lesser upperwing-coverts, slight orangy-yellow wash on outer edges of greater coverts; central rectrices grossly elongated, reduced to finely tapering blackish wires lacking webs except at bases, where same colour as tail; upper breast "cushion" blackish-brown, grading at lower border to dark brown and then to mid-brown on belly and medium pinkish-brown on thighs, vent and undertail-coverts; grossly elongated filamental flank plumes bright yellow at bases, streaked maroon, fading distally to dirty white; iris yellow; bill chalky pale bluish-grey; legs purplish grey-brown. Female is smaller than male, notably in wing length, with central rectrices shorter, narrower and more pointed than rest; entire head and upper breast dark brown, upperparts as on male but darker and lacking orangy-yellow wash, underparts similar to those of male. Juvenile undescribed; immature male like adult female; subadult male variable, like adult female with few feathers of adult male plumage intruding, initially about head, to like adult male with few feathers of female-like plumage remaining; males may take at least five or six years to acquire adult plumage, but study required; male progressively acquires longer central rectrices with age. Race *novaeguineae* differs from nominate in having paler upper breast, more maroon general coloration, and smaller size. Voice. Most common lek advertisement call by male a deep "wauk" or "wonk", delivered as 4–5 deliberate notes, first two equal in intensity and remainder increasingly louder and higher; also a more rapid series of "wauk" notes at one pitch, delivered in short bursts (each note usually accompanied by short wingbeats). Various calls during display phases: during Wing Pose a shrill sliding "eee-ak", usually repeated several times, but may be alternated with rapid "wauk"; series of rapidly repeated "wauk" notes of same pitch, delivered faster than above calls and, if given during Pump Display, notes often running together as "wa-wa-wa-wa"; at end of a Pump call, one or several drawn-out, harsh nasal "baa" notes given as male tips forwards and downwards; during Dance Display, male produces slow rhythmic "click", sometimes with faint nasal "bonk" as wings raised for a dance step; harsh, guttural "chug-ich", "chug-a" or "chug-a-la" may be given by male when bouncing along perch prior to "click" call, or when moving off from lek.
Habitat. Lowland forest and hill forest, to at least 950 m.
Food and Feeding. Few observations. Fruits and arthropods. Individuals in female-type plumage frequently in small groups, including with *Manucodia ater* and other avian frugivores; adult males away from lek typically solitary. Dietary preferences and foraging behaviour probably much as for *P. raggiana*.
Breeding. Breeding at least Mar, May and Aug–Dec; display at least Oct at Kiunga (in E of range). Polygynous, lekking promiscuous males on traditional tree display perches; female builds and attends nest alone. Lek consists of larger exposed horizontal boughs of large spreading tree(s), immediately beneath canopy, contains up to at least 15 adult males, which defoliate immediate area of display perches; leks traditional, persisting for many years in same tree or trees; some leks may be shared with male *P. raggiana*. Lekking males display both in absence of females and as latter approach or arrive at lek; three basic display phases are Convergence Display, involving upright Wing Pose and Pump (charging) Display, and Static Display with a Bow, and Copulatory Sequence involving dance phase that usually (but not always) follows Wing Pose–Pump–Bow sequence. One nest described, an open shallow basin-shaped structure 21 cm in total diameter, base of large leaves, and bowl of epiphytic orchid or vine stems and with some *Pyrrosia*-like fern fronds, egg-cup lining of long fine vine tendrils, built in large tree-branch fork. Clutch 1 egg; in captivity, artificial incubation 16–17 days, hatching 12–46 hours, chicks left nest at 18–20 days, start of independent feeding at 29–32 days.
Movements. Presumably resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in South Papuan Lowlands EBA. CITES II. Common and fairly widespread; probably commonest in lower foothills. In E of range, common in rolling lowland forest at c. 30 m to W & N of Kiunga; around Ok Tedi, recently declined conspicuously where hunting with shotguns occurred while remaining common where firearms not available. During extensive survey of Aru Is avifauna, this species was notably more abundant in N than in S, being moderately common Mar–Apr 1988; no males in adult plumage observed, however, these being regularly hunted for plume trade. Otherwise, although adult males heavily culled throughout range during height of plume trade, no serious adverse long-term impact apparent.

On following page: 38. Raggiana Bird-of-paradise (*Paradisaea raggiana*); 39. Goldie's Bird-of-paradise (*Paradisaea decora*).



Bibliography. Berlepsch (1911), Coates (1990), Cracraft (1992), David *et al.* (2009), Dinsmore (1969, 1970a, 1970b), Elliot (1873), Frith (2003), Frith & Beehler (1998), Frith & Frith (1997b), Goodfellow (1910), Iredale (1950), Jensen (2007), LeCroy (1981b), Mayr (1931c), McCarthy (2006), Wallace (1858, 1869).

38. Raggiana Bird-of-paradise

Paradisaea raggiana

French: Paradisier de Raggi **German**: Raggiparadiesvogel **Spanish**: Ave-del-paraíso de Raggi
Other common names: Raggi's/Count Raggi's/Red-plumed Bird-of-paradise

Taxonomy. *Paradisea raggiana* P. L. Sclater, 1873, Orangerie Bay, extreme south-east New Guinea. Genus name sometimes spelt *Paradisea* (see page 46). Has been suggested to form a superspecies with *P. minor*, *P. apoda*, *P. decora* and *P. rubra*. Hybridization with *P. minor*, *P. apoda*, *P. guilielmi* and *P. rudolphi* recorded. Race *salvadorii* sometimes treated as synonym of nominate. Additional proposed race *granti* (described from area inland from Huon Gulf) sometimes recognized, but probably better considered a linking population between *intermedia* and *augustaevictoriae*; two last-mentioned races hybridize in region of lower Mambare R. Four subspecies recognized.
Subspecies and Distribution.
P. r. salvadorii Mayr & Rand, 1935 – S & SE New Guinea from Fly/Strickland watershed E (extending into interior highland valleys, e.g. Wahgi and Tari Valleys) to Cloudy Bay.
P. r. augustaevictoriae Cabanis, 1888 – upper Ramu R and Huon Peninsula (and interior valleys to S, i.e. those of Markham, Wafa, Watut and Bulolo rivers), and also SE to Waria R watershed and coastally to lower Mambare R.
P. r. intermedia De Vis, 1894 – N coast of SE New Guinea from lower Mambare R E to Collingwood Bay.
P. r. raggiana P. L. Sclater, 1873 – S watershed of SE New Guinea from Cloudy Bay E to Milne Bay, and into N watershed as far as Goodenough Bay or Cape Vogel.

Descriptive notes. Male 34 cm (excluding tail wires), 234–300 g; female 33 cm, 133–220 g. Male nominate race has lores, forehead, ear-coverts, malar area, chin and throat iridescent yellowish emerald-green, nostril covered by feathers; rest of head, including nape and hindneck, pale orangy yellow, glossed iridescent silver, yellow extending as narrow collar across lower throat and also from hindneck onto mantle (there overlying dark brown, producing apparent mid-brown colour); remaining upperparts, including upperwing and tail, dark brown, washed maroon on back, rump and uppertail-coverts, with discrete pale orangy-yellow wingbar on lesser coverts and variable orangy-yellow wash on outer edges of greater coverts; central pair of rectrices grossly elongated, reduced to finely tapering blackish wires and lacking vanes except at bases; upper breast blackish-brown with iridescence of dark coppery-bronze, grading to medium brown on belly and to pinkish mid-brown on thighs, vent and undertail-coverts, the last softly filamental and elongated to half tail length; grossly elongated and tapering filamental flank plumes crimson to orange-crimson with buffish-white tips on lower surface and rusty-brown on upper surface; iris yellow; bill pale chalky bluish-grey, mouth pinkish-flesh; legs pale, dull fleshy brown. Female is smaller than male, notably in wing length and weight, and with central rectrices shorter, narrower and more pointed than rest; face, ear-coverts, chin and throat dark brown, crown, rear and side of neck and narrow foreneck-collar dark buff-yellow, collar quickly grading to pinkish light-brown on underparts, which paler on central belly. Juvenile is entirely dark brownish, but by four months of age like adult female; immature male as adult female; subadult male variable, like adult female with few feathers of adult male plumage intruding, initially about head, to like adult male with few feathers of female-like plumage remaining; male gains progressively longer central pair of rectrices; in captivity, first traces of adult male plumage acquired at c. 5 years, full plumage after at least a further year or two, two nestlings took three years to acquire completely yellow iris. Race *salvadorii* is like nominate, but brown mantle of both sexes lacking yellow, and scarlet of male flank plumes paler and plumes shorter; *intermedia* is similar to previous, but both sexes with yellow mantle–back and yellow streaking down to uppertail-coverts; *augustaevictoriae* is like last, but flank plumes apricot-orange, abdomen paler, and yellow throat-collar narrow, female much paler above and below than nominate female, with more buff-yellow on back, and yellowish collar on foreneck reduced or absent. Voice. Advertisement call of lekking males a series of loud far-carrying cries, increasing in intensity and sometimes in pitch, "wau wau wau wau wau wáú wááúú wááúú wáááúúú", end notes longest and coarsest, given at or away from leks; high-pitched call a more rapid, raspy "wok wok wok wak wak waagh waagh"; considerable variation in both these calls. Display call a long series of high-pitched, excited, insistent notes, given by male from lek perch and typically in presence of conspecifics during lek convergence; one or several males give display calls while vigorously performing charging displays.
Habitat. Lowland forest, hill forest and lower montane forest, secondary growth, forest edges, gardens, and casuarina (*Casuarina*) trees and copses in open deforested areas; adult males mostly remain in forest interiors; sea-level to c. 1500 m. Leks may be formed in almost any habitat type; traditional lek sites tend to occupy prominent position in local topography, such as high ridge crest, but also found in valleys or at sites lacking prominent relief.
Food and Feeding. Mostly fruits, mainly capsular ones and figs (*Ficus*); also arthropods. Nestlings fed with arthropods for first five days, thereafter with both fruits and arthropods. Frequents middle stage to canopy of forest. Gleans arthropods from bark, branches and canopy leaves. Joins other passerines in mixed foraging flocks, including those with New Guinea Babblers (*Pomatostomus isidorei*) and various pitohuis (*Pitohui*), sometimes with one or more other birds-of-paradise.
Breeding. Season at least Apr–Dec; nesting recorded Oct–Nov in Wau and late Jul and Aug at Varirata (near Port Moresby); males with gonads moderately enlarged in all months except Nov (sample lacking) but much enlarged only Apr–Oct and one in Jan; display months vary across range, peak Jun–Oct in Wau Valley and May–Aug at Varirata National Park, activity at each extending for at least a month before and after peak. Polygynous, lekking promiscuous males on traditional display perches; female builds and attends nest alone. Leks typically located in upper portion or top branches of a canopy tree in forest interior or forest remnant, most involving a single tree canopy but some can include another, and may hold several to as many as ten adult males; leks commonly long-lived, to more than 20 years; some leks may be shared with male *P. apoda*. Courtship involves three fundamental display phases, i.e. Convergence Display, Static Display and Copulatory Sequence dance phase, with small differences in detail of posturing, movements and feather presentation. Nest an open bowl-shaped structure of leaves, leaf pieces, rootlets, vine stems, orchids or ferns and fibres, with discrete egg-cup lining of horsehair-like material, built in tree branches 2–11 m above ground (higher in human-disturbed areas). Clutch 1–2 eggs, mostly 2, eggs laid on consecutive days in captivity; incubation period at one nest in wild 18 days, at one in captivity 20 days; nestling period in captivity (three nests) 17–20 days. Long-lived in captivity: 13-year-old female fertilized by a male c. 33 years old, and successfully raised two offspring.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. CITES II. Common, and widespread. In 2002, within Crater Mountain Wildlife Management Area (E New Guinea), estimates at 432–650 m were 16·3 individuals/km² in primary forest, 14·7/km² in old gardens and 20·9/km² in new gardens, and figures at 651–935 m were 42·7 in primary forest, 70·3 in old gardens and 70·8 in new gardens. In 1970s/80s, Brown R forest (Port Moresby) estimated to support 1 bird/ha, and in 200 ha on Mt Missim ten adult males were resident and formed two leks. No evidence of any significant potential threat.
Bibliography. Anon. (1998a), Beehler (1983a, 1983b, 1988), Beehler & Dumbacher (1996), Beehler & Pruett-Jones (1983), Bell, H.L. (1982a, 1983, 1984a), Cracraft (1992), Crandall (1931, 1932), David *et al.* (2009), Davis & Beehler (1994), Dharmakumarsinhji (1943), Diamond (1972), Forshaw & Cooper (1977), Frith (1981), Frith & Beehler (1998), Frith & Frith (1997b), Gilliard (1950, 1969), Goodfellow (1908), LeCroy (1981b), Mackay (1981), Marsden *et al.* (2006), Mayr & Gilliard (1954), McCarthy (2006), Muller (1974), Rimlinger (1984), Schodde (1976), Searle (1980), Stresemann (1924), Wahlberg (1992), Watson *et al.* (1962).

39. Goldie's Bird-of-paradise

Paradisaea decora

French: Paradisier de Goldie **Spanish**: Ave-del-paraíso de Goldie
German: Lavendelparadiesvogel

Taxonomy. *Paradisea decora* Salvin and Godman, 1883, Fergusson Island, New Guinea.
Genus name sometimes spelt *Paradisea* (see page 46). Has been suggested to form a superspecies with *P. minor*, *P. apoda*, *P. raggiana*, and *P. rubra*. Monotypic.
Distribution. D'Entrecasteaux Archipelago (Fergusson I, Normanby I), off SE New Guinea.

Descriptive notes. Male 33 cm (excluding tail wires), one 237 g; female 29 cm. Male has lores, lower forehead, malar area, chin and throat covered with fine iridescent plush yellowish-green to dark green feathering; crown and mantle to uppertail-coverts orange-yellow, richer on crown, iridescing white in some lights; upperwing-coverts pale orange-yellow, alula, flight-feathers and tertials pinkish, washed olive-brown, with yellow outer edges; uppertail similar to wing but darker, greatly elongated central rectrices reduced to fine wire-like shafts except at bases, where narrow tapering webs blackish with dark green iridescence; breast medium-grey with lavender suffusion, separated from iridescent green throat by narrow greyish-yellow collar, fading beneath lower breast to more pinkish-beige on vent, thighs and undertail-coverts; greatly elongated flank plumes silky crimson with white filamental tips ventrally, and rusty-brown with paler tips dorsally; thighs concealed by innermost flank plumes short, inwardly curving, and black with violet suffusion and iridescent gloss; iris sulphur-yellow; bill chalky blue-grey, interior mouth grey; legs purplish brown-grey. Female is considerably smaller (exclusively so in wing length) than male, except in bill length; forehead, lores, malar area, chin and throat dark brown, crown to upper mantle yellowish-buff, grading to brownish-olive on rest of upperparts; underparts cinnamon, darker on breast, and finely barred greyish throughout. Juvenile undescribed; immature male like adult female; subadult male variable, like adult female with few feathers of adult male plumage intruding, initially about head, central rectrices pointed and longer than rest, to like adult male with few feathers of female-like plumage remaining and central tail wires retaining some terminal webs as elongate spatulate tips; male gains progressively longer central rectrices with age. Voice. Advertisement calls of lekking male include "wok-wok" or "wark", usually given in absence of females; also soft "whick-whick" in absence of females, possibly as male-to-male contact, but a loud, liquid, ringing version of this given also when female on lek. Relatively soft "wuk wuk whik-whik-whik-whik" and explosively loud, clear, sharp, somewhat *Epimachus*-like "whit whit whit" call also known. Low growling call by male starting to display to a female; two males displaying simultaneously, often in presence of a female, may duet with loud, ringing metallic "waak" notes given alternately, these notes becoming increasingly rapid to produce continuous metallic rattling gurgle.
Habitat. Hill forest and forest edge, secondary regrowth, and fallow upland gardens; up to at least 600 m. A lek on SW Fergusson I was on steep S-facing slope, just below a ridge crest, at 400 m in mature rainforest with fairly even canopy c. 30–33 m high.
Food and Feeding. Little known. Fruits and arthropods. Forages both in trees and on ground.
Breeding. No data on season; one male in Sept and four in Dec had much-enlarged gonads; displays and matings observed second week of Nov. Polygynous, lekking promiscuous adult males on traditional display perches; female builds and attends nest alone. A lek in SW part of Fergusson I consisted of four main trees with display limbs at 20–23 m in middle canopy, nearer the trunk; c. 8–10 adult males attended this lek, usually two birds to each tree, and no more than two females and six unplumed males seen at any one time; males regularly defoliate display limbs. Courtship involves three fundamental display phases, i.e. Convergence Display, Static Display and Copulatory Sequence dance phase with additional postures and movements. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in D'Entrecasteaux and Trobriand Islands EBA. CITES II. Poorly known. Fairly common within tiny global range. Total population likely to be rather small, and probably declining as a result of habitat degradation. On other hand, this species seems to be tolerant of some small-scale logging. No imminent plans for large-scale logging on Fergusson and Normanby, but both islands have been targeted by multi-national logging companies; in addition, a proposal has been made to convert large areas of Normanby to cash crops. Contemporary assessments of this species' populations and habitats, and potential threats facing it, are needed.

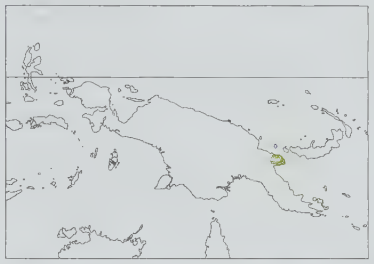
40. **Red Bird-of-paradise**

Paradisaea rubra

French: Paradisier rouge **German**: Rotparadiesvogel **Spanish**: Ave-del-paraíso Roja

Taxonomy. *Paradisea rubra* Daudin, 1800, Waigeo, West Papuan Islands, New Guinea.
Genus name sometimes spelt *Paradisea* (see page 46). Has been suggested to form a superspecies with *P. minor*, *P. apoda*, *P. raggiana* and *P. decora*. Monotypic.
Distribution. West Papuan Is (Waigeo, Gemien, Saonek and Batanta; presumably also Gam), off NW New Guinea.



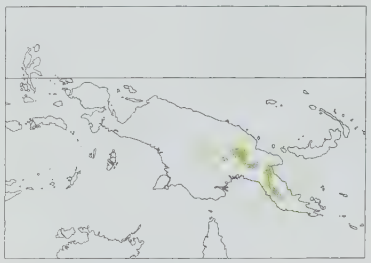
Descriptive notes. Male 33 cm (excluding tail wires), 158–224 g; female 30 cm, 115–208 g. Male has head to just behind eye, ear-coverts, chin and extensive throat area of finely scaled iridescent dark emerald-green feathering, feathers above each eye slightly elongated and curved to form erectile cushion-like structure; remainder of head, and nape, upper and central mantle and modified (mantle-like) upperwing-coverts pale orange-yellow, side and lower centre of mantle amber, washed yellow, with iridescent white sheen, grading to russet-brown on back; rump and uppertail-coverts pale orange-yellow, washed amber; upperwing, including alula and primary coverts, and uppertail reddish-brown; central pair of rectrices uniquely modified into grossly elongated, gently twisting, concave shiny black "tapes" 3–4 mm wide of plastic-like appearance and texture; somewhat stiff pale orange-yellow upper breast feathers, elongated and pointed to lower side, form small breast shield, and plumage beneath this glossy dark brown, washed maroon, becoming paler and less maroon on belly and grading to hazel on vent, thighs and undertail-coverts; elongate, slightly stiffened and downward-curving flank plumes carmine to crimson and variably dark brown to medium-brown on upper surface, with off-white filamental tips; iris dark reddish-brown; bill yellow, washed pale green; legs bluish-grey to grey-brown. Female is slightly smaller and clearly lighter than male, with central pair of rectrices narrower and more pointed than the rest; face (to posterior eye) and throat dark brown, rear crown, neck and nape buff-yellow, grading into dark brown on upperparts; upper breast with discrete broad glossy straw-yellow bar, remaining underparts brownish. Juvenile undescribed in wild, in captive-bred young yellow upper breast began to appear at 60 days and by 125 days was distinct and resembled that of adult female; immature like adult female, but on average larger; subadult male variable, like adult female with few feathers of adult male plumage intruding to like adult male with few female-type feathers remaining, central pair of tail feathers initially simply longer, narrower and more pointed than rest, to relatively short bare central shaft wire with elongate spatulate tip that becomes progressively longer and with smaller-webbed tips, male taking 5–6 years to acquire full adult plumage; male acquires progressively longer central pair of rectrices with age. VOICE. Most common advertisement call by lekking male a loud, clear repeated "wak", the bird building up to this with throaty "work – wok, wak, wak, wak, wak, wak", which then becomes loud "wok–wau-wau-wau". Other calls include similar but higher-pitched "ca–ca–ca–ca–ca–ca"; an oft-given corvid-like coarse, guttural "kaw, kaw, kaw"; also common is a soft pathetic-sounding "weep", and not uncommon are a soft high-pitched "meew" and a single snap of the mandibles, also a ticking sound that may be preceded by high-pitched "beep" and ended with low guttural "book", thus "beep t-t-t-t-t book".
Habitat. Lowland rainforest and hill forest, from sea-level to c. 600 m.
Food and Feeding. Little known. Fruits and arthropods recorded. In captivity, a female fed her single hatchling exclusively with regurgitated soft fruits for five days, then with animal food, when she continued to eat fruits herself but fed young only with cockroaches (Blattodea), crickets (Orthoptera), mealworms (*Tenebrio*) and pieces of new-born mice (Muridae); when offspring just over a month old, she started again to feed it with fruits, in addition to animal items.
Breeding. Females with enlarged oocytes indicative of breeding in Sept–Oct; display at least Jul and Sept. Polygynous, lekking promiscuous males on traditional display perches; female builds and attends nest alone. On Waigeo, lek in one gigantic tree in small forest clearing attended by up to ten adult males, which called and displayed on high defoliated limbs, usually after dawn (males most vocal early mornings and late afternoons). Courtship involves three fundamental display phases, Convergence Display, Static Display and Copulatory Sequence dance phase, with some additional postures and movements. No information of nest-site and nest in wild. In captivity, clutch 1–2 eggs, laid on consecutive or alternate days, incubation 14–17 days, nestling period 15–20 days.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in West Papuan Lowlands EBA. CITES II. Common in suitable habitats. Has very small global range, in which moderately small population likely to have declined as a result of habitat loss. On Waigeo, selective logging reported in N of island, SE corner suffered extensive fire damage in 1982, and concerns expressed over cobalt-mining concession on the island. On Batanta (where only 100 km² protected), logging has resulted in major habitat loss, but degree to which this species is tolerant of logged forest poorly known. It is hunted locally for skins and possibly for the cagebird trade. Extent of viable habitat and of collecting for bird trade require monitoring.
Bibliography. Anon. (2008j), Butchart & Stattersfield (2004), Collar *et al.* (2001), Crandall (1937a), David *et al.* (2009), Frith (1976), Frith & Beehler (1998), Frith & Frith (1997b), Gyldenstolpe (1955b), Heads (2002), Hundgen *et al.* (1991), Isenberg (1961, 1962), LeCroy (1981b), Stattersfield & Capper (2000), Todd & Berry (1980), Wallace (1869), Wilkinson *et al.* (2004), Worth *et al.* (1991).

41. **Emperor Bird-of-paradise**

Paradisaea guilielmi

French: Paradisier de Guillaume **Spanish**: Ave-del-paraíso Imperial
German: Kaiserparadiesvogel
Other common names: Emperor of Germany/White-plumed Bird-of-paradise

Taxonomy. *Paradisea Guilielmi* Cabanis, 1888, Kaiser Wilhelm's Land = Sattelberg, south-east Huon Peninsula, New Guinea.
Genus name sometimes spelt *Paradisea* (see page 46). Hybridization with *P. minor* and *P. raggiana* recorded. Monotypic.
Distribution. Huon Peninsula (Finisterre Range, Saruwaged Range, Cromwell Mts, Rawlinson Mts), in NE New Guinea.



Descriptive notes. Male 33 cm (excluding tail wires), 250–265 g; female 31 cm. Male has most of head and upper breast iridescent oily brilliant dark green or greenish-yellow, rear crown to neck and mantle pale straw-yellow with maroon feather bases; lower back, rump, uppertail, upperwing-coverts and tertials dark brown with maroon wash, remainder of upperwing and tail dark brown, central pair of tail feathers grossly elongated, only basally webbed, distally reduced to fine brown wires; yellow cowl extends down to lower side of green breast; lower breast dark maroon, belly dark dusky brown, vent, thighs and undertail-coverts dark brown, washed maroon; grossly elongated, fine, sparse filamental flank plumes ventrally and basally pale orangy yellow, elsewhere white, also a patch of elongate white feathers on each side of belly (impression of flank plumes expanding across underparts, almost meeting centrally); iris dark reddish-brown; bill chalky bluish-grey with pale tip, mouth (inside mandibles) chalky blue to pale aqua-blue; legs dull flesh-brown to brownish-pink. Female is smaller than male (exclusively so in wing length), lacks iridescent colours and elongated plumes; head and breast dark brown, and yellow on upperparts and side of breast duller; remaining upperparts dark brown, paler than on adult male, lower breast and belly mid-brown. Juvenile undescribed; immature male like adult female; subadult male variable, like adult female with few feathers of adult male plumage intruding to like adult male with few feathers of female-like plumage remaining; male acquires progressively longer central pair of rectrices, with slightly shorter outer ones, with age. VOICE. Loud advertisement calls of lekking males include a series of 6–8 notes, first shorter and lower in pitch, remainder a repeated high-pitched "whu, whow, whow, whow, whow, whow", and a series of 5 identical upslurred nasal "whai" notes of almost metallic quality. Lekking males also give "pop", "baupop" and "bau" notes repeated up to five times, the last sometimes followed by a "pop bau" call; the "pop pop" can be extremely loud, unlike soft introductory "poop" or "pop bau" calls, and when delivered rapidly said to sound like exploding firecrackers. Other calls include nasal, upward-inflected "whaaiy" or "whi", singly or in series, reminiscent of call of *P. raggiana*; and variable, quiet, nasal, conversational "whoh", "hah", "whaw", "oh" or "ow", singly or repeated several times at intervals of a few seconds. Distinctive preliminary display call, often preceded by loud rising liquid "whick, whop, whop, whop, whop", is a fairly rapid series of 4 or 5 downward-inflected bubbling notes, "whop-whop-whop…" or "whoc-whoc-whoc…"; variations by excited males include "whick", "whop", "whop" and "whick-whick, whop".
Habitat. Primary hill forest, including pockets of forest isolated by gardens and other disturbance; c. 450–1500 m, mainly 670–1350 m.
Food and Feeding. Little studied. Mostly fruits, with some arthropods. Undertakes much scansorial searching on trees, gleaning insects from bark. Forages singly or, particularly in case of adult males, in twos or in groups; forages in fruiting trees with other birds-of-paradise.
Breeding. Breeds at least Sept–Dec; male with gonads enlarged in Oct and much enlarged Nov–Dec; display months variable across range, in SE (Sattelberg) most frequent in late Jan to early Mar and less so Apr–May, in SW (Boana area) Jul–Aug. Polygynous, lekking promiscuous adult males on traditional display perches; female builds and attends nest alone. Leks consists of up to six adult males congregating in one or two adjacent trees within sight of each other, several males displaying synchronously in a tree; at one lek activity most intense from c. 15:15 hours, individuals displaying as low as 3–6 m above ground. Two fundamental display phases of Convergence Display and Static Display recorded, and in general lek behaviour similar to that of congeners (but Copulatory Sequence not yet observed); most striking departure from *P. apoda* is that, in Static Display, male may perch still and silently upright for a few moments, or suddenly call loudly, before turning under perch to hang upside-down with flank plumes expanded (forming white disc with two central yellow patches), wings and tail partly spread, and head turned upwards, and constantly rocking slowly while twisting from side to side (using legs as a fulcrum); a female may perch directly above inverted male to look down at him as he looks up at her. One nest (collected Sept), built on firm foundation of large broad leaves, was constructed mostly from creeper tendrils and vines, with egg-cup lining of fine tendrils; site not described. Clutch 1–2 eggs. No other information.
Movements. No information.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Adelbert and Huon Ranges EBA. CITES II. Fairly common, and reasonably widespread. Has small range and probably moderately small population, which thought probably to be undergoing fairly rapid decline. Forest habitat within its range is under threat from commercial logging, as well as from clearance for cultivation for rapidly increasing human population. Forest degradation appears to bring this species into contact with *P. raggiana*, a competitively dominant congener which eventually replaces it; such habitat degradation around Boana village resulted in a major decline of present species, coinciding with increase in *P. raggiana*. Although its plumes are still sought by local people and traders, this exploitation is evidently on only a small scale. In view of this species' restricted range, intensive survey of its distribution, population, habitat and foraging ecology, integrated with assessment of potential threats, is required. Any increase in habitat loss could result in its becoming globally threatened.
Bibliography. Anon. (2008j), Butchart & Stattersfield (2004), David *et al.* (2009), Coates (1990), Crandall (1932), Dratfan (1978), Frith (1971), Frith & Beehler (1998), Frith & Frith (1997b), Gilliard (1969), Heads (2002), LeCroy (1981b), Mayr (1931c), McCarthy (2006), Menegaux (1913), Ripley (1950), Stattersfield & Capper (2000), Stresemann (1924), Wagner (1938).

42. **Blue Bird-of-paradise**

Paradisaea rudolphi

French: Paradisier bleu **German**: Blauparadiesvogel **Spanish**: Ave-del-paraíso Azul
Other common names: Prince Rudolph's/Archduke Rudolph's Blue Bird-of-paradise

Taxonomy. *Paradisornis Rudolphi* Finsch and A. B. Meyer, 1885, Hufeisengebirge [Horseshoe Mountains = Mount Maguli], south-eastern New Guinea.
Genus name sometimes spelt *Paradisea* (see page 46). Hybridization with *P. lawesii* and *P. raggiana* recorded. Proposed race *ampla* (described from Mt Missim, in SE New Guinea) synonymized with nominate. Two subspecies recognized.
Subspecies and Distribution.
P. r. margaritae Mayr & Gilliard, 1951 – EC New Guinea (Tari area, Enga Highlands, Sepik–Wahgi Divide, Kubor Range, Mt Giluwe, Mt Hagen, Mt Karimui, Bismarck Range).
P. r. rudolphi (Finsch & A. B. Meyer, 1885) – SE New Guinea from Eastern Highlands (Okapa) and Herzog Mts SE to Owen Stanley Range.

Descriptive notes. Male 30 cm (excluding tail wires), 158–189 g; female 30 cm, 124–166 g. Male nominate race has head, neck and mantle glossy jet-black with iridescent bronzed-green sheen, rear crown and nape suffused with dark carmine-red; crescents of silver-white feathers forming broken eyering; back and rump blackish with iridescent blue-green (upper back), blue and indigo-blue sheens, uppertail-coverts dark cobalt-blue; upperwing variably blue on coverts and inner wing to purplish-blue on tertials, leading edges darker, flight-feathers matt blackish with blue outer edges on all except outer three primaries; uppertail purple-blue, central feather pair grossly elongated into "ribbons" of narrow matt bluish-black webs, paler spatulate tips showing iridescent blue; upper breast matt-blackish with slightest of dark blue iridescence, more pronounced sheen on lower breast, to jet-black belly and dark brownish-black thighs and undertail-coverts; grossly elongated fine, sparse filamental flank plumes basally dark purple-blue with violet sheen, becoming blue centrally and variably purplish-blue to mauve distally; upper surface of flank plumes rusty amber, two areas of inner flank plumes forming a black and a dark crimson linear patch on each side of belly, these meeting during display to form continuous bicoloured line; iris dark brown; bill palest chalky bluish-white, almost white, mouth greenish-yellow; legs purplish-grey. Female is smaller than male, lacks elongated feathers; head and upperparts similar to male, but black areas duller, more dark brownish-black, with only faintest iridescence and no carmine or magenta on head; chestnut-brown below, grading from blackish on throat to dark cinnamon on underparts, with slight matt blackish barring but less so on central belly (and absent in some populations); younger female has more extensive, blacker ventral barring and dark bill. Juvenile is like adult female, but wings darker, bill dark greyish, abdomen whitish, and white feathers around eyes fully developed; immature male like adult female; subadult male like adult female but with few feathers of adult male plumage intruding, grading to like adult male but with few feathers of female-like plumage remaining; with age, male acquires shorter outer rectrices while simultaneously gaining progressively longer and narrower central pair. Race *margaritae* is like nominate, but female underparts uniformly narrowly barred blackish, and tail (excluding central feather pair) and tarsus on average shorter. Voice. Advertisment call of male "kwank", reminisent of that of *P. raggiana* but lower-pitched and more bell-like; also a high-pitched, bell-like upslur followed by repeated hard downslurs, "kouwi–carr-carrr-carr-carr…", and slowly cadenced plaintive series of downslurred notes, "wahr, wahr, wahr, wahr, wahr, wahr", more nasal and higher-pitched than *P. raggiana* calls; also descending "we wah wah wah wah wah weh weh weh" series, each note upslurred, repeated loud, nasal "quoi", a series of several upslurred high-pitched notes on one scale, "waah-wah-wha-wha-wha-wha-wha", and single "quaa" or "kwaa" notes. Ventriloquial display call, given by inverted male alone or to female visitors, is rhythmical mixture of low nasal chitterings and chatterings interspersed with low "caw" notes (and often a strange vibrating twanging note) that becomes a fast rhythmic buzzing (sounding like electric motor); if a female moves away from male, this sound replaced with urgent chittering and chatterings.

Habitat. Lower montane forest, forest edge, and denser older secondary growth of fallow gardens; 1100–2000 m, mainly 1400–1800 m. Adult males tend to inhabit centre of elevational range, with young males at upper and lower zones.

Food and Feeding. Mostly fruits, especially figs (*Ficus*), drupes, berries; also some animals, mostly arthropods, possibly lizards. Forages in high canopy when seeking fruits; also often lower in forest when searching for arthropods, which obtained by bark-gleaning. Adult males usually alone, but sometimes in fruiting canopy with individuals in female-type plumage and other species of bird-of-paradise. Females will defend a food resource (fruits).

Breeding. Across species' range breeding can occur at any time of year, mostly Jul–Feb; egg-laying Apr, nestling Nov–Dec, and newly fledged chick with scolding parent mid-Dec; display in NW of range (near Kompiam) mostly Apr to late Nov. Polygynous, solitary promiscuous male advertisement-singing on traditional high perches and displaying on traditional low understorey perches; female builds and attends nest alone. Displays performed on slim, gently to steeply sloping branch, bamboo, grass or vine stem within 1–3 m of forest floor and with foliage directly above; male defoliates immediate area of display perches; two adjacent resident adult males were c. 300 m apart. Solitary courtship display consists of inverted Static Display only (lacks Convergence Display and ritualized Copulatory Sequence of congeners). Nest a sparse deep circular bowl of long, supple green stems of epiphytic orchids, pandanus (*Pandanus*) leaves, fibre of palm leaves, casuarina (*Casuarina*) needles, and few or no other leaves, lined with supple woody fine tendrils, possibly of vines, built c. 4–19 m above ground in variety of sites, from low bush to tall subcanopy tree. Clutch 1 egg, possibly rarely 2; incubation at one nest more than 18 days; parent aggressive towards conspecifics and to other bird-of-paradise species near nest with chick; no information on duration of nestling period.

Movements. Presumably resident.

Status and Conservation. VULNERABLE. Restricted-range species: present in Central Papuan Mountains EBA. CITES II. Uncommon throughout range; absent from some areas that appear suitable; somewhat more plentiful in certain areas, such as remnant forest and secondary growth on cleared mountain slopes of Kaindan area, near Kompiam. Global population estimated at fewer than 10,000 individuals. Main threat is habitat loss, combined with hunting for its plumes and tail feathers. Along one forest ridge 2 km long, 15 males called from non-overlapping advertisement territories, with mean nearest-neighbour distance c. 220 m, and mean distance separating 12 calling males on another ridge 3·5 km long was c. 400 m; advertisement-singing areas of these males did not apparently overlap, whereas all-purpose home ranges may have done. At another study site, density of males lower, each occupying up to 100 ha, this possibly due to more patchy nature of forest or greater hunting pressure. Although displaying males usually use patches of primary forest, this species is often seen in forest edge and nearby disturbed areas and may be able to survive in old secondary forest or fragmented primary forest; on other hand, it is likely excluded from more degraded habitats as a result of competition with more adaptable *P. raggiana*, combined with hunting of males. Vast areas of highland valleys and their slopes have aleady been cleared for agriculture and dwellings, and even today adult males continue to be hunted for their plumes; remaining forest is under pressure for clearance for agriculture by increasing human population. This species' relatively narrow elevational preference is very similar to that preferred by swidden gardeners, and ever-increasing human population will probably cause its extirpation from several intermontane valleys. Nevertheless, significant areas of its range are inaccessible and largely uninhabited, giving reason for some optimism with regard to its survival in the short term.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family CORVIDAE (CROWS)

- Medium-sized to large passerines with strong bill, sturdy legs, many species with black, grey or black-and-white plumage, often with metallic gloss, or blue, green, yellow, violet or brown.
- 20–69 cm.

- Almost cosmopolitan.
- Almost all terrestrial habitats; many species in towns and villages.
- 24 genera, 123 species, 359 taxa.
- 12 species threatened; 1 extinct in the wild since 1600.

Systematics

One of the best-known of avian groups, the family Corvidae has fascinated man for millennia. Images of these birds grace the cave walls of early humans. Their voices and actions stimulate human language and cultures, and their vernacular names, those of crow, raven, jay and magpie, are familiar almost everywhere. Exceptional memory, enormous curiosity, attractive movements, high sociability, varied vocalizations, and ecological plasticity are some features of the family that have so intrigued scientists and people around the world. Viewed as symbols of opportunism, quickly solving problems in laboratory experiments, and exploiting their wild environments with apparent cold calculation, as evidenced by such habits as the dropping of shellfish and nuts from suitable heights on to hard surfaces in order to break them, or the use of area-restricted search tactics to find eggs and nestlings of small birds, the crows have reached the position where few people remain indifferent to their abilities. With an extraordinary earlier adaptive radiation, the family Corvidae, with 24 genera and 123 species, has a worldwide distribution, its members living under a large variety of conditions, from the Arctic to the hottest deserts, at elevations from below sea-level to 6400 m, on islands and continents and in wild and urban areas.

Despite extensive radiation, all indications, from the first studies based on plumage patterns, behaviour, morphology and ecological affinities to recent investigations using a battery of molecular techniques, suggest that the family as presently constituted is derived from one ancestor. In other words, it is monophyletic. C. G. Sibley and J. E. Ahlquist proposed that the origin of the group could be traced to Australia, from which an ancestor was able to disperse to Asia. The group later radiated in Asia and Europe. Recent analyses by G. P. Ericson and collaborators of all genera of Corvidae, based on DNA sequences, support the proposal that the origin of this group dates to the splitting of the Australo-Papuan tectonic plate from Antarctica in the early Tertiary, some 53 million years ago. This was the time when the oscine passerines, to which Corvidae belongs, originated, as the Australo-Papuan plate came close enough to Asia to allow birds to disperse to that continent. The fact that the largest number of genera of Corvidae is found in Eurasia, which has been mentioned since D. Goodwin's first monograph on the group, is congruent with such a theory. From Eurasia, corvids dispersed to Africa and the Americas, resulting in the nearly worldwide present-day distribution; the family is absent only from Antarctica and some oceanic islands. The ancestor of Corvidae was, almost certainly, a forest-dweller. By the time when oscines started to radiate extensively, in the late Oligocene and the Miocene, 28–7 million years ago, the early Tertiary rainforests of Australia had been largely replaced by savanna-like forest or even drier vegetation. Such changes on the Australian continent likely challenged this forest-adapted ancestor and may have stimulated the movement and early radiation of Corvidae.

The relationship of Corvidae to other avian families has been debated for a long time. On the basis of similarity in egg-albumen protein, the family Laniidae, containing the true shrikes of the genera *Lanius*, *Corvinella* and *Eurocephalus*, was considered the sister-group of Corvidae in the 1980s. DNA annealing rates placed

The New World jays form a large, well-defined group, which has radiated to inhabit tropical, subtropical and mild temperate regions. Their ancestor would have reached North America some 8–10 million years ago. All the species share a characteristic configuration of the lower jaw known as the buttress complex. The ***Pinyon Jay*** *is the only member of its genus, and differs from other New World jays in having eleven rather than ten secondaries. The male of this dull blue crestless species has a brighter blue head.* Gymnorhinus *means "bare nostrils"; among corvids, the Pinyon Jay shares this feature only with the Rook* (Corvus frugilegus) *and the Crested Jay* (Platylophus galericulatus).

[*Gymnorhinus cyanocephalus*, Oregon, USA. Photo: Brian E. Small]

Little is certain about the taxonomic affinities of the ***Crested Jay****, a little-known species restricted to the Malay Peninsula and the Greater Sundas. It may not be a corvid at all, instead closer to the helmet-shrikes (Prionopidae) or bush-shrikes (Malaconotidae), and indeed an alternative name is "Crested Shrike-jay". Its long, nodding crest is unique, and it lacks both the nasal tuft of bristles and the unspotted juvenile plumage common to other members of the family. For the present, it is still treated as a member of Corvidae, though possibly a very primitive one.*

[*Platylophus galericulatus galericulatus*, Java. Photo: Roland Seitre]

the traditional corvid species as the tribe Corvini within the subfamily Corvinae in the family Corvidae. In this Sibley and Ahlquist classification of the 1990s, the subfamily Corvinae included, besides the tribe Corvini, the tribes Paradisaeini (the birds-of-paradise), Artamini (the woodswallows) and Oriolini (the Old World orioles); in this arrangement, the butcherbirds (Cracticidae) were included within Artamini. More recently, K. Helm-Bychowski and J. Cracraft, using molecular data, suggested that the family Corvidae is a sister-group of the birds-of-paradise (Paradisaeidae). This work concluded that the bowerbirds (Ptilonorhynchidae) were basal to the group composed of Paradisaeidae, Corvidae, Laniidae and Vireonidae (the vireos). The forest-dwelling habits of the Paradisaeidae seem also to corroborate the suspected forest-adapted habits of the ancestor of Corvidae.

Using a variety of molecular techniques, Ericson and collaborators suggest that the oldest branches of Corvidae include taxa that are mostly confined to the forests of south-eastern Asia, namely the genera *Crypsirina*, *Dendrocitta*, *Platysmurus*, *Temnurus*, *Cissa* and *Urocissa*. This area is the one in which the ancestral corvid presumably first arrived from the Australo-Papuan region some 53 million years ago. The exception is the chough genus *Pyrrhocorax*, which is distributed in mountain areas from the Himalayas west to western Europe. In an early molecular-genetic study, A. Cibois and E. Pasquet used cytochrome *b* analysis to suggest that *Pyrrhocorax* was the oldest lineage within the family. Recently, using characters of the tongue skeleton (apparatus hyobranchialis), A. Manegold corroborated the position of *Pyrrhocorax* as being outside the core-

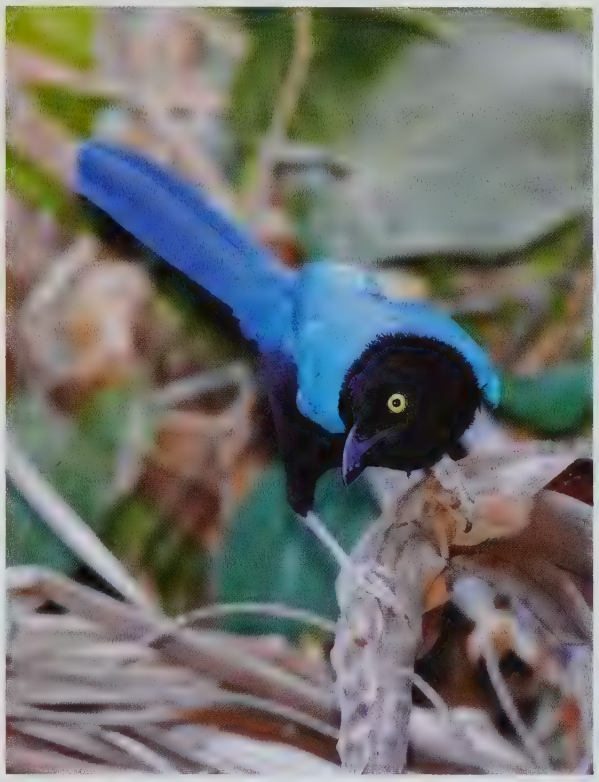
The two members of the genus Cyanocitta, *the* ***Blue Jay*** *and Steller's Jay* (C. stelleri), *are such close relatives that they interbreed where their ranges meet in the US Midwest. Both are woodland species, and in common with other woodland-dwelling members of the family, such as other jays and some magpies, they have relatively short, rounded wings which are flapped rapidly. Across the Blue Jay's range, which extends from Canada to Florida, there are four races, which become progressively smaller towards the south.*

[*Cyanocitta cristata bromia*, Maple Grove, Quebec, Canada. Photo: Scott Linstead/ VIREO]

Three of the five species of Aphelocoma *currently recognized were formerly considered races of the same species, known simply as the Scrub Jay. But although the Island* (A. insularis), *Florida* (A. coerulescens) *and* ***Western Scrub-jays*** *have very similar plumage, there are considerable vocal and behavioural differences between them. There have been further proposals to split the Western Scrub-jay into two species, based partly on the completeness of the blue breastband, and the differences between the stronger, more hooked bill of the acorn-feeding Pacific population and the slimmer bill of the pinyon-nut-feeding inland birds.*

[*Aphelocoma californica woodhouseii*, Franktown, Colorado, USA. Photo: Dave Maslowski/ Maslowski Productions]

group Corvidae. This was contrary to the traditional position of *Pyrrhocorax*, which was thought to be closely related to *Corvus* and *Nucifraga* because of common osteological, morphological and ecological characters. *Pyrrhocorax*, however, differs from those two genera in having smooth, rather than scaled, tarsi, very short and dense nasal feathers and brightly coloured bill and feet, and in being mainly insectivorous, using the slender and decurved bill to pick and dig its prey from ground or rock crevices. Two species of *Pyrrhocorax* are recognized: the Red-billed Chough (*Pyrrhocorax pyrrhocorax*) and the Yellow-billed Chough (*Pyrrhocorax graculus*).



The species commonly known as treepies (*Crypsirina*, *Dendrocitta* and *Temnurus*) and some of the genera called magpies (*Platysmurus*, *Cissa* and *Urocissa*) inhabit mainly tropical and subtropical forest. Treepies do not have bright colours and have a thick bill with a strongly curved culmen. Both D. Amadon and Goodwin considered *Dendrocitta* and *Temnurus* as subgenera of *Crypsirina*, but this treatment was not formally recognized. Recent DNA sequences indicated a closer relationship of *Temnurus* with *Platysmurus*, both of which have stiffened feathers on the forehead, than with the other two genera of treepies. *Crypsirina* is composed of two species, the Racquet-tailed Treepie (*Crypsirina temia*) and the Hooded Treepie (*Crypsirina cucullata*), which have ten tail feathers, whereas most of the other treepies have twelve. In addition, both *Crypsirina* have the two central tail feathers with an expanded spoon-shaped tip. The Ratchet-tailed Treepie (*Temnurus temnurus*), in a monoptypic genus, also has an unusual tail, which is graduated and composed of ten feathers each widely forked at the tip, the outer points of the fork projecting on each side of the closed tail. *Dendrocitta* has the longest tail among the treepies and forms a rather homogeneous group of closely related species. The Grey Treepie (*Dendrocitta formosae*), the Sumatran Treepie (*Dendrocitta occipitalis*), the Bornean Treepie (*Dendrocitta cinerascens*) and the White-bellied Treepie (*Dendrocitta leucogastra*) have similar and probably homologous plumage patterns and allopatric distributions, and they form a species group. The Rufous Treepie (*Dendrocitta vagabunda*) is variable in colour intensity over its wide range. The Collared Treepie (*Dendrocitta frontalis*), restricted to the eastern Himalayas, is smaller than the aforementioned members of its genus, and has a deeper bill with a much more strongly curved culmen and commissure. Perhaps it is the case that the Rufous Treepie and the Collared Treepie have only a distant relationship. The smallest *Dendrocitta*, however, is the Andaman Treepie (*Dendrocitta bayleii*), confined to the Andaman Islands. Placed in a genus of its own, the Black Magpie (*Platysmurus leucopterus*) is considered an early treepie, although it is more heavily built and has a proportionately shorter tail.

Another monotypic genus, *Platylophus*, was not evaluated in the molecular analyses of the family by Ericson and colleagues because its taxonomic position is not clear. In fact, the corvid affinity of the Crested Jay (*Platylophus galericulatus*) has for

Cyanolyca *jays are small and sleek. They are rather uniformly dark blue except for a black mask, and in some cases a patterned head, such as the azure-blue crown of this species. The* ***Azure-hooded Jay****, found in cloudforest and upland oak woodlands from Mexico to Panama, is the most widely distributed member of the genus. It forms a species pair with the Beautiful Jay* (C. pulchra), *which is found in similar habitat on the northernmost slopes of the Andes. Most* Cyanolyca *jays have very restricted ranges, usually in montane humid forests.*

[*Cyanolyca cucullata*. Photo: John S. Dunning/ Ardea]

*The **San Blas Jay** is one of four closely related species which were previously assigned to their own genus,* Cissilopha, *because they retain their immature bare-part colours for longer than other New World jays. Although similar in plumage, with black heads and underparts and blue upperparts and tails, the four differ from each other in habitat preference and social behaviour. The highly social San Blas Jay chooses open woodland in lowland areas, and takes readily to cultivated areas, having a particular affinity for coconut groves.*

[*Cyanocorax sanblasianus nelsoni*, Mismaloya, Jalisco, Mexico. Photo: Rick & Nora Bowers/VIREO]

long been questioned; this species may not be a corvid at all, or, at least, it must represent one of the most primitive of the family. It has been suggested that it would be better placed in the African family of bush-shrikes (Malaconotidae), but, for the time being, it is perhaps better to leave it in the crow family.

The three green magpies making up the genus *Cissa* and the five blue magpies in *Urocissa*, inhabiting mostly forests of south-eastern Asia, are among the most colourful species in the family. The Sri Lanka Blue Magpie (*Urocissa ornata*) links the green magpies and the blue magpies, illustrating the close relationship between the genera, which was supported in the genetic study of Cibois and Pasquet. The difference in head markings, used in the past as a criterion for separating the blue magpies from the green, have been shown to be unreliable, because juveniles of the Red-billed Blue Magpie (*Urocissa erythroryncha*) and Yellow-billed Blue Magpie (*Urocissa flavirostris*) have head markings very similar to those of the green magpies. The Taiwan Blue Magpie (*Urocissa caerulea*), the Red-billed Blue Magpie and the Yellow-billed Blue Magpie form a superspecies. The White-winged Magpie (*Urocissa whiteheadi*), with its dusky body, is a unique blue magpie, sometimes allocated its own monotypic genus, *Cissopica*. The species of green magpie form a group with complex taxonomic relationships. In the past, the number of species in the genus *Cissa* varied from six to no more than two. In the present treatment, three species are recognized. These are the Common Green Magpie (*Cissa chinensis*), the Indochinese Green Magpie (*Cissa hypoleuca*) and the Short-tailed Green Magpie (*Cissa thalassina*), and they form a superspecies.

Ericson and co-workers showed that the later radiation of the Corvidae was associated with an adaptation to drier habitats. For example, the genera *Cyanopica*, *Perisoreus*, *Garrulus* and *Pica*, with geographical distributions partly in Asia, represent an adaptation to drier conditions. Extreme specialization on dry habitats is demonstrated by *Ptilostomus* and *Zavattariornis*, which inhabit dry grasslands in Africa, and *Podoces*, which lives in deserts of Iran and Central Asia. Ericson and collaborators suggested that *Perisoreus* was closely related to *Cyanopica*, and that the clade of these two in turn formed a trichotomy with the New World jays of the genera *Cyanolyca*, *Cyanocitta*, *Gymnorhinus*, *Aphelocoma*, *Cyanocorax*, *Calocitta* and *Psilorhinus* on the one hand and, on the other, the large group of core Old World taxa represented by *Zavattariornis*, *Ptilostomus*, *Podoces*, *Garrulus*, *Pica*, *Nucifraga* and *Corvus*.

So, modern analyses do not fully support some old and widely held theories about the systematic relationships among jays. For example, the supposed relationship between the Palearctic jays in the genus *Garrulus* and the American jays in *Cyanocitta*, based upon the barred pattern in the wing and tail feathers, which had already been rejected by J. W. Hardy in the 1960s, is not supported at the present time. In addition, the relationship between the Palearctic jay genera *Perisoreus* and *Garrulus* is rather distant in the modern analyses, despite morphological similarities between the Sichuan Jay (*Perisoreus internigrans*) and the Black-headed Jay (*Garrulus lanceolatus*). Nevertheless, in the recent study by Manegold, using characters of the tongue skeleton, the position of *Perisoreus* was closer to that of *Garrulus* than would be expected from the findings of Ericson and collaborators.

The genus *Cyanopica* presents an interesting disjunct distribution, with the Asian Azure-winged Magpie (*Cyanopica cyanus*) in the eastern Palearctic and the Iberian Azure-winged Magpie (*Cyanopica cooki*) in Spain and Portugal. It was thought that Portuguese merchants and sailors brought this corvid from China to Europe, but differences between the two forms suggest that the European population has been isolated for an exceedingly long time. Similarities between Palearctic Asia and Iberia in the seasonally hot maritime climate make it possible that *Cyanopica* had a more continuous range in the distant past. The recent discovery of *Cyanopica* bones from late Pleistocene sites in Gibraltar, in the extreme south Iberian Peninsula, reinforces the idea that colonization of Europe by this genus was not the result of human introduction. In the genus *Perisoreus*, the least colourful of the jays, the three species probably represent a superspecies. Two of them occur over a large area in the higher latitudes of the Northern Hemisphere, the Siberian Jay (*Perisoreus infaustus*) in Europe and Asia and the Grey Jay (*Perisoreus canadensis*) in North America. In contrast, the third species, the Sichuan Jay, has a quite restricted distribution, limited to a small area in central China. *Perisoreus* is unique among the Corvidae in having special mucus-secreting glands inside the mouth. *Cyanopica* and *Perisoreus* are thought to have diversified in the Old World before a Siberian form of the latter dispersed across the Bering landbridge to North America 1·5 million years ago.

*Although jays and magpies generally have longer tails than other corvids, the tail of the **Black-throated Magpie-jay** is exceptional, making up more than half the length of the bird. The waving tails draw even more attention to groups of these noisy and conspicuous birds, which are found only in a small area of north-west Mexico. This species overlaps slightly with its sole congener, the much more widespread White-throated Magpie-jay* (Calocitta formosa), *which has a shorter, but still exceptional, tail. They are most closely related to* Cyanocorax *jays, and have sometimes been considered a single species. The two interbreed in Jalisco and Colima, where birds with intermediate plumage are locally common.*

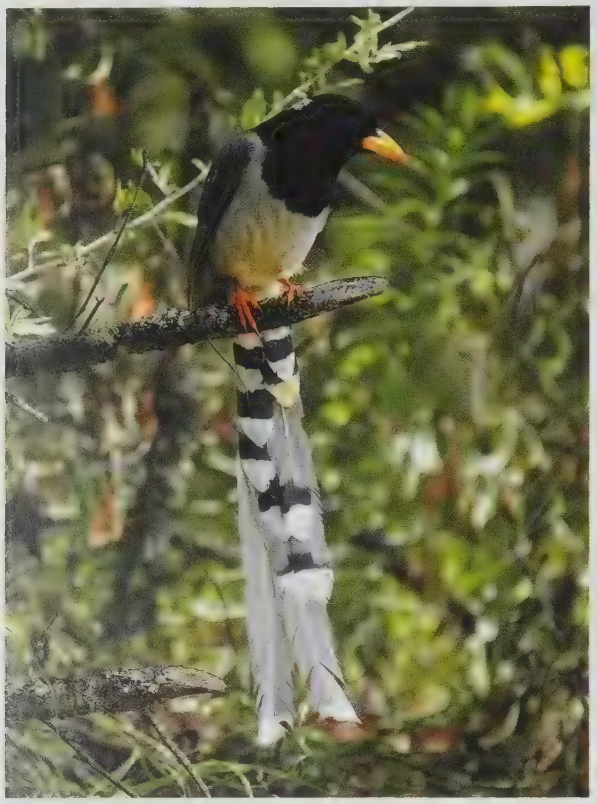
[*Calocitta colliei*, Mexico. Photo: Roland Seitre]

*Some New World jays are described as dull, relative to other members of their group, but only the **Brown Jay** could be called dingy. This species, assigned to a genus of its own, has one particularly distinctive feature: when calling, it inflates a small, bare pouch on its chest. There are two colour morphs, the plain-tailed, shown here, and the white-tipped. Once thought to be separate species, the two forms occur within the same populations in Mexico.*

[*Psilorhinus morio palliatus*, Texas, USA. Photo: Brian E. Small]

The New World jays comprise a well-defined and large group of corvids which have radiated extensively to inhabit tropical, subtropical and mild-temperate regions. The monophyly of this Corvidae group is supported not only by data derived from DNA sequencing, but also by the structural configuration of the jaw articulation, the buttress complex (see Morphological Aspects), described by R. L. Zusi. The ancestor, probably a jay-like bird closely related to *Cissa* and *Urocissa*, reached North America in the Miocene, 10–8 million years ago, presumably by following the trans-Bering route, later entering South America in the early Pliocene when the Isthmus of Panama was formed, 5·3–3·6 million years ago. A. Espinosa de Los Monteros and Cracraft used cytochrome *b* sequences to suggest that *Cyanolyca* is the most basal of the New World jays, with the genera *Cyanocitta*, *Aphelocoma* and *Gymnorhinus* as the most derived clade of that group, and the clade formed by *Cyanocorax*, *Calocitta* and *Psilorhinus* as the intermediate one. Such an arrangement was corroborated by Ericson and collaborators, using the mitochondrial DNA control region. Thus, modern analyses do not support the behavioural and morphological hypothesis of Hardy, who had proposed two main evolutionary lineages of New World jays, one an "Inornate Line", with the genera *Aphelocoma* and *Cyanolyca*, and the other an "Ornate Line", with the remaining genera. Hardy's arrangement had placed *Aphelocoma* at the base of New World jays and closely related to *Cyanolyca*, but this has not been borne out by molecular analyses.

In the most recent study of phylogenetic relationships of New World jays, E. Bonaccorso and A. T. Peterson used DNA sequences from three mitochondrial and two nuclear loci from 16 species, combined with their historical biogeography. Besides supporting the relationships as presented above, the results indicated that the ancestral distribution area of New World jays is restricted either to Middle America or to the combined region of Middle America and North America. The genus *Cyanolyca* and the *Cyanocorax–Calocitta–Psilorhinus* clade originated in Middle America, whereas the Green Jay (*Cyanocorax yncas*), the



The Palearctic genus Garrulus *includes both the widely distributed Eurasian Jay* (G. glandarius), *which exhibits the most extreme racial variation of any corvid, with 34 subspecies, and the **Black-headed Jay**, a monotypic form confined to the forested slopes of the western Himalayas. There are striking similarities in the barred pattern of the wings and tail of Black-headed, Eurasian and Blue Jays* (Cyanocitta cristata), *but this is not thought to signify a close relationship between* Garrulus *and the New World genus* Cyanocitta.

[*Garrulus lanceolatus*, Sat Tal, Uttarakhand, N India. Photo: Marc Guyt/AGAMI]

Small and superficially not looking much like a typical jay, the ***Siberian Jay*** *is one of the most widespread of the corvids. Its North American equivalent is the Grey Jay* (Perisoreus canadensis) *and together the two span the higher latitudes of the Northern Hemisphere. Both are characteristic species of the boreal taiga forest. Siberian Jays vary in colour, being greyest in central Siberia, and more rufous towards the east and west, with further variations, particularly in the amount of rufous in the wing, from south to north. There is much debate over how many races should be recognized, with some authorities proposing as many as 17 and some as few as four; nine are recognized herein. Along with the third member of the genus, the restricted-range Sichuan Jay* (P. internigrans), *the Siberian and Grey Jays are alone among the Corvidae in having mucus-secreting glands inside the mouth. The mucus is used to produce food balls which are stuck firmly to trees for storage.*

[*Perisoreus infaustus infaustus*, Kuusamo, Finland. Photo: Markus Varesvuo]

The ancestral corvid from the Australo-Papuan subregion probably arrived in the forests of southern and eastern Asia some 53 million years ago. Molecular studies suggest that the genera found here are some of the oldest branches of the Corvidae, including the green magpies (Cissa) *and the blue magpies* (Urocissa). *The* ***Yellow-billed Blue Magpie*** *replaces the Red-billed Blue Magpie* (U. erythroryncha) *at higher elevations in the Himalayas.* Cissa *and* Urocissa *are very closely related, and juvenile Yellow-billed and Red-billed Blue Magpies have head markings very similar to those of the green magpies.*

[*Urocissa flavirostris flavirostris*, Bhutan.
Photo: Michael Noonan/ VIREO]

South American *Cyanolyca* and the South American *Cyanocorax* each represent an independent invasion of South America.

Cyanolyca species are small and sleek jays, uniformly dark blue except for a black mask, inhabiting forests of Middle and South America, where they are usually found at higher altitudes, at up to 4000 m above sea-level. All four of the species living in South America have a restricted geographical distribution, centred in the northern Andes. Three of these South American species, the Black-collared Jay (*Cyanolyca armillata*), the White-collared Jay (*Cyanolyca viridicyanus*) and the Turquoise Jay (*Cyanolyca turcosa*), form a superspecies; the Beautiful Jay (*Cyanolyca pulchra*) probably forms a species pair with the Middle American Azure-hooded Jay (*Cyanolyca cucullata*), which has the largest distribution of any member of this genus. The other Middle American forms, namely the Black-throated Jay (*Cyanolyca pumilo*), the Dwarf Jay (*Cyanolyca nanus*), the Silvery-throated Jay (*Cyanolyca argentigula*) and the White-throated Jay (*Cyanolyca mirabilis*), may comprise a separate superspecies. In a recent study based on the analysis of two mitochondrial and three nuclear loci, such general relationships among the *Cyanolyca* species were strongly supported. In this study, Bonaccorso suggested that *Cyanolyca* comprises two major clades, one containing most of the Middle American jays and the other consisting of two subgroups; one of these subgroups comprised the Beautiful Jay and the Azure-hooded Jay, and the other the remaining South American species.

The genus *Cyanocorax*, occurring from the southern USA southwards to Uruguay, is quite diverse. Its 16 species include colourful ones, such as the Plush-crested Jay (*Cyanocorax chrysops*), and drab ones, such as the Purplish Jay (*Cyanocorax cyanomelas*), and they are found in a variety of habitats ranging from forest and forest borders to savanna and dry scrub. One possible new species of *Cyanocorax*, not yet formally described, was recently discovered in Amazonia. Particularly in South America, there are several members of this genus living in open terrain, perhaps because of the absence on that continent of *Corvus* crows, a genus of open country; one such example is the Curl-crested Jay (*Cyanocorax cristatellus*). The Green Jay, occurring in both Middle and South America and formerly accorded a monotypic genus, *Xanthoura*, was placed by Bonaccorso and Peterson at the base of the *Cyanocorax* tree. Four species of *Cyanocorax* in Middle America, namely the Bushy-crested (*Cyanocorax melanocyaneus*), San Blas (*Cyanocorax sanblasianus*), Yucatan (*Cyanocorax yucatanicus*) and Purplish-backed Jays (*Cyanocorax beecheii*), are similar to each other in plumage pattern, but exhibit strong differences in habitat use and social behaviour. In the past they were grouped in a separate genus, *Cissilopha*, being unusual among the Corvidae in retaining immature colours for prolonged periods. Bonaccorso and Peterson's analysis indicated that the Bushy-crested Jay and the Yucatan Jay are sister-species, a relationship already detected in earlier morphological studies. Among the other species of *Cyanocorax*,

Over time, the number of species recognized in the genus Cissa *has varied from six to no more than two. Three are currently recognized: the Common* (C. chinensis), *Indochinese* (C. hypoleuca) *and* ***Short-tailed Green Magpies****. Together they form a superspecies. The Short-tailed, the most restricted in range, with two isolated populations on Borneo and Java, is sometimes lumped with the Indochinese species. Their bright colours—pea to emerald green bodies, black bandit masks and red bills and legs—blend surprisingly well with tropical forest vegetation. In direct sunlight, in captivity and in museum collections, the bright green plumage can fade to a dull pale blue.*

[*Cissa thalassina jefferyi*, Borneo.
Photo: Roland Seitre]

The discovery of fossil Cyanopica *bones in Gibraltar laid to rest the myth that sailors had brought azure-winged magpies from China to the Iberian Peninsula. Differences between the Iberian* (C. cooki) *and* ***Asian Azure-winged Magpies*** *suggest the European population has been isolated for a very long time; DNA studies suggest at least one million years. Both are found in seasonally hot, maritime regions, and it is possible that prior to the last glaciation, they were at opposite ends of a range that spanned southern Eurasia. There are examples from other families of species pairs with similarly disjunct ranges.*

[*Cyanopica cyanus japonica*, Tokyo, Japan. Photo: Tadao Shimba]

the Plush-crested Jay, with a large geographical distribution in central South America, forms a species pair with the White-naped Jay (*Cyanocorax cyanopogon*) of north-eastern Brazil, the two showing similarities primarily in plumage pattern and secondarily in voice. It was suggested that these two species could form a superspecies with the Cayenne Jay (*Cyanocorax cayanus*), the Black-chested Jay (*Cyanocorax affinis*) and the White-tailed Jay (*Cyanocorax mystacalis*) in South America and with a species living in a tiny area of west Mexico, the Tufted Jay (*Cyanocorax dickeyi*). A stronger relationship between the Plush-crested and Tufted Jays, but not between the latter and the other Middle American species (the old genus *Cissilopha*), was corroborated in the study by Bonaccorso and Peterson. The Purplish Jay and the Azure Jay (*Cyanocorax caeruleus*), owing to similarities between them in plumage pattern and voice, are traditionally considered to be closely related to each other; the relationships of the Violaceous Jay (*Cyanocorax violaceus*) are not clear, although it is similar in plumage pattern to those two species. The Curl-crested Jay has a voice quite similar to that of the Azure Jay, but its plumage pattern seems closer to that of the Plush-crested Jay. Finally, the relationships of the Azure-naped Jay (*Cyanocorax heilprini*), a poorly known species that inhabits savanna woodland in Amazonia, are more uncertain.

Calocitta, containing the Black-throated Magpie-jay (*Calocitta colliei*) and the White-throated Magpie-jay (*Calocitta formosa*), occurs in open woodlands of Middle America. Both species are colourful, and possess an extraordinarily long tail and a tall, curving frontal crest. This genus is closely related to *Cyanocorax*.

The Brown Jay (*Psilorhinus morio*), restricted to Middle America, is a drab corvid with a bare inflatable sac on the chest. This structure, termed the "furcular pouch", is formed by hypertrophy of the cleido-traquialis muscles, which creates a median, non-paired extra interclavicular diverticulum. The pouch produces strange clicking sounds when the jay is vocalizing. The Scientific Committee of the American Ornithologists' Union placed the Brown Jay in the genus *Cyanocorax*, but Bonaccorso and Peterson, in their study of the phylogenetic relationships of New World Jays, suggested that this species be maintained in the monotypic genus *Psilorhinus*.

Combination of genetic and morphological characteristics is not conclusive for determining which one of the genera *Cyanocitta*, *Aphelocoma* and *Gymnorhinus* is basal for the Nearctic species. Bonaccorso and Peterson, however, proposed that *Cyanocitta* and *Aphelocoma* are more closely related to each other on the grounds of a morphological novelty: both genera present a unique bar lateral to the sclerotic ring. The two species of *Cyanocitta*, namely the Blue Jay (*Cyanocitta cristata*) and Steller's Jay (*Cyanocitta stelleri*), are close relatives of each other; indeed, they interbreed in contact zones in the Midwest region of the USA. Both of them inhabit forest and woodland habitats, including those in urban areas. *Aphelocoma*, with five species, is

The name ***Rufous Treepie*** *could be applied more or less to all of the* Dendrocitta *species. These closely related forms present variations on the same basic plumage pattern, though all can be easily distinguished. There are few overlaps in range, and where two do overlap, they have distinct habitat preferences. Where the Rufous Treepie coincides with the Grey Treepie* (D. formosae) *in the Himalayan foothills, it is found at lower altitudes, and is far more tolerant of cities, gardens and other human-adapted landscapes. Treepies are noisy birds with a distinctive, dipping flight, each dip terminated by an upward jerk. All have a short, stout bill with a curved culmen.*

[*Dendrocitta vagabunda vagabunda*, Ranthambore National Park, India. Photo: Marc Guyt/AGAMI]

The treepie genera Crypsirina *and* Temnurus *are black or black and grey birds with more ornately structured tails than most other corvids. The two central tail feathers of the Hooded* (C. cucullata) *and* ***Racquet-tailed Treepies*** *flare out to form a spatulate tip. They have only ten tail feathers, rather than twelve, like other treepies. They also have a cushion of short, soft feathers over the forehead and lores, instead of the nasal bristles of most corvids. Both are relatively small, at 30–33 cm including the long tail.*

[*Crypsirina temia*, Java.
Photo: Roland Seitre]

distributed in dry habitats of North America. Current genetic evaluations are contradictory and unable, therefore, to shed light on the question of whether the Western Scrub-jay (*Aphelocoma californica*) or the Unicoloured Jay (*Aphelocoma unicolor*) is basal to the other species of *Aphelocoma*. The Western Scrub-jay, the Island Scrub-jay (*Aphelocoma insularis*) and the Florida Scrub-jay (*Aphelocoma coerulescens*) are closely related to each other, having similar plumage patterns, but they exhibit strong differences in their breeding systems. They were formerly considered to be representatives of a single species, known as the "Scrub Jay", but it was suggested recently that this be split into two or three species. The remaining member of the genus, the Mexican Jay (*Aphelocoma ultramarina*), includes seven subspecies that are typically separated into three groups, but are now thought to constitute four. A monotypic species in a monotypic genus, the Pinyon Jay (*Gymnorhinus cyanocephalus*) is a New World corvid which, in bill morphology and foraging behaviour, resembles the nutcrackers (*Nucifraga*). This is the result of convergent evolution, all of these species having evolved to exploit large, nutritious seeds of pines (*Pinus*).

The mitochondrial genomes of the Common Magpie (Pica pica) *of Eurasia, and those of the Black-billed* (P. hudsonia) *and* ***Yellow-billed Magpie****, both of North America, are so close that they could be considered subspecies of a single species. The ancestor of the two North American species probably crossed the Bering land-bridge around 1·5 million years ago. Although the birds can appear simply black and white, their black feathers have an iridescent sheen which can shine blue, purple or green. Whereas tropical magpies are arboreal forest-dwellers,* Pica *magpies are terrestrial birds of more open country, with relatively long legs.*

[*Pica nuttalli*, Los Alamos, California, USA.
Photo: Rafael Armada]

The long legs of the four species of Podoces *ground-jay enable them to run very quickly, unlike all other corvids. They fly reluctantly and only for short distances, the extensive white on the wings making them conspicuous. On the ground, their cryptic coloration makes them hard to find and follow. In shape and posture they are unlike other corvids, and* ***Henderson's Ground-jay*** *and others are said to look like very large hoopoe-larks* (Alaemon).

[*Podoces hendersoni*, Buutsagaan, Mongolia. Photo: Andreas Buchheim]

In the molecular-genetic analysis by Ericson and colleagues, the ground-jays (*Podoces*) and the Piapiac (*Ptilostomus afer*) were grouped together, an unexpected result when one considers their different geographical distributions. These authors suggested that the adaptation of both genera to truly arid conditions was a single evolutionary event and that the disjunct distributions of the extant species could reflect later dispersal events and further specialization. The four species of ground-jay, with a geographical distribution restricted to Central Asia, are remarkable within the family because they run extremely well on their relatively long legs and hold the body in a horizontal posture. Pander's (*Podoces panderi*) and Pleske's Ground-jays (*Podoces pleskei*) form a species pair, while Henderson's (*Podoces hendersoni*) and Biddulph's Ground-jays (*Podoces biddulphi*) form another one. The Piapiac, in a monotypic genus, resembles the Long-tailed Glossy Starling (*Lamprotornis caudatus*) and occurs only in West and Central Africa.

It should be mentioned here that the Ground Tit (*Pseudopodoces humilis*) was, until recently, placed in the Corvidae, often in the genus *Podoces*. Osteological, morphological and vocal char-

In general, the bills of corvids are stout, strong and fairly long, with a slight hook at the tip of the upper mandible. More specialized versions include the straight, pointed bill of the ***Spotted Nutcracker*** *and its two congeners, which has a ridge on the inside of the lower mandible enabling the bird to crack nuts open. Although widely distributed in Eurasia, the Spotted Nutcracker, like its congeners, is closely linked with mountain coniferous forests. Nutcrackers are important dispersers of pine seeds, and Clark's Nutcracker* (Nucifraga columbiana) *and the whitebark pine* (Pinus albicaulis), *on which it depends, may have enabled one another's spread through the mountain ranges of western North America.*

[*Nucifraga caryocatactes caryocatactes*, Hanko, Finland. Photo: Markus Varesvuo]

Once considered to be close to the Corvus *crows and nutcrackers, the Red-billed* (Pyrrhocorax pyrrhocorax) *and* ***Yellow-billed Choughs*** *differ from them in having smooth, rather than scaled, tarsi, very short and dense nasal feathers, and brightly coloured bills and feet. They are specialized insectivores, using their long, curved bills to pick and dig up invertebrates. The Yellow-billed, also known as the Alpine Chough, replaces the Red-billed at higher elevations, though the two can occur together.*

[*Pyrrhocorax graculus graculus*, Dolomites, Italy. Photo: Harri Taavetti/FLPA]

acters, however, indicate that it belongs, in fact, with the tits and chickadees in the family Paridae, a conclusion supported by molecular-genetic details.

Stresemann's Bushcrow (*Zavattariornis stresemanni*), in another monotypic genus, is an unusual corvid that, because of its small size and sociable behaviour, resembles some starlings (Sturnidae). Its geographical distribution is quite restricted, being confined to a small area in southern Ethiopia. This species could be classified in a monotypic family, Zavattariornithidae, on the grounds that it exhibits a number of atypical features and several anatomical peculiarities, but DNA sequences have indicated that it is a true corvid, most closely related to *Podoces*, *Pica* and *Ptilostomus*.

From the available molecular data, the relationships of the genus *Garrulus* are not altogether clear, although it is evident that it forms part of a clade consisting of several Old World core groups. The Eurasian Jay (*Garrulus glandarius*) inhabits wooded areas, and is closely associated with several species of oak tree (*Quercus*) throughout its large geographical range in Eurasia. This species presents the most notable racial variation of any corvid, with some 34 subspecies normally recognized. In contrast, the Black-headed Jay and Lidth's Jay (*Garrulus lidthi*) occur in re-

From a distance, the ***Piapiac*** *can resemble a Glossy Starling* (Lamprotornis), *a similarity reinforced by its calls, and by its long graduated tail, though at closer quarters contradicted by its heavy crow-like head and stout bill. Isolated from most of the rest of the family in West and Central Africa—on a continent generally poor in corvid species—the Piapiac is placed in a monotypic genus for a number of morphological reasons. It is notable for commonly associating with mammals, feeding around their feet or sitting on their backs, where it will pick off ectoparasites. The bird with the pink bill in this picture is a juvenile.*

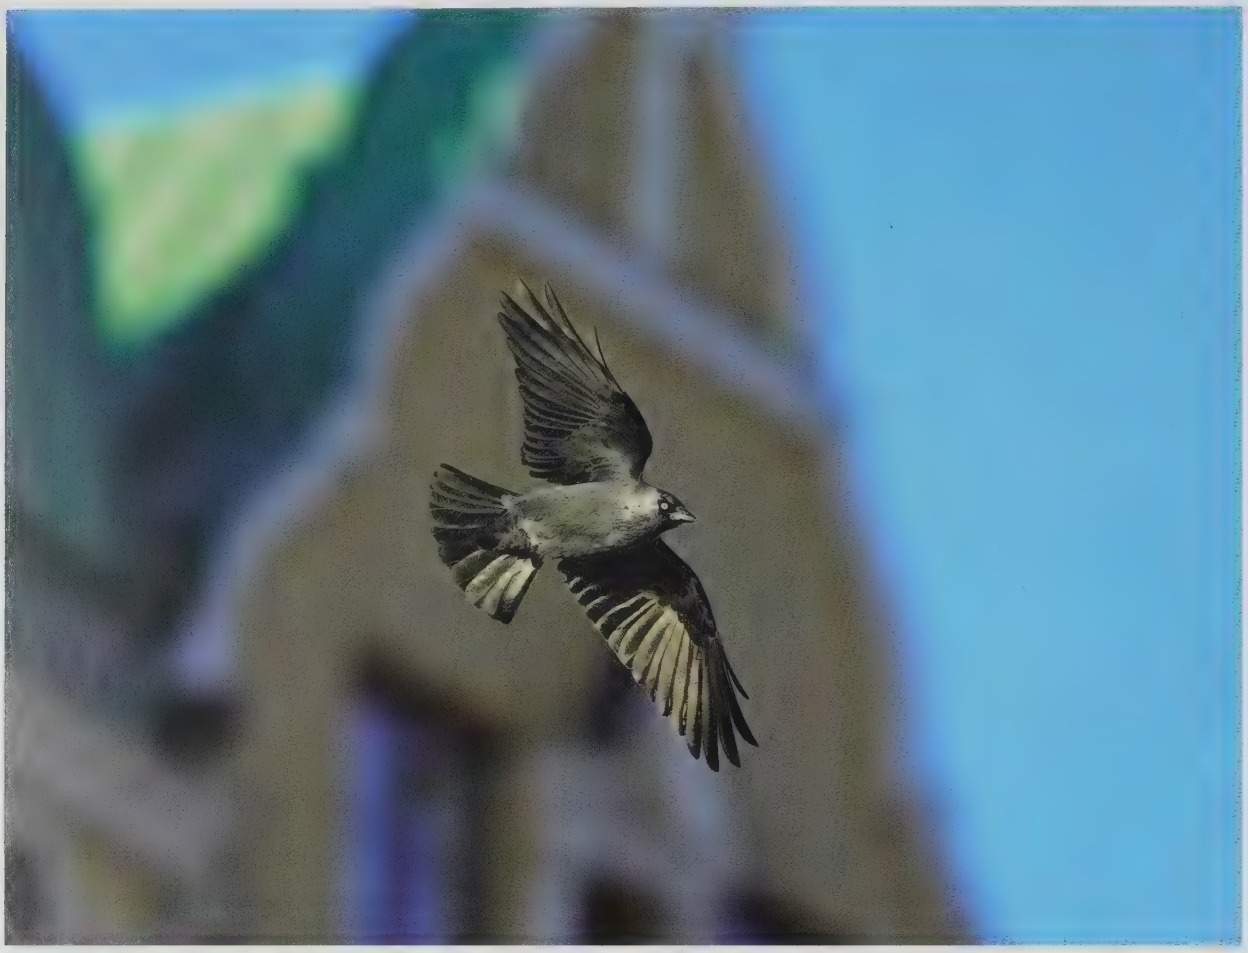
[*Ptilostomus afer*, Niokolo Koba National Park, Senegal. Photo: Jesús Rodríguez-Osorio]

stricted areas of, respectively, the western Himalayas and the islands of Japan.

The four magpies in the genus *Pica* are well-known corvids with a long tail and striking black-and-white plumage. Within the family, only the genera *Corvus* and *Perisoreus* have distributions larger than or comparable to that of the genus *Pica*. Greater homogeneity among magpie species compared with those genera may be due to the relatively recent spread of *Pica* over its present distribution or to a considerable resistance to variation. Evidence suggests a recent spread, because the mitochondrial genome of the Common Magpie (*Pica pica*), living in Eurasia, and those of the Black-billed Magpie (*Pica hudsonia*) and the Yellow-billed Magpie (*Pica nuttalli*), both living in North America, are so closely related that the three could be considered subspecies of a single species. Based on 1·6% mitochondrial DNA substitutions per million years, R. M. Zink and collaborators estimated that the ancestor of the Black-billed and Yellow-billed Magpies likely crossed the Bering land-bridge 1·5 million years ago, these two species then diverging in the middle Pleistocene. The Arabian Magpie (*Pica asirensis*) has usually been treated as a subspecies of the Common Magpie, but its very restricted range and isolation, coupled with differences in vocalizations as well as structural features, suggest that this taxon should be elevated to species rank.

With similarities in morphological characteristics and habits, the genera *Nucifraga* and *Corvus* are considered sister-taxa, a close relationship supported by recent genetic studies. The nutcrackers, in *Nucifraga*, have a long and pointed bill and a strong dependence during the winter months on the seeds of conifers. Three species are recognized. These are the Spotted Nutcracker (*Nucifraga caryocatactes*), living in Eurasia, the Kashmir Nutcracker (*Nucifraga multipunctata*), living in the western Himalayan forests of southern Asia, and Clark's Nutcracker (*Nucifraga columbiana*), living in North America. It is likely that an ancestor of Clark's Nutcracker, a Siberian form of the Spotted Nutcracker, crossed the Bering land-bridge when the climate cooled and conifer forests spread during the Pliocene, 5·3–1·8 million years ago; this was after the ancestor of the New World jays crossed the warmer, deciduous-forest land-bridge during the Miocene, 10–8 million years ago. This climate change would have favoured *Nucifraga*. This scenario is consistent with the recent expansion into North America of the whitebark pine (*Pinus albicaulis*), which is derived from the Eurasian stone pine (*Pinus cembra*). The strong co-evolutionary history of Clark's Nutcracker and the whitebark pine suggests that nutcrackers facilitated the pine's dispersal in North America. In addition, Clark's Nutcracker may have taken advantage of the earlier dispersal of the New World jays in North America, because these jays also assist the dispersal of some species of pine, such as the limber pine (*Pinus flexilis*), the Mexican pinyon (*Pinus cembroides*) and the common pinyon (*Pinus edulis*), providing nutritious seeds for colonizing nutcrackers.

The most species-rich genus of Corvidae is *Corvus*, which comprises the crows, rooks and ravens, a total of 44 species. This genus has an almost worldwide distribution, its members living in a variety of conditions, but it does not occur in South America. The species of *Corvus* have, in general, similar body shapes, featuring strong, stout legs with well-clawed, grasping feet, and a large head sporting a distinctive bill.



Recent molecular study has revealed that the Eurasian Jackdaw (*Corvus monedula*) is distantly related to other members of the genus *Corvus*. Moreover, it differs from them morphologically and behaviourally, having a slender bill and nesting in cavities. The monophyly of the genus *Corvus* as currently constituted is, therefore, poorly supported. This is reflected in some revised taxonomic classifications, which place the Eurasian Jackdaw and the Daurian Jackdaw (*Corvus dauuricus*) in a separate genus, *Coloeus*. The two jackdaws are so similar to one another that they could even be lumped in one polymorphic species if it were to be found that hybridization was more frequent in the region of Lake Baikal and Mongolia where the two overlap in range.

The remainder of the genus *Corvus*, however, appears certainly to be monophyletic, and the species are so similar that, in some cases, it is difficult to determine species boundaries. The Carrion Crow (*Corvus corone*) and the Hooded Crow (*Corvus cornix*), for example, have often been treated as conspecific, differing only in plumage colour, the former being all black and the latter grey and black. The two interbreed where their ranges overlap, and hybrids have variable and intermediate plumage features. The number of hybrid pairs, however, is lower than expected,

*The **Common Raven** is the largest corvid, and also the largest passerine in the world, reaching 69 cm in length and 2000 g in weight—although some Thick-billed Ravens* (Corvus crassirostris) *reach a similar size and weight. This species, like others that fly long distances, moults its larger primaries slowly, so that its flying ability is never impaired. The Common Raven is one of the most widespread bird species in the Northern Hemisphere, and is part of a relatively recent and rapid radiation of ravens. Speciation is continuing: at least three groups of Common Raven, in the Old World, the New World and the Canary Islands, are currently taking relatively independent evolutionary paths, with little if any genetic exchange.*

[*Corvus corax corax*, Kuusamo, Finland. Photo: Markus Varesvuo]

More than a third of the corvid species—44 out of 123—belong to the genus Corvus. *They are generally fairly similar in shape, with strong, stout legs ending in well-clawed, grasping feet, and large heads with powerful bills. The* ***Eurasian Jackdaw****, one of the smallest of this genus, has a comparatively slender bill, and unlike other* Corvus *species, nests in cavities. Recent molecular study suggests it is only distantly related to most of the rest of the genus, and some authorities place it, together with the very closely related Daurian Jackdaw* (C. dauuricus), *in their own genus,* Coloeus. *At the other extreme in overall size and massiveness of bill, the White-necked Raven* (C. albicollis) *of eastern and southern Africa and the* ***Thick-billed Raven*** *of the Ethiopian highlands form a species pair, and are also sometimes considered to represent a separate genus,* Corvultur. *However, with the probable exception of the jackdaws,* Corvus *crows appear to be monophyletic, and in several cases are so similar that it is difficult to determine species boundaries. Carrion* (C. corone) *and Hooded Crows* (C. cornix) *are often treated as conspecific, differing only in plumage colour, and interbreeding where their ranges overlap. The American Crow* (C. brachyrhynchos) *is extremely closely related to the Carrion Crow, the two species sharing a recent common ancestor.*

[Above: *Corvus monedula soemmerringii*, Helsinki, Finland. Photo: Markus Varesvuo.

Below: *Corvus crassirostris*, Ethiopia. Photo: Dick Forsman]

Found in central and southern Africa, the ***Pied Crow*** *has the largest range of any African corvid. Its distinctive white collar and breast set it apart from all other crows and ravens in its range except the White-necked Raven* (Corvus albicollis), *which is relatively massive in all its proportions, particularly the bill. Part of a radiation of African ravens which began 3·8–2·3 million years ago, the Pied Crow is known to hybridize with the Ethiopian Raven* (C. edithae) *where their ranges overlap. All members of Corvidae have ten primaries, the outermost being considerably reduced.*

[*Corvus albus*, Western Division, Gambia. Photo: Dick Forsman]

and sexual selection appears, therefore, to reinforce reproductive isolation between the forms. In a European context, it is likely that during the last ice age, in the Pleistocene, the two populations were forced to retreat to refugia, the grey-and-black form in the Balkans and the all-black one in Iberia. When climatic conditions changed, the two populations expanded and interbred, producing fertile hybrids. Differences between Carrion and Hooded Crows in vocalizations, as described by C. Palestrini and A. Rolando, and different levels of aggressiveness, have contributed to premating isolation of the two taxa. The striking plumage differences, the subtle differences in vocalizations, and both the narrowness and the plasticity of hybrid zones all suggest, therefore, that speciation has been at least partially achieved. The Carrion and Hooded Crows, and possibly also the Collared Crow (*Corvus pectoralis*), are presently best regarded as forming a superspecies complex.

The Carrion Crow is closely related to the American Crow (*Corvus brachyrhynchos*) of the Nearctic. According to R. C. Fleischer and C. E. McIntosh, they are only 5% divergent in cytochrome *b*. It is believed that a common ancestor of today's Carrion and American Crows inhabited Beringia 2–3 million years ago, and that it radiated in North America to produce the clade that includes the present-day American Crow, Northwestern Crow (*Corvus caurinus*), Jamaican Crow (*Corvus jamaicensis*), Cuban Crow (*Corvus nasicus*) and White-necked Crow (*Corvus leucognaphalus*). It is further thought that a second colonization of North America, either from Beringia or perhaps via a more southerly route, involved a common ancestor of Asian and Pacific crows that radiated into the Fish Crow (*Corvus ossifragus*), the Sinaloa Crow (*Corvus sinaloae*) and the Tamaulipas Crow (*Corvus imparatus*). These last three species are quite similar in appearance to the American Crow, but they can be separated by voice. Hybridization between the Northwestern Crow and the American Crow has led to debate over the years as to whether the former is merely a subspecies of the latter. J. Marzluff and T. Angel recently postulated that land conversion by humans facilitated the westward spread of American Crows and increased the incidence of their hybridization with Northwestern Crows to the point at which it is now unlikely that genetically distinct Northwestern Crows exist. The Palm Crow (*Corvus palmarum*) and the Hawaiian Crow (*Corvus hawaiiensis*) are probably the result of a more recent colonization by a mainland corvid; preliminary genetic analysis by Fleischer and McIntosh suggests that these species are actually more closely related to ravens than they are to crows.

In eastern Asia, the Large-billed Crow (*Corvus macrorhynchos*), with numerous subspecies and with a large distribution which includes islands, is possibly made up of a complex of as many as seven species. More research is, however, required, and this should include not only genetic and vocal comparisons, but also determination of their parasite lice (Mallophaga) and whether differences among forms are gradual or abrupt. Because of the head and bill shapes, it is suggested that the House Crow (*Corvus splendens*) has a close affinity to the Large-billed Crow complex. In Micronesia, the Mariana Crow (*Corvus kubaryi*) lives

Eurasian (Corvus monedula) *and* ***Daurian Jackdaws*** *are so similar that they could perhaps be lumped as one polymorphic species. They are more or less identical in size, and apparently identical in diet, calls and social behaviour. The primary differences are in the piebald plumage of the Daurian—though immature birds are all dark, like Eurasian Jackdaws—and the colour of the irides, which are pale grey in Eurasian and dark in Daurian Jackdaws. These differences, plus minor discrepancies in nesting behaviour, seem enough to keep the two species separate where their ranges overlap, and there is little evidence of hybridization.*

[*Corvus dauuricus*, Beijing, China. Photo: Yilun Qiao]

*The bare, pink face sets the **Grey Crow** apart from any other corvid. It also has an atypical juvenile phase, with pale, greyish brown plumage and a pink bill, shown here. Adults, though mainly dark in plumage, can have randomly bleached-looking wing and tail feathers. Confined to New Guinea, where it is widespread, the Grey Crow is part of an old endemic group of Melanesian island crows, many of them with very restricted ranges.*

[*Corvus tristis*, near Madang, NE New Guinea. Photo: Brian J. Coates]

on the islands of Rota and Guam and appears to be derived from the House Crow.

The Slender-billed Crow (*Corvus enca*) of south-eastern Asia has eight recognized subspecies falling in two groups, the "nominate group" and the "*violaceus* group". In the same region, the Banggai Crow (*Corvus unicolor*), confined to the Banggai Islands, off east Sulawesi, and the Piping Crow (*Corvus typicus*), restricted to the island of Sulawesi and the smaller islands of Muna and Buton, perhaps form a species pair, which has been considered to be related to the Slender-billed Crow complex; in fact, both species seem to represent an early offshoot of the "*Corvus enca* complex". The pied plumage of the Piping Crow, unique among Indonesian corvids, suggests that it may belong in its own genus (*Nesocorax*), which perhaps should also include the Banggai Crow. Possibly closest to the Banggai and Piping Crows is a unique little species known as the Flores Crow (*Corvus florensis*), which is endemic on the island of that name in the Lesser Sundas. The Long-billed Crow (*Corvus validus*) has also been considered closely related to the Slender-billed Crow, but its pale eyes suggest an affinity with the Australian crows.

The White-billed Crow (*Corvus woodfordi*), the Bougainville Crow (*Corvus meeki*), the Bismarck Crow (*Corvus insularis*), the Brown-headed Crow (*Corvus fuscicapillus*) and the Grey Crow (*Corvus tristis*) apparently form part of an "old endemic" Melanesian group. The New Caledonian Crow (*Corvus moneduloides*) is restricted to New Caledonia and the nearby Loyalty Islands.

Five species of *Corvus* live sympatrically in Australia. They are quite similar to each other, forming a closely related complex of crows which, in adulthood, have white eyes with a blue inner ring. Melanesian crows may be related to Australian crows, since all also have blue eyes at some stage of immaturity. Field identification of the Australian members of the genus is rather difficult, as the species form mixed gatherings outside the breeding season; their vocalizations, particularly those related to territory, are the key factor for field identification. The Australian Raven (*Corvus coronoides*), the Little Raven (*Corvus mellori*) and the Forest Raven (*Corvus tasmanicus*) are probably most closely related to each other. The Little Crow (*Corvus bennetti*) lives in arid areas of Australia. The Torresian Crow (*Corvus orru*) occurs in Australia, New Guinea, the Moluccas and other, nearby islands; the Australian population was formerly regarded as a full species, "*Corvus cecilae*".

Having an extensive geographical distribution in Europe and Asia, the Rook (*Corvus frugilegus*) is unique among the *Corvus* species on account of its unusual pointed bill and naked face, its strong association with open habitats and its sociable lifestyle. It probably evolved in grass steppes. In the analysis by Ericson and collaborators, using DNA sequences, the Rook was placed closer to the Common Raven (*Corvus corax*) than to the Australian Raven and the Eurasian Jackdaw.

The Common Raven, one of the most widespread of all bird species in the Northern Hemisphere, is part of a recent and rapid radiation of ravens. Four major raven lineages diverged from one another between 3·8 million and 1·7 million years ago; they have been considered to represent a complex of a few species of large-bodied birds that vary subtly in overall form and plumage. This radiation probably began some 3·8–2·3 million years ago, when the Pied Crow (*Corvus albus*) and the other African ravens diverged from each other. Because of the widespread distribution, at least three groups of the Common Raven are currently taking relatively independent evolutionary paths, with little, if any, genetic exchange: these are the Old World group, the New World group, and the Canary Islands group. The Common Raven crossed the Bering land-bridge about 2 million years ago; from this originated the "California clade" of the Common Raven and the Chihuahuan Raven (*Corvus cryptoleucus*). A second invasion by the Common Raven occurred about 25,000 years ago, again across the Bering land-bridge, this time probably with humans and grey wolves (*Canis lupus*), giving rise to the "Holarctic clade" of *Corvus corax*. The two Common Raven clades, although colonizing at different times, are now interbreeding and merging their gene pools, rather than continuing to diverge. For the groups of the Old World and the New World a variety of subspecies is recognized, and these may have been especially distinctive a million or so years ago. Today, however, such subspecies commonly reproduce in areas where they overlap in range, which reduces the genetic distinctiveness of the forms, with the result that they intergrade extensively and do not have unique mitochondrial signatures.

Marginally overlapping with the Common Raven in some regions of Africa are the closely related Brown-necked Raven

Social organization in corvid species can be complex, and can vary within the same species according both to season and region. ***Green Jays****, for example, are solitary breeders in the north of their range, but assemble in large flocks after breeding. Further south, they form territorial groups of three to nine birds, and they maintain these groups throughout the year. Flocks are much bolder than solitary birds. Hierarchies within groups can change quickly, without overt confrontations, and it is thought that the superior intelligence of corvids enables them to assess the physical and psychological fitness of other flock members.*

[*Cyanocorax yncas yncas*, San Isidro, Ecuador. Photo: Tui de Roy/ Roving Tortoise Photos]

(*Corvus ruficollis*), the Ethiopian Raven (*Corvus edithae*) and the Pied Crow, which comprise a superspecies. As with the Carrion and Hooded Crows, the Pied Crow and the Ethiopian Raven frequently hybridize, mainly in the south-eastern highlands of Ethiopia. The Cape Crow (*Corvus capensis*) is probably related to the Brown-necked Raven and the Pied Crow, although it resembles the Rook, especially in bill shape. Goodwin suggested that the bill-shape convergence reflects an adaptation for feeding in similar manner to that of the Rook, by probing and digging for invertebrates.

The two deep-billed ravens living in Africa, the White-necked Raven (*Corvus albicollis*) and the Thick-billed Raven (*Corvus crassirostris*), form a species pair, and are sometimes considered to represent a separate genus, *Corvultur*. Another mainly African raven, the Fan-tailed Raven (*Corvus rhipidurus*), also sometimes separated generically, in *Rhinocorax*, seems to

Gregarious throughout the year, there are three units in the social organization of the ***Red-billed Chough****: the pair; the family group; and the flock. Like most other corvids, this species mates for life, but although breeding pairs defend a territory, they join flocks when away from the nest. Towards the end of the summer, choughs can be found in flocks of 200 or more, but seem to maintain the family group within these large flocks when foraging. Both species of chough may make daily altitudinal movements of several kilometres between roosting and feeding sites.*

[*Pyrrhocorax pyrrhocorax*, China. Photo: Zhang Ming]

Large animal carcasses provide an important source of food, particularly in winter. But research has found that while resident single ***Common Ravens*** *or pairs defend carcasses from other ravens, vagrant birds without territories go out of their way to attract other ravens to feed with them at the carcasses they discover. The resident ravens will chase away single vagrant birds, but when these arrive in groups, will tolerate them and even feed with them. By recruiting other birds, the vagrants can overcome the aggressiveness of the resident birds. It has been suggested that an individual's status is enhanced by the number of followers it leads to carcasses.*

[*Corvus corax corax*, Finland.

be more closely related to the two deep-billed species than it is to the Common Raven.

Morphological Aspects

Members of this family are quite variable in body size. Crows and ravens can be large to very large, whereas some jays, magpies and others are only medium-sized. The Common Raven is the world's largest corvid, and also the largest passerine, reaching 69 cm in length and 2000 g in weight. The Dwarf Jay of Mexican humid pine–oak–fir (*Pinus–Quercus–Abies*) forest, with a size of 20–23 cm and weighing 40–42 g, is the smallest corvid. Bergmann's Rule, which predicts that individuals living in cooler climates tend to be larger than those of the same species in warmer climates, and Allen's Rule, which predicts that individuals in hotter environments tend to have longer appendages such as feet and bill, have been corroborated for some corvids, as was found in the extensive study of the Red-billed and Yellow-billed Choughs by P. Laiolo and Rolando.

According to Konrad Lorenz, an old German proverb says that one crow will not peck out the eye of another, and in his extensive studies of corvids Lorenz found this to be true. Fights between corvids, such as these ***Iberian Azure-winged Magpies****, are frequent, especially during breeding, when they may involve two or more pairs and their helpers. The birds fall to the ground with interlocked claws, pecking at one another, but fights are usually brief, and rarely end with serious damage. Appeasement displays involving presentation of vulnerable parts prevent real injury, and can avert aggression altogether.*

[*Cyanopica cooki*, Spain.
Photo: Luis Casiano]

Particularly when resources are short, corvids can be aggressive towards other species. Common Ravens (Corvus corax) *and other corvids have been observed tugging the feathers of feeding raptors such as Bald Eagles* (Haliaeetus leucocephalus) *until the larger birds are forced to give up their prey. This* ***Hooded Crow*** *may have similar intentions towards the young Herring Gull* (Larus argentatus), *and the young Great Black-backed Gull* (L. marinus) *appears interested in the possible outcome. The corvids exhibit the most complex play behaviour of all passerines, which includes playing tricks on other species, even when they have nothing to gain by doing so. Play behaviour has been studied in the Hooded Crow's near relative, the Carrion Crow* (C. corone), *and particularly in the Common Raven. It contains elements of practice for the serious business of life, and also of showing off prowess to potential mates and rivals. But some playful behaviour, such as repeatedly sliding down snow banks, appears to be done just for the fun of it. Sophisticated play behaviour is just one indication of the superior intelligence of the corvids. Their large heads accommodate a correspondingly large brain, considerably larger in relation to their body size than in any other birds. Perhaps surprisingly, the American Crow* (C. brachyrhynchos) *tops the list, having a larger brain than would be expected for its modest body size, relegating the Common Raven to second place. These are followed by other* Corvus *species, and then by other genera such as* Garrulus.

[*Corvus cornix cornix*, Oulu, Finland. Photo: Markus Varesvuo]

The fearless aggressiveness of the ***House Crow*** *has contributed to the seemingly irresistible spread of this highly invasive species. Its targets include any species which could constitute a threat, including all raptors, dogs and cats, and even humans. However, this fruit bat, an Indian flying-fox* (Pteropus giganteus), *is probably being pursued as potential prey. In Kenya, where introduced House Crows are a serious threat to native biodiversity, they are often seen noisily chasing fruit bats which may be killed and eaten.*

[*Corvus splendens splendens*, Tamil Nadu, India. Photo: Hanne & Jens Eriksen]

The basic morphological features of the family are the long tarsus, which is scaled in front and booted behind, the nature of the primaries and tail feathers, which are stiffened, and the presence of a tuft of nasal bristles extending to the nostril opening. The unspotted juvenile plumage is also a feature of the group, but with one exception, that of the Crested Jay.

Corvids of the genus *Corvus*, the jackdaws, crows and ravens, are characterized by their basic black coloration, although some variations include black and grey, black and white, and shades of grey. They are completely without bright colours, although the plumage often exhibits a purple, blue, green or silver sheen. In contrast, some species of jay and magpie are among the most colourful and brightest of birds. It seems that the genus *Corvus*, having lost the ability to produce carotenoid pigments or structural blue, is now inevitably limited to a narrow range of plumage hues. Black plumage has physiological advantages, bearing in mind that heavy deposition of melanin makes the feathers less susceptible to wear and tear and that black plumage is more efficient at absorbing solar energy, which is important for maintaining body heat in lower temperatures. In addition, it is easier to see the black coloration against most backgrounds in the open areas where most of the crows live, and this brings social advantages; colourful species, such as jays and magpies, tend to live closer to the trees than crows. Bright and very conspicuous contrasting areas of plumage are frequently related to a social function, as illustrated by the pure white at the end of the tail of several Neotropical jays; the tail is moved up and down in the darkness of the forest interior as a warning of the presence of potential predators. Several of the jays and magpies possess ornate patterns, such as a highly developed crest and a long or bizarre-looking tail. No corvid has the cryptic streaked plumage pattern found commonly in passerines, although some relatively bright species, such as the green magpies, are cryptically coloured in their natural environments. Interestingly, the Common Green Magpie can lose its green plumage and "fade" to blue when kept in captivity, and this can happen even in the wild after prolonged exposure to direct sunlight. Specimens collected for scientific purposes commonly fade in similar fashion. The majority of the Corvidae have a dark or blackish bill, legs and feet.

Females tend to be duller and smaller than their respective males, but geographical variation can lead to overlap in size between the sexes when individuals from different locations are compared. In wild-living populations, pair-members tend to be about the same in size or the male appears to be the larger, but never the reverse. In a study of American Crow populations living in Saskatchewan and Alberta, in Canada, the sex of 87% of adult crows was determined by using wing length alone; if measurements of the tarsus and the head with bill are included, in addition to wing length, it was possible to reach correct sex determination in 92% of cases. Another study, of the Iberian Azure-winged Magpie, revealed sexual dimorphism in several standard measurements: weight, lengths of tail, bill, tarsus and claw of middle toe, and depth of bill. Sexual differences in postures and voice have been described for some species, and there is evidence that, for most calls, there may be differences in pitch between the two sexes.

Chicks of corvids are naked or have a very sparse amount of down at birth. The nestling down of nutcrackers is more profuse, presumably an adaptation to cold climates. Juveniles in the genera *Cyanopica*, *Nucifraga* and *Platylophus* have buff tips on the upperwing-coverts and tertials, a feature more typical of other passerine families. A juvenile plumage replaces the nestling down or follows the naked phase. The contour feathers of the juvenile plumage are usually looser and more "woolly" in texture than the adult feathers, and the wing and tail quills of juveniles are slightly weaker and shorter. Juvenile and adult plumages are similar in the majority of crows, but there are some evident exceptions; the Yucatan Jay, for example, displays striking colour differences according to the age of the individual. The iris, bill and mouth of juvenile corvids are usually different from those of the adults. The juveniles of many of the species are distinguishable for a reasonably long period, sometimes for about two years. Such differences between juvenile and adult plumages are probably related to the highly social habits of corvids, and reduce the chances of aggressive contacts. Further, it is possible that adults may find birds having immature characters less sexually attractive.

Corvids moult completely once a year, commonly after the nesting season. In the case of the Common Raven, as well as other species that fly considerable distances, the moult of the larger primaries proceeds rather slowly, so that flying ability is never impaired. Differences in the timing and duration of the moult exist among different populations of a species, especially when it has a wide latitudinal range.

Among all members of the family, the wings tend to be rounded, with ten primaries. The outermost primary is somewhat reduced, its length being 35–65% that of the longest. The Pinyon Jay has eleven secondaries, instead of ten, which is the

Birds of prey are routinely mobbed by the much more manoeuvrable corvids, even when the raptor is unlikely to present an immediate threat, as demonstrated by this ***Fan-tailed Raven*** *chasing a juvenile Black Kite* (Milvus migrans). *In more extreme cases, for instance when the raptor threatens a nest or recently fledged young, these attacks can escalate from close "buzzing" of the raptor to physical contact. Common Ravens* (Corvus corax) *have even been seen clinging to the backs of Golden Eagles* (Aquila chrysaetos), *pecking them and tugging at the feathers of their heads and necks, in order to rescue a member of the group that has been caught. Corvids will also mob birds that present no danger at all, such as the Common Kestrel* (Falco tinnunculus) *and Grey Heron* (Ardea cinerea). *They often have species-specific alert, alarm or mobbing calls, which are given with more or less intensity to indicate the proximity of the predator and seriousness of the threat. Siberian Jays* (Perisoreus infaustus) *use as many as 14 different calls when mobbing predators, providing other group members with specific information about the category of predator and, degree of risk. The alert call of an American Crow* (C. brachyrhynchos) *surprised while feeding on the ground is sharp, intense and rapid, whereas the call of a crow that catches sight of a hunter approaching at a distance is less sharp and intense, and spaced at greater intervals.*

[*Corvus rhipidurus stanleyi*, Oman. Photo: Daniele Occhiato]

pattern for the New World jays. The tail is variable, from short to very long, is often rounded, and generally consists of twelve feathers. Relatively long wings and a short, rounded tail are characteristic of several species, mostly in the genus *Corvus*, which often make fairly long, continuous and strong flights, with rather deliberate wingbeats. Ravens, which usually soar or glide for long periods, have a long and graduated tail, as well as long wings. Arboreal species, such as jays and magpies, tend to possess shorter wings, reaching only to the base of the tail, and have a more laboured flight, with more frequent wingbeats. Jays and magpies frequently have a longer tail than crows; the most extreme case is the Black-throated Magpie-jay, with an extremely elongated tail. In these instances, the function of the tail as a balancing mechanism seems no longer to be associated with the arboreal way of life, but with displays.

The bill of corvids is quite variable in size and shape, but in general it is stout, strong and fairly long, with a slight hook at the tip of the upper mandible. It is used in various ways, such as for digging in loose soil, for flicking aside earth and debris, for hammering hard food items until they break, for cracking seeds and for probing under leaves and crevices; as Marzluff and Angel mentioned, the corvid bill could be likened to a Swiss Army knife because of the versatility with which it is used. Besides this general pattern, there are corvid species which have a rather specialized bill. Examples are the long and curved bill of the choughs, which are utilized in digging and probing the surface of the ground, and the long, pointed straight bill of the nutcrackers, which has a ridge on the inside of the lower mandible enabling the bird to crack nuts open. Corvids are known to use the bill in a foraging action termed "open-billed probing", whereby the bird inserts the closed bill into a small cavity and then attempts to open it (see Food and Feeding). The New World jays possess what is known as the buttress complex, a unique configuration in the lower jaw and quadrate, that braces the partially opened lower jaw and enhances its use as a chisel; the origin of the buttress complex may be associated with the habit of acorn-eating. The nostrils are usually rounded, and are closely covered by dense bristles.

Food transportation in short or quite long flights is common among corvids, and the bill is frequently used for such purposes. Some corvids have structural adaptations for carrying food: the Rook and the Common Magpie have a large and extendable buccal cavity, the antelingual pouch, the nutcrackers have a sublingual pouch, and the jays, such as those in the genera *Cyanocitta* and *Gymnorhinus*, have an extendable oesophagus. These features enable corvids to transport conifer seeds for long distances. The Azure Jay, a Neotropical species, takes only one of the large seeds of the Parana pine (*Araucaria angustifolia*) at a time, holding the seed by its apex. The legs, instead of the bill, are sometimes employed for carrying food. For example, some crows have a habit of carrying shellfish in the feet high into the air and then dropping the food item on to a hard surface in order to break it open.

The legs and toes of corvids are sturdy. Those species with more terrestrial habits, such as the choughs, tend to have relatively longer legs in relation to their body size. The tarsus is large and strong, and is scutellated in front and booted behind, but the choughs are an exception, having smooth tarsi. Movement on the ground is usually achieved by means of one or more hops, or with a bounding gallop in which the legs leave the ground one after the other. Several species, however, walk and run, the choughs again being a good example of this.

Habitat

Corvids are found in a quite wide range of abiotic and biotic environments, occupying almost all terrestrial habitats around the world. In fact, the strong adaptative radiation of this group, constantly mentioned in the literature, makes the concept of habitat hardly applicable for several species. Corvids are found from the tropical humid forests to deserts and from the arctic zone to the mountains, such as the Himalayas. The success of this family is explained largely by its non-specialized way of life; its omnivorous habits, combined with a high cerebral capacity, which helps it to explore different food opportunities, and several particular morphological adaptations, are all undoubtedly contributing factors. Adaptability and opportunism, together with the effects of human intervention in extending suitable mixed habitats, have contributed to the historical advance and distributional expansion of several species.

Well known for their tireless mobbing of larger birds, ***Pied Crows*** *are themselves the targets of smaller birds, such as this Common Black-shouldered Kite* (Elanus caeruleus). *A few smaller corvids regularly fall victim to raptors. For example, the Eurasian Jay* (Garrulus glandarius) *is commonly taken by species such as the Northern Goshawk* (Accipiter gentilis). *However, at least one relationship with raptors seems to work to the corvid's advantage: the nests of Asian Azure-winged Magpies* (Cyanopica cyanus) *are less hidden by leaf cover when there are Japanese Sparrowhawks* (A. gularis) *residing nearby, which suggests that the magpie exploits the threat of the hawk to deter potential nest predators.*

[*Corvus albus*, Western Division, Gambia.
Photo: Dick Forsman]

This Blue-grey Gnatcatcher (Polioptila caerulea) *has good reason to mob a* ***Western Scrub-jay****, since this species is an occasional nest predator and has been identified as the major reason for the failure of Blue-grey Gnatcatcher nests in at least one nature reserve in the USA. Although often conspicuous and noisy, the Western Scrub-jay can also be furtive in its behaviour. The species is well known for attacking cats from behind, pecking their tails and escaping before the animal can turn and retaliate.*

[*Aphelocoma californica woodhouseii*, Colorado National Monument, Colorado, USA. Photo: Andy & Gill Swash/ WorldWildlifeImages.com]

Studies have shown that some corvids can survive in harsh conditions, ranging from the long and very cold nights of higher latitudes in the Northern Hemisphere to the very high temperatures of deserts. For example, the Grey Jay, weighing 65–85 g, is one of the few small birds which are year-round residents at high latitudes of North America. A small bird has problems in maintaining basal-level metabolism during the long winter nights at higher latitudes, where the temperature may drop to minus 40°C or even lower; it needs to put on 50% of its body weight in fat each day in order not to perish during the cold nights. In these regions, however, the period of daylight available in which to feed is short, only 4–6 hours each day. The Grey Jay may save appreciable amounts of energy during the long and cold nights of the arctic winter by means of hypothermic response. It has been demonstrated that this bird's body temperature may drop at night by 4·5–6·1°C when compared with its mean daytime temperature.

Among the corvids, the genus *Corvus* is clearly the most successful in living in a variety of conditions. The Common Raven is one of the species with a wide geographical distribution, occupying various habitats, but this species avoids the interior of forest, scrub-woodland, thickets, shrubby terrain, and wetlands with tall aquatic vegetation. It is not particularly associated with human settlements; indeed, it has been considered, along with wolves and bears (Ursidae), to be a symbol of the "wild country". In contrast, the majority of the species in the genus *Corvus* live in towns and villages, or, at least, in rural and agricultural areas. Crows are common in large cities such as New York, Chicago, London, Paris or Berlin. In rural and agricultural areas around the world, several species of crow are quite characteristic in the landscape, as evidenced by the Eurasian Jackdaw, the Rook and the Carrion and Hooded Crows in Europe, the Pied Crow in Africa, the American Crow in North America, the Large-billed and Collared Crows in Asia, and the Australian Raven in Australia. Some of these species have in modern times extended into further suitable habitats with the expansion of agricultural activities. In natural conditions, crows tend to avoid the interior of forest, preferring to live in woodland edges, in riparian forest or other linear habitats adjoining open grasslands or croplands, and in open areas with scattered trees, usually below 2000 m. The Large-billed Crow, however, occurs on the Himalayan slopes up to the limit of the tree-line and beyond; mountain-climbers have reported that this species accompanied them to as high as 6400 m on the route up to Mount Everest. In deserts, the most typical *Corvus* is the Brown-necked Raven, distributed from northern Africa eastwards to Central Asia, but other species also are found in desert and in arid or semi-arid regions; these include, for example, the Fan-tailed Raven of Africa and the Middle East, the Sinaloa and Tamaulipas Crows and the Chihuahuan Raven of Mexico, and the Little Crow of Australia. In eastern North

Preening, as an essential feather maintenance activity, can take place at any time of day, and during or after activities such as feeding, fighting and copulation, when feathers become disarranged. Studies of the Tufted Jay (Cyanocorax dickeyi)*, which may form a superspecies with the* ***Plush-crested Jay****, found that several hours resting and preening occupied the middle part of the day, between two lengthy foraging bouts. One study found that New World jay species from arid areas preened less than those from forests, and did not habitually bathe.*

[*Cyanocorax chrysops chrysops*, Foz do Iguaçu, Brazil. Photo: Geneviève Vallée]

Mutual preening, or allopreening, as demonstrated by these ***Thick-billed Ravens****, is almost always directed at the head and neck, which the birds enjoying the attention cannot reach with their own bills. It also has a function in maintaining bonds between pairs and group members. Konrad Lorenz emphasizes the element of trust that must exist before a bird will allow the dagger-like bill of another raven near its eye. An appeasement display found in New World jays, and perhaps in other species, involves fluffing the feathers, while holding the bill directed downwards; the other bird responds by "peck-preening", gently pecking at the neck and face. This behaviour is also used as a greeting.*

[*Corvus crassirostris*, Ethiopia.
Photo: Jürgen Schneider]

America, the Fish Crow, in contrast, is typically found close to water, such as in marshes, both fresh and brackish, in low-lying riverine plains with scattered trees and on coastal seashores. In general, tidal estuaries, saltmarshes, inshore islands and coasts are foraging places exploited by several crows and ravens.

Although the general tendency is to avoid the interior of forests, there are several species of *Corvus* that live in forested areas, especially in the canopy. Examples are the crows of the south-west Pacific islands and New Guinea, namely the White-billed Crow, the Bougainville Crow, the Bismarck Crow, the Brown-headed Crow and the Grey Crow. Besides seeking food in the canopy, the Mariana Crow, confined to the southernmost part of the Northern Mariana Islands, is known to forage noisily in the forest understorey. Similarly, West Indian crows, such as the Palm and Cuban Crows, live in forest areas; the White-necked Crow, which is confined to Hispaniola, shuns areas that have been opened up by forest clearance.

The Common Magpie, with an extensive distribution, inhabits a wide range of open areas with scattered trees, from lowland farmland to mountains. In common with several *Corvus* species, it has recently expanded into urban areas; it has become a scavenger around human habitation, and this may have permitted its considerable expansion and successful colonization of many areas in Europe. It avoids not only large tracts of open country lacking trees but also densely forested areas. It prefers lowlands with open or lightly wooded country, offering good opportunities for foraging on the ground; the micro-climatic conditions in the foraging sites near the surface of the soil in the shadow of trees tend to suit this species. A study in Denmark showed that competition for food with Hooded Crows is a possible reason for the Common Magpie's preference for habitats near tree cover. In England, the amount of tree cover has increased in the area near Manchester, and this may explain the higher breeding densities near the city when compared with those in farmland; in addition, the magpies in Manchester prefer to nest in poplar (*Populus*) trees, because these offer some protection from predators owing to their close-knit canopy. The Black-billed Magpie occupies similar habitats, but lives also in mountainous country. A detailed study of temperature regulation of magpies in North America revealed that climate, rather than an effect of food availability, restricts the Black-billed Magpie to the "Cold Type Steppe Dry Climate"; the Yellow-billed Magpie, confined to California, tolerates warmer climates.

Humidity levels also characterize the habitats of the two species in the genus *Cyanopica*, although these two are not sympatric. The Iberian Azure-winged Magpie lives from sea-level to 700 m in Iberia, where it inhabits sand dunes overgrown with planted stone pines and eucalypts (*Eucalyptus*), and open cultivated or grass country with groups of trees and scrub, whereas the Asian Azure-winged Magpie lives in more humid habitats such as riverbanks and river islands, woodland areas and forest edge, in both mixed and deciduous forest.

Having a large geographical distribution does not necessarily mean that a species lives in a great variety of habitats. The Spotted Nutcracker, with a wide distribution in Eurasia, is closely linked with mountain coniferous forests, although it can also be found in mixed forest of conifers and birch (*Betula*); only during eruptive movements, however, is this species observed in other habitats with trees, including urban areas. Two species in the genus *Perisoreus*, likewise with relatively large geographical ranges, are typical of certain habitats; the Siberian Jay is considered an important representative of the boreal taiga in the Old World, and in the New World the Grey Jay also is typical of coniferous forest, although it sometimes occurs in areas of mixed forest. In the genus *Garrulus*, the Eurasian Jay, one of the most widely distributed of all corvids, is closely associated with forest, both mixed and deciduous, but it may occur also in conifer forests in higher latitudes, as well as in orchards and woodland areas. As with crows and magpies, the Eurasian Jay is often found in city parks and large gardens, but it is more secretive in its habits and, as a consequence, more difficult to watch.

There are several true forest-dwelling species of corvid in the Oriental Region, some of them exhibiting noticeable specialization. The genus *Crypsirina* is found commonly at the edge of lowland open forest of various types, including mixed deciduous woodland, secondary forest, bamboo and mangroves, while the Ratchet-tailed Treepie is associated more with the interior of forest, especially with extensive areas of bamboo. In the genus *Dendrocitta*, the Collared Treepie also prefers humid evergreen forest with extensive stands of bamboo. The *Dendrocitta* species, in general, live in forested areas from the lowlands up to 2600 m. Some, such as the Grey Treepie, visit

cultivation, scrub, secondary forest and ravines, but others, such as the Andaman Treepie, are more restricted to dense evergreen forest. The Rufous Treepie is the only member of this genus that is found in gardens and parks, and it seems to avoid denser forest areas, preferring both dry and moist broken deciduous woodlands. The Black Magpie, the sole member of *Platysmurus*, lives in lowland forest at up to 200 m. The green magpies, in the genus *Cissa*, and the blue magpies, in *Urocissa*, also live in tropical and subtropical evergreen forest in both lowland and hilly areas. Several species in these two genera prefer forest borders, bamboo thickets and shrubbery along watercourses, while some can be found at high altitudes, reaching the tree-limit; the Yellow-billed Blue Magpie ascends to 3600 m and the Short-tailed Green Magpie to 2400 m.

Similarly, in the Neotropics, the genus *Cyanolyca* is strongly associated with forests. Borders and secondary growth of humid luxuriant cloudforest are the typical habitats of these jays, which live in the mountains of Middle America and the Andes, commonly between 1500 m and 3000 m. Some species of *Cyanolyca* occur in elfin forest, examples being the Turquoise Jay and the White-collared Jay. The Azure-hooded Jay and the Black-throated Jay occur also in oak woodland, while the Dwarf Jay and the White-throated Jay are linked more with mixed stands of oak, pine and fir with abundant epiphytic growth.

The other genera of Neotropical jays, *Cyanocorax*, *Calocitta* and *Psilorhinus*, are less associated with tropical forests, some species being characteristic of other habitats. This is the case with the Curl-crested Jay and Azure-naped Jay, living in the Brazilian savanna type known as *cerrado*, the White-tailed Jay in mesquite forest, a type of dry forest, the Purplish-crested Jay in the Pantanal, a flooded area in south-central Brazil, the White-naped Jay in *caatinga*, a shrubby cactus steppe in north-eastern Brazil, and the San Blas Jay, found in areas of coconut palm groves. None, however, is restricted to those habitats. *Cyanocorax* jays occur also in tropical deciduous forest and evergreen rainforest; in these cases they avoid the interior of the forest, preferring watercourses in the lowlands of hilly areas, as demonstrated by the Tufted Jay, the Green Jay and the Cayenne Jay. In Amazonia, the Violaceous Jay is associated with the borders of large rivers. Besides other forest types, the Azure and Plush-crested Jays colonize the southern temperate forest, at higher altitudes in southern Brazil, where the conifer *Araucaria angustifolia* dominates and the temperature often drops to –5°C during the winter months. *Cyanocorax* species frequently visit scrub not far from forest areas, as well as riparian forest, patches of forest in open country, ravines with scattered trees, savanna in sandy soils, mangroves, and rural areas and cultivation, especially of banana, corn and coffee. Few species in this genus are reported as frequenting gardens or towns, but the Cayenne Jay, the Curl-crested Jay and the Plush-crested Jay do so. The two magpie-jays live in drier habitats, including arid bushy open country, thorn-forest, deciduous woodland and gallery forest. The Brown Jay inhabits a mosaic of habitats, having a notable preference for disturbed areas such as the edges of plantations, rather than undisturbed areas.

Among the five species of *Aphelocoma*, there are strong differences in habitat occupation. The Western Scrub-jay is the most generalist, being found throughout the mixed woodlands of oak, pine and juniper (*Juniperus*), scrublands, chaparral and brushlands

Blue Jays *bathe in shallow water by first immersing the head, then using the wings to flick water over the rest of the plumage. Although they can become regular visitors to garden bird baths, they remain wary while bathing, raising the head every few seconds to peer about, and sometimes hopping out of the water to get a better all-round view. There is a report of a Blue Jay which hopped out of the water between splashes to give an almost perfect imitation of the call of a Red-shouldered Hawk* (Buteo lineatus). *The observer suggests that this was done to keep other birds away while the jay was vulnerable.*

[*Cyanocitta cristata bromia*, Quebec, Canada. Photo: Daniel Houx]

of western North America. Less of a generalist is the Island Scrub-jay, found in chaparral dominated by low-growing oak; and likewise the Unicoloured Jay, largely restricted to humid forests of Middle America; and the Mexican Jay, living in montane pine/juniper–oak woodlands. The Florida Scrub-jay is the most specialized member of the genus, living in isolated patches of oak growing on sand ridges.

The two *Cyanocitta* species, which have relatively large geographical distributions in North America, live in mixed deciduous woodland and conifer forests, preferring borders and forest clearings. Both species frequent parks and gardens, even in cities. Steller's Jay is a quite familiar bird around camping sites and picnic spots in the Rocky Mountains, while the Blue Jay is a popular bird in urban areas of central and eastern North America. The sympatric Pinyon Jay in Arizona and New Mexico shares the dry mountain slopes and foothills dominated by pines, the scrub areas and the gardens in that region with the two species of *Cyanocitta*.

Some corvid genera of the Old World tend to live in particular specialized habitats. The choughs are found in rocky and grassy habitats in the mountains, usually up to 6000 m; the Red-billed Chough also inhabits rocky coasts and inshore islands in Britain, Ireland and north-west France. The ground-jays are typical species of desert, whether sandy or flat and stony with scattered bushes, and Stresemann's Bushcrow is restricted to a small area in southern Ethiopia consisting of acacia (*Acacia*) scrub in park-like country of short-grass savanna. The reason for the latter's confinement to so small a range is not known (see Status and Conservation). The Piapiac, with a larger geographical distribution across Africa, lives in dry savanna with scattered trees.

Although several species of corvid may live in a variety of habitats, sympatric species can exhibit clear differentiation in relation to use of the habitat. For example, where populations of the Carrion Crow and the Hooded Crow live in the alpine zone, the former selects pastures and meadows, whereas the latter prefers maize stubbles when these are available. The hybrids between these two species tend to occupy intermediate habitats. These observations suggest that the alpine hybridization zone may be a mosaic of populations differentiated in relation to the locally diverse ecological conditions. The hybrid zone seems to be dynamic, depending on variations in climatic conditions, as was shown in Scotland, where the hybrid zone has moved northwards during the last century.

General Habits

A large number of impressive observations, both in the field and in captivity, may lead one to believe that corvids are quite intelligent birds. The playing of tricks on other animals, hiding and recovering stored food both in nature and in the laboratory, the act of pulling towards themselves food hanging on a string, the ability to recognize people who are carrying guns, avoidance of trapping, the following of predators such as wolves and coyotes (*Canis latrans*) in order to obtain food, the digging of big holes under an aviary in order to escape, the habit of dropping shellfish from a height on to a hard surface in order to break them open, and the use of objects as tools are among many other equally impressive examples of the behaviour of corvids in the field and in captivity. In fact, this aura of intelligence is one of the most recognizable of endowed features of this avian family around the world.

It is true that corvids have a large head accommodating a large brain, which could explain their "mental capacities". In fact, studies have indicated that the members of the family Corvidae have a considerably larger brain in relation to their body size than other birds; only two species of parrot, namely the Red-and-green Macaw (*Ara chloroptera*) and the Blue-and-yellow Macaw (*Ara ararauna*), approach the corvid species in this respect. Furthermore, among the corvids, the American Crow is top of the list, having a larger brain than would be expected for its modest body size; the Common Raven appears in second position, followed by other *Corvus* species, and then by other genera such as *Garrulus*. In corvids and parrots (Psittacidae), the inner portion of the forebrain, especially the nidopallium, is pronounced, and is densely packed with nerve cells, making it an efficient storage, processing and co-ordinating centre. Another part of the forebrain, known as the hippocampus, may be most important in spatial memory, something which is particularly valuable when caching stored conifer seeds (see Food and Feeding). The relative brain

*This rain-bathing **Eurasian Jay** has adopted an upright but relaxed posture, bill slightly agape and crest partially raised. When anting, Eurasian Jays take up a similar position, with the wings drooping and tail and vent pressed against the ground. Unlike most passerines and other corvids that have been studied, they do not actively place the ants on their feathers, but remain passive, letting the ants run over them, although they may run their bills through their feathers. After anting, they often bathe, shaking themselves vigorously, before preening.*

[*Garrulus glandarius glandarius*, Hungary.
Photo: Markus Varesvuo]

*This sun-bathing **Steller's Jay** has raised its crest, spread its wing and tail feathers, and fluffed its body feathers to allow maximum penetration of the sun's rays. These normally wary birds have been observed sunning themselves for many minutes at a time. They take advantage of the early morning sun to warm themselves after a night's roosting, even when the surrounding temperature is below freezing. The gaping bill is characteristic of the trance-like state that many birds enter while sunning. But sunny places are also exposed places, and in contrast to some other passerines which seem to become oblivious to their surroundings while sunning, these jays remain alert, turning their heads to scan for danger.*

[*Cyanocitta stelleri stelleri*, Anchorage, Alaska, USA. Photo: Pete Morris]

size of crows and ravens is closer to that of mammals, including most primates, than to that of other birds. Marzluff and Angel commented that crows and ravens are more like "flying monkeys" than they are like other birds, meaning that they are able to learn, to remember, and to use insight in order to solve natural and experimental challenges. One can say that corvids are the creatures possessing the highest capacity for memory and learning when viewing their surroundings from the air, which gives them a tremendous advantage when it comes to surviving in different environments.

Evidence for the learning capacity and long-term memory, in this case of auditory stimuli, of corvids was provided by J. Brown, who studied dominance interactions in a colour-banded population of Mexican Jays in Arizona, in the southern USA. A whistle was blown just before food was put out for the jays; the latter rapidly learned to associate this sound with the availability of food. It was possible also to test cultural transmission of this knowledge when the observer returned some years later and performed the same procedure; yearlings and unringed migrants learned from the older and experienced individuals.

Although the highly developed mental ability of corvids may be related chiefly to food and the acquisition of it, there are other situations in which the exceptional capabilities of these birds seem to be adaptive, as illustrated in their complex social life. Since the majority of species live in flocks, memory of discrete events and fine details is important to their social life, such as in partner recognition. Another important factor in social life is individual hierarchy, which is commonly observed among the members of the flock; this subject has stimulated researchers on behaviour since the seminal study by K. Lorenz of the Eurasian Jackdaw. In captivity, the subordinate individuals must wait their turn at the food dish and must submit to having food that they have hidden stolen by other, more dominant individuals; females tend to be subordinate to males. Some researchers have suggested that hierarchy of this kind does not exist, arguing that, in reality, there would be a quick evaluation of the condition and determination of the rival. Since such hierarchy tends not to be permanent, and because of the speed at which social rank among captive corvids may change, without any physical fighting, it is suggested that these birds are competent at judging the physical and psychological condition of others. In the wild, the long-term study of the Florida Scrub-jay carried out by G. Woolfenden and J. W. Fitzpatrick offers important insights into the function of hierarchy; unlike the classical view, in which hierarchy is interpreted as being linked to intraspecific competition for limited food, dominance among Florida Scrub-jays appears to be associated with optimizing the reproduction potential of each individual. With Florida Scrub-jays, the male breeder is dominant over all other individuals in the family, male helpers dominate over all females, and the female breeder is weakly dominant over female helpers. Juve-

*Corvid songs are not well developed, but several species do have a soft, prolonged subsong. That of the **Curl-crested Jay** is a conglomeration of muted croaks, chittering and piping. A study found that New World jays uttered sounds like this, including toots, whistles, clicks, and metallic noises, with no particular pattern, and that subsongs were unique to individuals. They are performed most commonly, but not exclusively, during the courtship period, although they are often delivered when the individual is apparently beyond the hearing of other birds.*

[*Cyanocorax cristatellus*, Das Emas National Park, Goiás, Brazil. Photo: Tui de Roy/ Roving Tortoise Photos]

The most frequent call of ***Clark's Nutcracker*** *is a far-carrying, grating "kraaaa" or "kraaak", repeated several times in succession. Sometimes the call is repeated regularly and monotonously, and at other times with more variation—a long note followed by three shorter, quicker ones, for example. The calls may be uttered in duet, with pauses while the other bird, often out of sight, replies. In spring, Clark's Nutcracker delivers a more musical version of its call, perhaps the closest this species comes to a song for proclaiming a territory. Other calls associated with breeding and courtship include a succession of alternate crackles and whistles, accompanied by bowing. Despite the difference in coloration between the dove-grey Clark's Nutcracker and the dark-brown, profusely spotted Spotted Nutcracker* (Nucifraga caryocatactes)*, the two species are closely related. The Spotted Nutcracker has a similar—though brisker—version of the same call, but a quite different song, which includes a variety of whistles, plaintive dog-like whining notes, and some mimicry. Corvid repertoires can vary seasonally, and at least in the western part of its range, the Spotted Nutcracker is quite silent in the winter.*

[*Nucifraga columbiana*, USA.
Photo: Mike Read]

niles, subordinate to all other family-members, seem to establish a hierarchy among themselves by means of investigative encounters during their first summer; breeding opportunities develop in accordance with the established hierarchy among the male helpers, the dominant male helper being the first to depart and to form a pair with a female.

The communication behaviour of corvids includes numerous displays, consisting of visual and/or acoustic signals, which possibly reflect the high complexity of social organization of this bird family. Vocal communication (see Voice) is quite complex, and perhaps helps to explain the ability of corvids to count up to about six; N. S. Thompson suggested that such ability developed in corvids as a result of their vocal communication, in which different vocal messages varied only in the number of calls. Visual communication, based on displays, has been quite well studied, and shows some similarities to that of other passerine groups. Goodwin provided excellent descriptions of the displays of the Eurasian Jay. The threat display consists of an approach during which the head is held up, often with the bill pointing upwards and the plumage sleeked; snapping-together of the mandibles may also be used as a threat. Actual physical combat can occur, when the fighting jays grapple with the feet and peck with the bill, although they do not damage the opponent's eyes. In the defensive threat, when the jay is attempting to prevent a fight from developing, as during nest defence, it erects all feathers of the plumage, especially the feathers of the head and back, and points the partly opened bill in the direction of the enemy. Self-assertive display has different functions according to the context. When given by the mate, it seems to be a greeting or a means of stimulating or "backing up" the partner in the presence of mutual enemies, but in territorial contexts it is essentially a signal of defiance or hostility to the rival. In self-assertive display the corvid presents itself either frontally or laterally, with different areas of the plumage fluffed up; in sexual situations, the individual moves around the one to which it is displaying and, in the case of long-tailed species, may twist the tail towards it. Submissive display is given by the female as an invitation to coition, but it is exhibited also by individuals towards socially superior ones; it is possible that this display, sometimes called the "quivering display", first evolved as the receptive female's signal of her desire for copulation. The begging display is associated with the begging of a hungry fledgling, but females, too, perform it during the period when they are laying, incubating, or brooding young nestlings. In captivity, both sexes often beg towards humans if they are very hungry. Besides the request for food, the begging display seems to indicate dependence in relation to the human keeper or other individual. The feeding by one individual of another, usually a subordinate, is common, the latter adopting a low-intensity submissive quivering display. Among mated pairs, the male frequently feeds the female during laying, and this is an important source of food for the female.

Some of the displays described for the Eurasian Jay have been recorded also, with some variations, for other corvids. Hardy provided detailed descriptions of the displays of some species in the genus *Cyanocorax*; for the Purplish-backed Jay, for example, he mentioned that during the threat display the pupils are constricted, so that the bright yellow irides are boldly evident. Another display described by Hardy, and commonly seen in

The most frequently heard vocalization of ***Pander's Ground-jay*** *is a series of far-carrying, clear-ringing notes, "chweek chweek chweek chweek...", delivered from the top of a bush in the early morning, or, less frequently, in the evening. Poor vocalizers among non-passerines tend to have only two or three pairs of syringeal muscles. But despite their limited vocal range, examinations of corvids, mostly* Corvus *species, reveal that they have six or seven pairs, like many "true" songbirds.*

[*Podoces panderi*, SE of Lake Balkash, Kazakhstan. Photo: Per Schiermaker-Hansen]

Belonging to a recent radiation of crow species in North America, the ***Fish Crow***, *Sinaloa Crow* (Corvus sinaloae) *and Tamaulipas Crow* (C. imparatus) *are quite similar in appearance to the American Crow* (C. brachyrhynchos), *but can all be separated from this species and from one another by voice. Compared to the very varied range of calls of the American Crow, with more than 20 described, the Fish Crow's repertoire is limited. The species with the highest number of distinct calls identified is the Common Raven* (C. corax), *for which 80 calls have been documented.*

[*Corvus ossifragus*, Cambridge, Maryland, USA. Photo: George M. Jett]

The calls of ***Rooks*** *in flight over a breeding colony can vary from a flat "caw" to a high-pitched yelp. Their most frequent calls are their contact calls, and these vary individually in timbre and pitch, and are recognizable by other Rooks, particularly the bird's breeding partner. Rooks sometimes call in duet, proclaiming their territory, which can be a very small area around the nest in a crowded colony. The female's call is longer and higher-pitched than the male's. Around 20 calls have been documented for this species during the breeding season alone. These calls are used in various social contexts, and can vary in intensity according to circumstances. The Rook's "song", consisting of soft cawing, gurgling, rattling and crackling calls, has been compared to that of a loud Common Starling* (Sturnus vulgaris).

[*Corvus frugilegus frugilegus*, Rhineland-Palatinate, Germany. Photo: Mathias Schäf]

Non-breeding ***Brown-necked Ravens*** *gather noisily at roosts, which can include many foraging groups. Studies of the Common Raven* (Corvus corax) *suggest that such roosts serve as information centres, where birds can learn the whereabouts of food sources. The Brown-necked Raven's calls are much less deep and resonant than the Common Raven's, and have been likened to those of the Rook* (C. frugilegus). *Brown-necked Ravens are fairly similar in structure to Common Ravens, but significantly smaller. Larger birds typically emit lower-pitched calls because of the larger syrinx.*

[*Corvus ruficollis*, Yalooni, Oman. Photo: Hanne & Jens Eriksen]

Neotropical jays, is the "up-fluffing" of the plumage: the bird extends its neck to a greater or lesser extent and slowly erects the feathers of the neck and head, thereby revealing the pinkish skin. In a more intense form of the fluffing display, the bill is directed downwards and the head cocked slightly to one side away from the target of the display. Fluffing is a form of appeasement, being a substitute action for any tentative pecking or threat, and it has been considered to be a greeting. A positive response to the fluffing display is the peck-preening, consisting of a gentle pecking at the neck and face.

Some specific studies of spatial variation of bird displays have been carried out. Brown, studying ecogeographical variation and the aggressive behaviour of Steller's Jay, found that the increased visibility in less humid and more open environments resulted in an increased frequency of aggressive encounters. This led to the evolving of individuals with more developed crests.

Living in flocks has advantages. For example, it facilitates the discovery and maximum use of food supplies during foraging, and the pairing of unrelated individuals during reproduction, and it makes it easier for the birds to detect predators and to mob them. Nevertheless, in several situations when corvids are observed in a group, such as during migration or foraging, it is difficult to determine if the group is a genuine flock, with a higher level of cohesion among the individuals, or is simply an aggregation of individuals; in general, it is only the relationship between individuals in a pair-bond that can be easily recognized

Most treepie species are arboreal foragers, and their short legs and long tails make them clumsy in their movements when they do descend to the ground. ***Grey Treepies****, however, come to the ground frequently, where they forage by hopping with the tail cocked. The small parties of six to eight birds advance together, pecking amongst the leaf litter on the floor of the open deciduous forest they frequent.*

[*Dendrocitta formosae sinica*, Nanjing, Jiangsu, China. Photo: Li Hang]

Hooded Crows *feed by picking and probing with the bill, often leaning so far forward that the bill reaches back between their feet. They turn over stones, move sticks and straws, and push grass and weeds aside in search of small animal food, such as worms, insects, frogs, small mammals, and birds' eggs. In short grass and other terrain where prey is more easily visible, they also hunt by sight. In urban parks and playing fields they can be seen turning their heads as they stride about, and pausing frequently to examine potential food items, such as discarded sandwich crusts.*

[*Corvus cornix cornix*, Oslo, Norway. Photo: Ketil Knudsen]

for what it is. The same level of uncertainty could be said to exist with regard to territorial behaviour. In several species, individuals that are dispersed in pairs or small groups during the day may gather in a tree to pass the night together, such communal roosting behaviour being typical of many passerines. The American Crow is known to forage over large areas and to roost in aggregations during the non-breeding season, when territoriality seems not to exist; in this case, groups of four or five crows leave their stable territories each day early in the afternoon and travel to large communal roosts. Wandering American Crows, which do not maintain a territory, may be present in the same area and use the same roost-sites as those of territorial individuals. Little is known about how or why a particular site is chosen as a communal roost, but the behaviour may be continued for long periods, individuals returning day after day to the same place. In the case of the American Crow, roosts containing large numbers of individuals tend to be situated close to superabundant food supplies, while roosts with only small numbers seem to be sited so as to avoid detection by predators or to reduce heat loss. During the winter months, the Yellow-billed Magpie roosts only in dense

During the spring the ***Siberian Jay*** *feeds actively in the crowns of conifers, but in other seasons it forages much lower in the trees. It will search along branches and the main trunk, pecking at the scaly bark, before moving on to adjacent trees. This bird is taking an item of food placed in a hole in a tree by the photographer. Uniquely, the members of* Perisoreus *attach food items firmly to trees using sticky mucus in their saliva.*

[*Perisoreus infaustus infaustus*, Posio, Finland. Photo: Markus Varesvuo]

*The **Common Magpie** forages on the ground in grassland, preferring humid areas where soil invertebrates are more abundant and occur near the surface. Co-existence with other corvids is made possible by differences in foraging strategy and diet. In Granada, in southern Spain, arthropods comprise the most important animal foods in Common Magpie and Carrion Crow* (Corvus corone) *diets, whereas carrion is the most important item for the Common Raven* (C. corax). *In Denmark, competition for food with Hooded Crows* (C. cornix) *is a possible reason for the Common Magpie's preference for habitats near tree cover. Note the patch of bare, blue skin behind this bird's eye, characteristic of the North African race.*

[*Pica pica mauritanica*, Sidi Bettache, Morocco. Photo: Daniele Occhiato]

evergreen vegetation, avoiding wind exposure, thereby reducing its metabolic demand; in addition, this species displays a preference for warmer micro-habitats such as riparian forest, probably because of the moderating effect that water or moist soil may have on night-time temperatures. Having a greater tolerance of cold conditions, the Black-billed Magpie roosts in deciduous vegetation and may be exposed to lower temperatures.

Young corvids tend to follow older individuals, and the recruitment of new members at a communal roost is a common event. Therefore, in addition to the advantages of decreasing the chances of a predator's approach going unobserved, and providing some physical protection against the elements, communal roosting may, for some species, facilitate the meeting and pairing of unrelated individuals. So, the numbers of individuals in these roosting areas can be very high; in the western USA, for example, a roost of Common Ravens along 6 km of power transmission lines in Idaho attracted up to 2013 individuals. Seasonal fluctuations in the number of individuals attending the roost are typical, the total increasing in early summer and declining through the autumn. For the Eurasian Jackdaw, both residents and non-

*Although little is known about its food or feeding habits, the **Turquoise Jay** is said to forage in the subcanopy and canopy in small flocks, sometimes mixed with other species. The birds will hop along the branches, rummaging in bromeliads and other epiphytes, and stopping to peer through the foliage. This species has at times been considered conspecific with the Black-collared* (Cyanolyca armillata) *and White-collared Jays* (C. viridicyanus). *The Turquoise and Black-collared overlap, but while both are found in humid, mossy cloudforest, the Turquoise is also found in stunted elfin forest at higher altitudes. It seems to favour extensive stands of alders* (Alnus).

[*Cyanolyca turcosa*, Bellavista Cloud Forest Reserve, Ecuador. Photo: Tui de Roy/ Roving Tortoise Photos]

residents roost communally at traditional sites for most of the year; during the breeding season, however, residents tend to roost in or near their nests while non-residents often continue to use the communal site. Among the crow species living in the tropics, communal roosting is documented for the Mariana Crow.

The size and structure of corvid groups vary greatly through the course of the year. This is linked with the annual cycle of the species, in particular for those species living in temperate zones, such as the Pinyon Jay, the Eurasian Jackdaw, the Spotted Nutcracker and the Eurasian Jay. Among the Neotropical jays, the temporal variation in numbers observed in the flocks is not so great, as has been recorded for the Green Jay in Colombia.

Within flocks, individual perching distance tends to be higher for jays, which are solitary nesters, and lower for colonially nesting species such as the Eurasian Jackdaw. In jays in general, physical contact occurs only during fluffing-up of the plumage and when one individual is feeding another; in jackdaws, the pair-members habitually perch side by side, in contact with each other. Crows are intermediate in this respect, individuals perching very close to one another, but usually not in physical contact.

Several species in this family use sentinels, individuals being posted high up and in strategic positions with a good view around, from where they can warn the rest of the flock of the approach of a predator. Such behaviour has been documented especially for species living in forests, such as the Pinyon and Azure Jays; it is particularly obvious during the nesting period, at which time helpers at the nest also act as sentinels. For some species, such as the Rook and the Carrion Crow, there is some uncertainty about apparent sentinel behaviour, which could be accidental, rather than deliberate. The Rook or the Carrion Crow perched in a strategic spot perhaps flies off and emits alarm calls because of its own fear and, as a consequence, causes the others in the group, foraging on the ground, to follow it or to become alert to the danger; there are several observations, however, indicating that the foragers do not always react. Birds in larger flocks normally spend less time alert, presumably because there are more eyes to share the task, and this seems to be true of at least some corvids. During foraging on the ground, individuals of the Common Magpie vary the time of scanning behaviour, which is defined as the length of time spent in standing motionless with the bill horizontal or raised; this time tends to be shorter when the individuals are close to a protective vegetation cover. In central Texas, USA, the Western Scrub-jay is characterized as a generalist in terms of habitat selection; however, it is a specialist in one aspect alone, namely in its use of tall oak trees during sentinel behaviour.

Although corvids drink water regularly, some of the species living in arid regions, the *Podoces* ground-jays being a good example, are less dependent on this, as they obtain food having a high water content. Other species, such as the choughs, use snow as a source of water. Bathing in water and sun-bathing are regular aspects of corvid behaviour, and they are performed in a manner similar to that of other passerines. Anting has been documented for several members of the family, and is commonly followed by bathing and preening. Allopreening, the preening of one individual by another, is always concentrated on the head and upper neck, areas which the bird cannot reach with its own bill. Besides the practical aspect of removing ectoparasites, allopreening has a social function.

Species of crow that have been reared by hand from a very young age, before they are about half-feathered, usually become completely imprinted on humans and show no recognition at all of their own kind later in life. The studies by Lorenz on the imprinting and general behaviour of the Eurasian Jackdaw are famed throughout the world. Lorenz's jackdaws became sexually and socially fixated on humans. Although imprinted on man, these jackdaws responded positively to other *Corvus* species and flew with them when they were on the wing nearby; Lorenz suggested that this was an innate recognition of black corvine wings in flight. Experiments have revealed that imprinting seems more marked among crows than it is among magpies and jays; an explanation for this difference is that the former co-exist with allied species, which are similar in colour, whereas magpies and jays do not.

Corvids are active in the mobbing of predators, such as birds of prey. Even birds that present no danger, such as the Common Kestrel (*Falco tinnunculus*) and the Grey Heron (*Ardea cinerea*), are mobbed. This sense of defence of the group is common among corvids. Lorenz reported that tame Eurasian Jackdaws attacked him when he carried a pair of black swimming trunks, and he explained this as being innate predator-attacking behaviour by the jackdaws. Quantitative data on the American Crow demonstrated that the presence of a black object stimulates corvid aggressiveness towards what appear to be potential predators.

Voice

Corvids emit a wide variety of calls, but songs, which characterize other passerines, are less well developed in this family. The existence of such a range of calls is explained by the complex social organization of the Corvidae, in which social interactions

*The **New Caledonian Crow** routinely uses tools to extract beetle larvae from dead wood. These crows have been observed working hooked twigs under the larvae to lift them out of inaccessible crevices, or provoking the grubs to grab the poking stick, so that they can be hauled out. They also cut off the barbed edges of* Pandanus *leaves with their bills to create tools. The high degree of standardization suggests knowledge is transferred between crows, but they are also able to adapt their techniques to new situations. In the laboratory, one crow made a hooked tool out of wire.*

[*Corvus moneduloides*, Nouméa, New Caledonia. Photos: Alain Petit Nicolas/ Bios]

All corvids are more or less opportunistic, but the harsh, often arid habitat of the ***Brown-necked Raven*** *forces it to investigate all potential sources of food. These birds are often recorded perching on camels and donkeys, picking ectoparasites such as ticks from their heads, necks and bodies, sometimes clinging head down to reach ticks on the mammal's belly. Similar behaviour has been recorded in jays of the genus* Aphelocoma, *which regularly pick ticks and perhaps other ectoparasites from the skin of deer. House Crows* (Corvus splendens) *ride on the backs of cattle, mules and pigs, not only picking off ticks, but also pecking at sores, which prevents healing and can lead to the weakening and even death of livestock. Brown-necked Ravens also peck and aggravate sores on livestock, and will pick grain and other edible matter from animal dung.*

[*Corvus ruficollis*, Ksar Ghilane, Tunisia. Photos: Manfred Pfefferle]

The Cissa *green magpies are mainly carnivorous, with a diet that includes lizards, small frogs, snakes and birds' eggs and nestlings, beetles, crickets and mantises.* ***Common Green Magpies*** *have also been observed feeding on carrion, and may take fruit. They forage through the dense undergrowth, often in noisy mixed flocks with babblers (Timaliidae) and drongos* (Dicrurus). *They cross open ground reluctantly, moving quickly from thicket to thicket. Under cover, they may also feed on the ground, noisily turning over leaf litter, before working their way up through the shrub layer, clambering between hanging creepers, and sometimes ascending to the upper canopy.*

among individuals in a flock are constant, and in need of co-ordination. Corvids tend to live in monogamous pairs for life, and a large vocal repertoire is important for maintaining the pair-bond and in co-ordinating the partners' actions. Ornithologists studying corvid calls use a variety of words to give an acoustic impression of an astonishingly large vocal repertoire. Whistles, harsh notes, nasal calls, raucous sounds, chatters, barks, yelps, stuttering notes, and clicking and rattling notes are described, besides such expressions as rolling and resonant, deep croaking, rasping guttural notes, a buzzing quality, liquid guttural sounds, and a loquacious character. Single calls or combinations of calls are related to specific types of behaviour to determine their meaning and to develop a vocabulary, in theory. Because of the variety of sounds emitted, however, studies of the vocal repertoire of corvids are difficult, even considering all the advances in technology, such as precise video-cameras and programmes for fast sonogram analyses, that have been made in recent decades. In the Common Raven, for example, B. Heinrich stated that, despite the fact that this species' voice has received probably more attention than any other aspect of its life, he is convinced that there is no aspect of this corvid about which less is known. The Common Raven may well be the most dramatic example, since it has been recognized as having the largest vocal repertoire among the corvids.

Study of the vocal repertoires of corvids is further complicated by the fact that the unique calls emitted by a species often become blurred owing to intergradation. Distinctions between one call and another are often rather arbitrary, and sometimes alternative descriptions given by different authors studying the same species are hard to reconcile. Corvids are able to incorporate information on the degree of urgency into many calls by varying the intensity and pitch, just as humans yell more loudly and in a higher voice as they become more excited. The situation is, however, even more complex. A call may be used in different behavioural contexts, so that one specific call may be uttered in a context different from those "normally" eliciting it. There is also individual variation, frequent vocal mimicry, which may be incorporated and combined with innate calls or used instead of them, and variations due to regional differences. In fact, Marzluff and Angel highlighted the ability of crows and ravens to combine sounds in complex ways in a variety of contexts in order to vary and enrich their meaning. In view of this ability, they even went so far as to argue that corvids possess basic language skills.

Despite the problems outlined above, several authors have attempted to assessed the vocal repertoire of some species. These estimates in some cases have been qualified and in others are total counts of calls uttered. Examples in the first category are that, during the breeding season, Rooks use 20 calls and, in captivity, Red-billed Choughs use 18; in the second, that the Carrion Crow has 23 calls, the Pinyon Jay 15, the Yucatan Jay 24 and the Azure Jay 14 calls. As already noted, the species with the highest number of distinct calls is the Common Raven, for which 80 calls have been documented. One individual, however, does not emit all 80, but usually utters about 20 basic calls. It is important to bear in mind that for a considerable number of species, mostly

Corvus *crows are always ready to take advantage of an abundant food source. In springtime, in southern Manitoba, red-sided garter snakes* (Thamnophis sirtalis) *emerge in vast numbers from their underground wintering dens, forming perhaps the largest concentration of snakes in the world.* ***American Crows*** *are waiting for them! Over a ten-day period in May 1997, researchers recorded 590 red-sided garter snakes killed at or near their dens, almost all taken by American Crows. The crows inflicted injuries of several kinds, usually involving removal of the snake's liver.*

[*Corvus brachyrhynchos pascuus*,
Everglades National Park,
Florida, USA.
Photo: Hanne & Jens Eriksen]

Corvids locate food by probing with their bills, and by sight, but a series of experiments demonstrated that magpies can also use olfactory cues to smell food. Magpies frequently cache surplus fresh food, as this ***Arabian Magpie*** *appears to be doing with a small rat. In trials, magpies discovered caches of rotten chicken or bread soaked with cod-liver oil far more often than fresh chicken or plain bread. Thus, as food such as cached rodents begins to decay, it will become easier for the magpie to relocate it. Previously treated as a race of the Common Magpie* (Pica pica)*, the Arabian Magpie is now separated as a full species.*

[*Pica asirensis*, Taïf Breeding Centre, Saudi Arabia. Photo: Michel Gunther/ Bios]

from the tropics, the extent of the vocal repertoire is virtually unknown; there are few recordings of some species. Repertoires can vary seasonally. Some species are quite silent during the winter, one such example being that of the Spotted Nutcracker in at least the western parts of its range, while others are conspicuously vocal throughout the year, as typified by the choughs and the Carrion Crow.

One way in which to begin to understand the varied function of the many calls emitted by corvids is to separate the vocalizations according to their carrying capacity. Sounds that are able to carry in the environment are associated with distant communication, for example to repel or attract individuals from a territory. Sounds less able to carry are usually given when individuals are near each other. These are frequently combined with a strong visual display.

Frequently, the most characteristic call of a species is a loud one that is easily transmitted in the environment. This is, for instance, the "quork" or "crok" of the Common Raven, the "kraaah" or "aaaah" of the Carrion Crow, the "kraaaa" or "kraaaack" of Clark's Nutcracker, the "weep" of the Florida Scrub-jay, and the "jeer" or "jay" of the Blue Jay. Although behavioural ecologists generally avoid naming calls with terms indicative of their perceived function, some authors have attributed different names to these vocalizations; examples are the "assembly call" of the American Crow, the "chatter call" of the Yucatan Jay, and the "social call" of the Azure Jay. All of these calls are species-specific, and they are produced in a variety of situations where communication is usually addressed to more than one individual in the flock, as when flock-members are congregating or during foraging. Unlike some other passerines, corvids do not have an elaborate song for territory proclamation, and this loud call performs that function for territorial species. It is used, for example, to discriminate among closely related species, as in the study by L. I. Davis of North American crows, and in analyses of evolutionary relationships, as in Hardy's study of the American jays. Adult Common Ravens accompany such vocalizations with rolls or dives on closed wings in territorial defence. The Rook, the Common Raven and the American Crow may emit this call type in duet, by the two partners, when proclaiming territory. Duetting may also help in maintaining the pair-bond, as in some other bird families. In the case of the Eurasian Jay, it is possible that only males emit the "kraah" call, its function being similar to that of the duet. This call can be quite variable according to differences in motivation or behavioural context. With the Common Raven, for example, it can change from "crok" to "tork-tork", "tork-te-tork-tork" and "glonk". In the extreme, it becomes a kind of high-intensity alarm call, which may be used by a flock when mobbing a bird of prey. For the Blue Jay, Hardy mentioned, in addition to the "jay" sound, a "cleeop-cleeop" which is given with the bobbing display in low-intensity predator intimidation, as well as when challenging conspecifics in territorial skirmishes.

Corvids often have species-specific alert, alarm or mobbing calls. These vocalizations are graded and may be compounded with other calls according to the proximity of the predator or to the immediacy of the danger. Graded systems of alarm calls are

Large-billed Crows *have been found well above 5000 m in Tibet. But in winter, when the continental interior freezes, northern populations move to the milder climate and more plentiful food supplies of estuaries and coasts. In the south of its enormous range, in Malaysia and Bangladesh, it is often a bird of coastal regions, found in mangroves and around fishing ports, where the pickings for such versatile hunters and scavengers are rich. In some towns and cities, Large-billed Crows, like House Crows* (Corvus splendens)*, still play an important role in keeping the streets clean.*

[*Corvus macrorhynchos levaillantii*, Sundarbans, Bangladesh. Photo: Gertrud & Helmut Denzau]

In Seattle, USA, large groups of ***Northwestern Crows*** *have been watched as they fished systematically for Pacific sand lance* (Ammodytes hexapterus) *buried in sandy areas during very low tides. Although a valuable and predictable resource for the crows, these fish are only available during suitable tides, which occur for a few days twice a month. Northwestern Crows also collect clams from the seashore and cache them. They are short-term hoarders, and return within a few days, by which time the clam shells have opened.*

[*Corvus caurinus*, Homer, Alaska, USA. Photo: Charles W. Melton]

especially adaptive in species that live in groups, and they co-ordinate the responses of the flock-members in thwarting predators, as in the case of corvids. Marzluff and R. Balda showed that Pinyon Jays live in flocks which are conglomerates of many families, so that the relatives are in close association, and the jays quickly form a tight flock when attacked by a bird of prey, thus fitting Morton's criteria exactly. In a quantitative study of the variations in the alarm calls of the Florida Scrub-jay, a total of twelve call types or subtypes was recognized. The alert signals of the American Crow vary among individuals, and also in intensity, frequency, duration and the number of notes; the alert call of a ground-feeding individual surprised by a predator is sharp, intense and rapid, whereas that uttered by a crow that catches sight of a hunter approaching at a distance is less sharp, less intense and spaced at greater intervals. In some cases, when the predator is already close to the flock, there is a soft alert sound with almost no frequency modulation, acoustic features that make it more difficult for the predator to pinpoint the location of the caller, as in the studied case of Steller's Jay.

During foraging, soft contact calls, which appear to co-ordinate mates, family-members or group-members, are common. American Crows maintain cohesion in large groups, as, for instance, during roosting and migration, by answering each other with identical or similar contact notes, quite different from the assembly call. They also use a different announcement call to recognize and contact individuals joining a gathering, such as at feeding grounds or roosts. The contact calls of the Neotropical jays of the genus *Cyanolyca* are frequently heard as individuals

Generally arboreal, ***Red-billed Blue Magpies*** *will come to the ground especially to scavenge, where they hop about with the tail raised but drooping towards the tip. Usually found in hill forests, they have also been recorded in mangroves around Hong Kong. They are generally encountered in groups of six or seven. Although generally rather shy, and easily overlooked despite their brilliant plumage and bare parts, they can become bolder around settlements where they are accustomed to scavenge, and are also increasingly at home in wooded parks and large gardens.*

[*Urocissa erythroryncha*, China. Photo: Zhang Ming]

*In winter, some northern populations of **Hooded Crow** move to the coast, where they join others which exploit the abundant resources of the inter-tidal zone all year round. A stranded salmon has proved irresistible to this bird, despite the obvious risk from the aggressive gulls. Hooded Crows can apply intelligence, as well as boldness, when foraging: for example, in Finland, they have been seen pulling in lines left by fisherman in holes in the ice.*

[*Corvus cornix cornix*, Lokka, Finland. Photo: Markus Varesvuo]

move away from each other while proceeding in the same direction in loose flocks at different strata of the forest interior. With the Rook and the Eurasian Jackdaw, both of which breed in colonies, the contact call is the most common vocalization. Individual variation in the Rook's contact call is obvious, and is important in enabling paired adults to co-ordinate the feeding of their nestlings in rookeries (see Breeding). This is the case also for colonial Pinyon Jays. For several non-colonial breeders, however, such as the Red-billed Chough and the Iberian Azure-winged Magpie, the contact call is likewise the most common vocalization heard in the field. The Siberian Jay has a high-pitched contact call of varying strength, and this may be used also as a warning of the presence of predators, both avian and mammalian. It is evident, therefore, that it is difficult to count the number of calls considered to be contact calls in the vocal repertoire of corvids, as some of them have additional functions other than the localization of the caller.

During flock movement or in other situations, adult females are often fed by their mates. At such times, the female vibrates her wings and tail while emitting prolonged chirring calls similar to the juvenile begging call. This call type is heard also during courtship feeding prior to nesting, as well as while the female is incubating eggs or brooding chicks, when her mate presents sticks during nest construction, and when she solicits copulation. Nestlings and fledglings utter begging calls while crouched and shaking their wings to receive food from the adults. The begging calls of the female and those of the juvenile sound quite similar to each other.

*A **Common Raven**, two **Common Magpies** and a **Hooded Crow** wait their turns at a fish being eaten by a White-tailed Sea-eagle* (Haliaeetus albicilla). *The dominance hierarchy at such kills is based on size, so the raven will probably feed next, though a single raven will be unable to prevent the smaller species from picking at the carcass. Ravens cover great distances in search of food, and are usually the first species to discover carrion. Hooded Crows have been found to associate with White-tailed Sea-eagles, perhaps recognizing them as reliable providers of food.*

[*Corvus corax corax*, *Pica pica pica* and *Corvus cornix cornix*, Feldberger Lake, Mecklenburg, Germany. Photo: Bernd Zoller/ www.photolibrary.com]

*One study found the diet of the **Forest Raven** to be 31% carrion, 41% invertebrates, and 28% plant material, but this is likely to vary according to habitat, season, and competition with other corvids. Although it is the only corvid in Tasmania, it also occurs on the adjacent coast of Australia, where it meets both Little* (Corvus mellori) *and Australian Ravens* (C. coronoides). *This mainland population of the Tasmanian Raven is regarded as a relict. The Little Raven manages to co-exist with the sedentary and territorial Australian Raven by adopting a nomadic lifestyle.*

[*Corvus tasmanicus tasmanicus*, Nigretta, Victoria, Australia. Photo: Rob Drummond/ Lochman Transparencies]

Soft contact calls between individuals are difficult to study in the wild. In descriptions of the vocal repertoire, therefore, there is frequently a lack of clarity in the way in which the meaning of these calls is related. In fact, soft calls probably represent a large range of different vocalizations that is currently poorly understood outside captivity. There is some knowledge of the way in which calls vary from those in neutral or "attractive" situations to those in aggressive ones. The American Crow, for example, uses a graded threat call that varies from screams to cackles and to staccato and rattling notes while competing for perches during roosting. At Rook colonies and raven roosts, aggressive calls, including hoots, yells, trills, yacking, snarling and squalling calls, are frequently recorded. S. Hope, studying the form of Steller's Jay calls in relation to their function, found threat calls to be of low frequency and narrow range, as expected from Morton's findings. Similarly, Lorenz recognized in the vocal repertoire of the Eurasian Jackdaw a rattle call, which was associated with a warning of the approach of a predator. Individual Azure Jays in captivity emitted a rattle sound very often when others tried to steal food from their beak. Adult female Pinyon Jays do likewise when a mate sidles up too closely or when another pair attempts to steal nest material. A throaty, almost snorting , explosive "tchurch" is used by captive Common Magpies towards humans, this call being accompanied by an aggressive display and commonly being a prelude to attack. Several corvids perform bill-snapping during aggressive encounters.

In situations of appeasement or low aggressiveness, for example during fluffing or peck-preening displays (see General Habits), Hardy recorded several high-pitched vocalizations by some species in the genera *Cyanocorax* and *Cyanolyca*. Common Magpie females utter a short, soft and very high-pitched "trirr", inaudible beyond 25 m, in response to a mate which is returning, with or without food, to the nest. For the Eurasian Jay, Goodwin described "chirruping notes" in appeasement situations, especially between pair-members; these consist of a series of soft, stammering calls, with much variation in tone and inflection. Pinyon Jays emit a "rick" call, which is short and soft, probably in similar situations of low aggressiveness and between members of a pair. Clearly, the appeasement calls intergrade with calls related more to courtship, increasing the size of the vocal repertoire. Most of the calls uttered during courtship, preening, copulation and other close-contact situations probably serve to strengthen and to maintain the pair-bond.

Although corvids do not sing in the way in which most other passerines do, several species do utter a clear, complex, lengthy, soft subsong, called *sotto voce*, an Italian term related to music and frequently used by W. Brewster to describe such calls. Hardy, studying American jays, reported subsong as consisting of a complex series of different notes, usually toots, whistles, clicks, and metal sounds and others that were unique to individuals, emitted in a sequence with no apparent pattern, even for the same individual. They last for a few seconds to several minutes. Subsong does not have a territorial function, but it is most common during the courtship period. Individuals often deliver subsong alone, even outside the breeding season, in the apparent absence of any stimulus. In the case of magpies, the subsong may be related to stimulation of the female in the days prior to egg-laying. Hardy thought that, with Neotropical jays, subsong was associated with bright irides and constriction of the pupil, but it was recorded also for species having dark irides, such as the Azure Jay and the Curl-crested Jay.

Corvids mimic a variety of sounds, both natural and anthropogenic. The species can be divided into two groups according to their mimicry behaviour. Some imitate sounds mainly, but not only, when kept in captivity, the Common Raven being one such example, while others commonly indulge in mimicry in the wild, the Eurasian Jay being a good example. The Common Raven, the American Crow and the Common Magpie mimic the human voice and whistles if the individuals are sufficiently attached to humans; they also mimic other bird species and even inanimate sounds. Indeed, part of the charisma of the Common Raven is its ability to imitate the human voice, even responding with human words in appropriate situations. Goodwin suggested that mimicry may be most common in captivity because the birds have "spare time" available. Species that are frequent imitators, including the Eurasian Jay, copy many other species in the wild; this jay mimics, among others, the Carrion Crow and the Grey Heron, as well as several other species of passerine. There are several documented records of corvids imitating the calls of birds of prey, this being a characteristic particularly of the Neotropical jays, especially those in the genus *Cyanocorax*. Researchers have tentatively proposed some possible functions of this behaviour. Goodwin suggested that, for the Eurasian Jay, the utterance of a copied sound may be connected with the original emotional state aroused when the sound was first heard. Deceiving others as to the presence of a predator, or an individual's status, have also been mentioned as possible functions of mimicry. The truth is, however, that the full function of mimicry by corvids, as well as by other birds, remains mostly a matter of conjecture.

***Common Ravens** will distract vultures at a carcass by tweaking their feathers, creating an opportunity for themselves or another member of the group to grab some carrion. In the absence of a strong-jawed mammalian predator, both raven and vulture may have to wait a number of days before decomposition softens the hide of an ungulate carcass. Ravens are "shy" of carcasses, exhibiting an obvious fear of approaching them. A study of Eurasian Griffons* (Gyps fulvus)*, on the other hand, found that they seemed to need the presence of ravens at a carcass as evidence of safety, before they too would land to feed.*

[*Corvus corax hispanus*, Campo de San Pedro, Segovia, Spain. Photo: Luis Miguel Ruiz Gordón]

The vocalizations discussed above give an impression of the vocal repertoire commonly utilized by corvids, but this is just a beginning. Playback experiments have repeatedly demonstrated that calls are graded and that they convey multiple types of information simultaneously. For example, Marzluff and Balda analysed the vocal repertoire of Pinyon Jays, in both captive and wild settings, by using observation and playback of recorded calls. The contact calls, the "near" and the "kaw", caused jays to respond with the same call and to move towards the source of the sound. In contrast, the alarm call, the "multiple rack", elicited both mobbing or silent freezing by individuals. Pinyon Jays were able, however, also to recognize the identity of the caller and to temper their response to contact and alarm calls according to the identity of the jay which emitted the call. Strongest responses were given to mates, offspring and flock-members. Lesser responses were given to individuals from other flocks. Alarm calls were also of graded intensity, informing listeners of the motivation of the caller, and this led to different and appropriate responses.

Recent experimental studies of the calling behaviour of Siberian Jays, a group-living species, showed that as many as 14 different calls were used by the birds when mobbing predators. It was found that the different calls provided particular and specific information to others of the group about both the category of predator and, simultaneously, the risk posed by the predator at the time.

Recoveries and reintroductions of grey wolf (Canis lupus) *populations in North America have resulted in increased feeding opportunities for scavengers liked this **Black-billed Magpie**. Instead of waiting for deer and elk to succumb to harsh weather—which often means a long lean period followed by a glut in late winter—scavenging corvids are assured a relatively constant supply of carcasses. Common Ravens* (Corvus corax) *have been observed to associate with wolf packs, following them as they travel, feeding beside them at kills, and even, it has been claimed, leading them to prey.*

[*Pica hudsonia*, Jasper, Canada. Photo: Mark Bradley/ Boreal Nature Photos]

*In addition to its Australian range, the **Torresian Crow** is also found in New Guinea, the northern Moluccas and the eastern Lesser Sundas. Like many other corvids, it has adapted quickly to the scavenging opportunities offered by roadkill. In the Mojave Desert, USA, populations of Common Ravens* (Corvus corax) *have increased so dramatically as a result of the "food subsidy" provided by roadkill that they threaten the survival of the desert tortoise* (Gopherus agassizii). *Highway fencing, to prevent roadkill, has been proposed as a measure to reduce the raven population.*

Food and Feeding

Corvids tend to be omnivorous, taking both animal and vegetable foods. The list of food types that a species consumes can be quite impressive. For example, the Rook eats beetles of several families, including at least Scarabaeidae, Curculionidae, Carabidae and Elateridae, Lepidoptera, flies (Diptera), Orthoptera, bugs (Hemiptera), Hymenoptera, spiders (Araneae), earthworms (Oligochaeta), the eggs of vertebrates, carrion, and cereal grain and other crops, besides several other plants. From watching corvids in the wild, the observer may think that they can live on anything, but this is not the case; omnivorous behaviour has its limits, since the birds cannot utilize larger amounts of non-nutritious vegetable food than most other birds. Nevertheless, it is true that the members of this family are quite opportunistic with regard to food types, as evidenced by the Australian Raven, which opportunistically exploits nectar from flowers, and by several Neotropical species in the genus *Cyanocorax*, which prey on the nests of social wasps (Vespidae) or attend swarms of army ants (Formicidae). Corvids will also attack adults of various other bird species if they have the chance to do so. Among many published reports in the literature, some of the more interesting refer to Common Ravens killing roosting Black-legged Kittiwakes (*Rissa tridactyla*) in Alaska, a White-necked Raven attacking and killing a Superb Starling (*Lamprotornis superbus*), a Florida Scrub-jay attacking, killing and feeding on a Northern Mockingbird (*Mimus polyglottos*), a Western Scrub-jay capturing a Hermit Thrush (*Catharus guttatus*) in flight, a Steller's Jay capturing a Pygmy Nuthatch (*Sitta pygmaea*), and a Blue Jay capturing a Yellow-rumped Warbler (*Dendroica coronata*). Equally impressive was an observation made in January 2009 in southern Myanmar, where several Large-billed Crows were watched as they captured bats (Chiroptera) which emerged from a roost at dusk.

When seeking food opportunistically, corvids sometimes exploit other animals. For example, jays of the genus *Aphelocoma* regularly pick ticks (Ixodoidea) and perhaps other ectoparasites from the skin of mule deer (*Odocoileus hemionus*) and white-tailed deer (*Odocoileus virginianus*). In some regions, there is a strong relationship between the wolf and the Common Raven, to the extent that it could be interpreted as a symbiotic association; evidence exists that ravens will lead predators to food, and then partake of the leftovers from kills. Heinrich mentioned that the ravens are dependent on wolves not only to kill for them and to open carcasses, but also to help them to overcome their innate suspicion of large food items; ravens, when alone, are, for reasons that are unclear, strikingly "shy" of carcasses, exhibiting an obvious fear of approaching them, but they do not show such inhibition when wolves are present. According to Heinrich, the wolves in the northern regions and, farther north, the polar bear (*Ursus maritimus*) are indispensable to the Common Raven's survival. Researchers studying wolves have reported that ravens accompany the mammals on their travels or are attracted to the howls of the wolves.

*Acorns, when they are available, probably form an important part of the diet of northern races of the **Green Jay**. This species forages in forest trees by hopping along the branches, stretching upwards to take an item from the foliage directly overhead, or hanging down to reach the branch immediately below. It rarely consumes food items immediately, but carries them in its bill to a perch, where it holds them in its feet and pecks them apart, swallowing them in small bits.*

[*Cyanocorax yncas luxuosus*, Laguna Atascosa National Wildlife Refuge, Texas, USA.
Photo: Dave Maslowski/ Maslowski Productions]

When prising pine seeds out of cones, nutcrackers either wedge them into a suitable crevice, as this ***Spotted Nutcracker*** *has done, or hold them down with the inner and middle toes of one or both feet. The seeds are then crushed in the bill, using the ridge on the inner side of the lower mandible, or, if particularly hard-shelled, held in the feet and hammered with the bill. The tree species preferred vary regionally, but typically include the local pines, as well as spruce, hazel and cedar. Spotted Nutcrackers are the main dispersers of seeds for several of their favoured trees.*

[*Nucifraga caryocatactes*, Urals, Russia. Photo: Konrad Wothe]

The corvid diet varies locally and seasonally. Seasonal variation is particularly evident for species living in temperate and arctic zones, as they frequently specialize in one food type in certain periods, so that an annual feeding cycle may be identified. The Siberian Jay, which lives in the boreal taiga, feeds mainly on insects in early spring, on berries and insects during the summer and autumn, and on seeds of conifers during the winter, having stored these seeds a few months previously, in the autumn. The Carrion Crow consumes a higher proportion of plant material, especially cereal and root crops, in autumn and winter and takes more animal prey, chiefly invertebrates, eggs, nestlings and other small vertebrates, in spring and summer; in areas with little arable agriculture in winter, its diet shows an increase in small mammals, carrion and discarded food scraps. In studies of the Eurasian Jackdaw, ants were the most important part of the animal component of the diet in three different areas of southern Spain, but were barely recorded as a food item elsewhere. For the Common Magpie, grain and fruits are important during the autumn and winter and invertebrates during the spring and summer, but various studies indicate that the proportions of specific items taken by this widespread Northern Hemisphere species differ according to region. In the Neotropics, the Azure Jay feeds mainly on the seeds of the conifer *Araucaria angustifolia* during autumn and winter, on insects during the spring, and on arthropods and fruits in summer. Even with species living in more constant and warmer climates, however, it is possible to recognize variations in the diet during the year; a detailed study in Costa Rica revealed that the White-throated Magpie-jay ate a larger proportion of caterpillars during the wet season but a greater proportion of fruits during the dry season.

Living in a large variety of habitats, corvids obtain food from varied micro-habitats or substrates. Some preferences or clear tendencies may exist, however, as in the case of the choughs in the Alps of southern Europe, which obtain their food only on the ground, or some jays of the genus *Cyanolyca* in the forests of the Andes, which forage only in the forest canopy and subcanopy. The Common Magpie forages on the ground in grasslands, but it prefers humid areas where the soil invertebrates are more abundant and occur near the surface. The Eurasian Jay forages mostly in trees during the breeding season, but outside that period it feeds mostly on the ground. During foraging, species have to face a constant conflict between gaining benefits and the risk of predation. It has been demonstrated that the local foraging choice made by the Siberian Jay is strongly influenced by the degree of predation risk.

Corvids also explore, opportunistically, more specific types of terrain. Several members of the genus *Corvus*, for example, commonly seek food on the seashore at low water. In the USA, large groups of Northwestern Crows were watched as they fished systematically for Pacific sand lances (*Ammodytes hexapterus*) buried in sandy areas during very low tides in north Seattle. Similar behaviour by Carrion Crows is a common sight in parts of northern Europe. Cultivated areas, gardens and parks are particularly attractive to certain corvids as foraging sites.

Steller's Jay *harvests the large seeds of pinyon and whitebark pine* (Pinus albicaulis)*, which it carries up to 3 km before caching them for later consumption. This species has no particular morphological adaptations for carrying food in this way, although it manages to cram up to 18 seeds into its bill at once. Jays in the genera* Cyanocitta *and* Gymnorhinus *have an extendable oesophagus to enable them to transport larger quantities of seeds.*

[*Cyanocitta stelleri stelleri*, Metchosin, British Columbia, Canada. Photo: Jukka Jantunen/ VIREO]

The problem with caching food is that it may be discovered and exploited by other birds. This ***Mexican Jay*** *has discovered the "granary tree" of a family of Acorn Woodpeckers* (Melanerpes formicivorus), *although it may struggle to remove the tightly-wedged acorns from the holes individually drilled by the woodpeckers. Mexican Jays themselves cache thousands of pine seeds and acorns every autumn, in hundreds of locations, carrying up to five seeds as a time in their bills. Because newly made caches can be robbed, corvids are reluctant to hide food if conspecifics or other species are watching them, and seldom hide large amounts of food in the same place. Remembering and recovering food from hundreds of different locations requires an extraordinary spatial memory. Development of this capacity may be a primary reason for the large brain and high intelligence of corvids. The* ***Eurasian Jay*** *is another prolific hoarder of acorns. Throughout autumn and into winter it caches up to 3000 acorns a month, burying them individually in leaf litter or beneath clumps of brambles or ferns. By the following summer, many overlooked acorns will have germinated. Eurasian Jays have learned to recognize oak seedlings, and will pull them up to get at the remains of the acorn.*

[Above: *Aphelocoma ultramarina arizonae*, Cave Creek Canyon, Arizona, USA. Dave Maslowski/ Maslowski Productions.

Below: *Garrulus glandarius glandarius*, Scandinavia. Photo: Uno Berggren/ Ardea]

*The feeding habits of the **Sichuan Jay** have been little studied. This bird may be collecting berries to cache them, although such behaviour does not appear to have been recorded in this species. The congeneric Grey Jay* (Perisoreus canadensis)*, is a prodigious hoarder of excess food, and in Alaska, a single bird may make more than 1000 caches in a single summer day, and a total of 100,000 during summer and autumn. The Sichuan Jay probably has the enlarged salivary glands which are used by the other two species in this genus to coat and stick hoarded food to the bark of trees.*

[*Perisoreus internigrans*, Sichuan, China. Photo: John & Jemi Holmes]

Although the members of this family are not specialists in their food-capturing strategies, some do at times utilize a specific technique such as flycatching or "fishing", as when they pick up floating food from the sea or an inland water. Along the river Rhine in Germany, for instance, the Carrion Crow is frequently seen to pick floating food from the water's surface. When seeking food, they may inspect any substrate in the search for nutritious material: they dig in loose soil, using a typical side-to-side flicking of the bill; they tear off loose bark; they tear apart leaves that are stuck together; and they use the technique of open-billed probing in cavities (see Morphological Aspects). This last method involves the inserting of the closed bill into a hole, crevice or rolled-up leaf and then attempting to open the bill. H. Álvarez mentioned that small corvids probably employ a greater variety of techniques for reaching food items than do larger ones, and he described the foraging strategy of a tropical species, the Green Jay. The Green Jay forages in forest trees by hopping along the branches, stretching upwards to take an item from the foliage directly overhead, or hanging down to reach the branch immediately below; it also sallies in pursuit of fleeing insects, and hovers to take food from the tips of small shrubs and ferns of the understorey. When exploring the foliage at the tips of slender branches, this jay often hangs upside-down in the manner of a parid tit or chickadee.

For sympatric species, co-existence may be possible as a result of different foraging strategies and diet, as described by Rolando and collaborators in a detailed study of the two choughs. It was found that the Yellow-billed Chough fed mainly at the ground surface, stayed at a feeding site for a relatively short time, on average 2·1 minutes, and fed quickly, taking an average of 9·2 items per minute; in contrast, the Red-billed Chough was almost exclusively an undersurface feeder, digging and probing, it stayed at a site for twice as long, 5·4 minutes, and it fed much more slowly, taking 2·2 items per minute. Having different foraging strategies, the two species of chough clearly exploited different food items, such as, for example, the particular animal matter taken during the year. In June, the Yellow-billed Choughs collected mostly cranefly larvae (Tipulidae), whereas Red-billed Choughs fed mainly on Lepidoptera larvae; from July onwards, Yellow-billed Choughs consumed mainly grasshoppers (Acrididae), while Red-billed Choughs also collected cranefly pupae, the larvae of Lepidoptera and of bibionid flies, and beetles of the families Scarabaeidae and Staphylinidae. In the Granada region of Spain, differences were detected in the food preferences of three corvid species: arthropods comprised the most important animal groups in Carrion Crow and Common Magpie diets, whereas carrion was the most important item for the Common Raven. The sympatric Azure Jay and Plush-crested Jay differ in terms of their preferred foraging strata in the forests of southern Brazil. Field observations suggest that the former prefers the canopy, which accounted for 78% of observations of foraging, and is almost never seen on the ground, while the latter is found more frequently in the middle level and the understorey, where 57% of foraging occurred, and on the ground, where 15% of foraging was done.

Several corvids are known to use inanimate objects as tools with which to reach an immediate target, in particular during feeding, something that should not be surprising in view of the large brain and considerable cognitive abilities possessed by the Corvidae (see General Habits). A Green Jay was watched as it picked up a small twig in its beak and flew to a branch of a dead tree, where it inserted the twig under a piece of bark and moved it back and forth several times; it then withdrew the twig, placing it under its feet, and proceeded to consume an insect that was attached to the twig. Even more impressively, an American Crow was seen to modify a piece of wood and then use it as a probe. The crow took a triangular piece of wood and placed it under its feet, with the wide end closest to its body, and hammered several times at the tapered end; it then picked up the piece of wood by the wide end and probed a hole, where supposedly a spider lurked, with the pointed end. In a different situation, a Fan-tailed Raven was observed to use stones in an attempt to break open an egg.

The most famous tool-using corvid, however, is the New Caledonian Crow. This species uses tools to extract the larvae of an endemic cerambycid beetle from dead wood, the technique seemingly an important part of the foraging behaviour of this crow throughout the year. Two different types of tool have been reported: a hooked-twig tool, made from a live secondary twig, has a hook-shaped wide end, and a stepped-cut tool, made by cutting out along the edges of a *Pandanus* leaf, has a jagged edge. The crow moves both tool types rapidly back and forth in order to obtain prey from the bases of leaves and holes. Tool-

In parts of its large range in central South America, the ***Purplish Jay*** *lives all year round in dry forest and scrub with little available water, so moisture-containing foods like fruit (papaya here) are important to its survival. A study in dry forest in Mato Grosso do Sul, Brazil, looked at the use made by birds of the fig* Ficus calyptroceras*, which bears abundant fruit in all months of the year. The Purplish Jay was one of the species found to increase its consumption of these figs greatly during the dry season, when other fleshy fruits and foods were unavailable.*

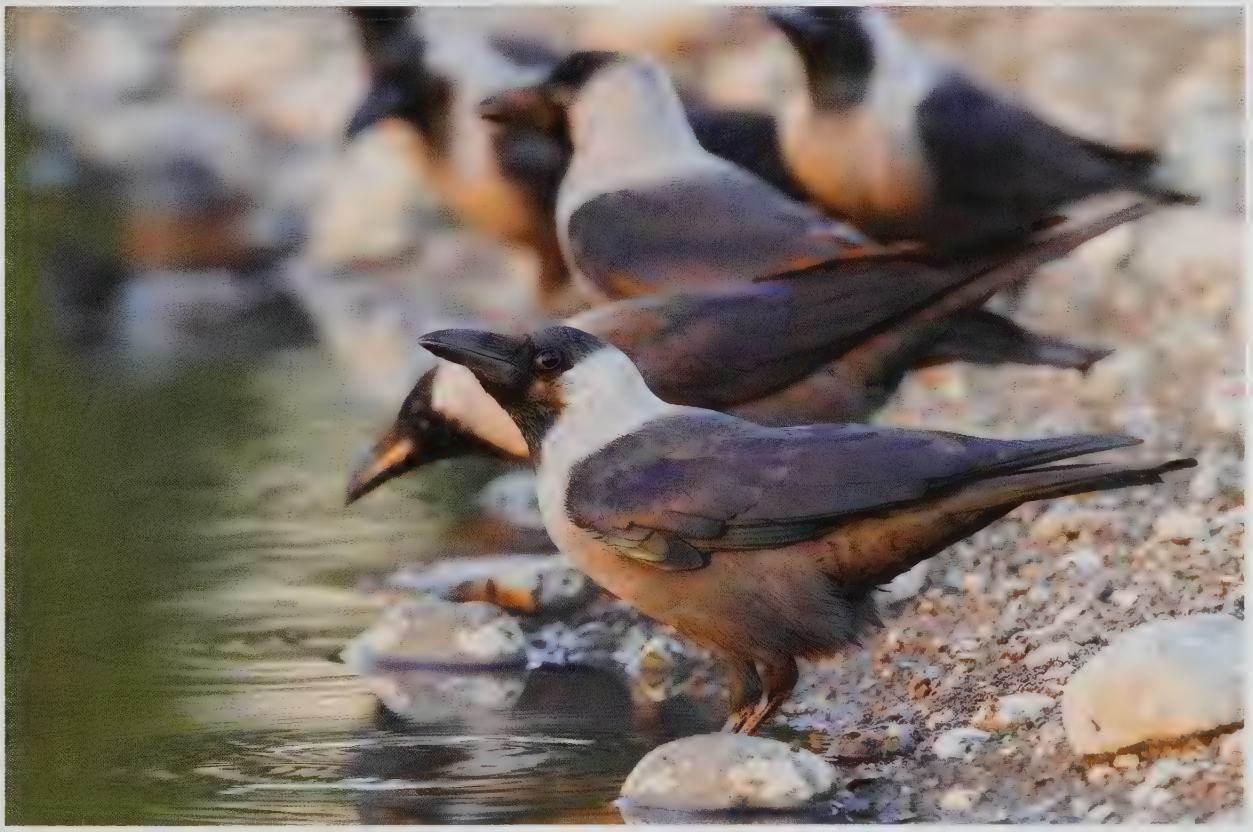
[*Cyanocorax cyanomelas*, Caiman Ecological Refuge, Pantanal, Brazil. Photo: Mark Jones/Roving Tortoise Photos]

making by New Caledonian Crows has three features: a high degree of standardization, distinctly discrete tool types with definite imposition of form in tool-shaping, and the use of hooks. Recent laboratory experiments with one individual showed that this species did not mechanically apply previously learnt movements to new situations, but, instead, sought a new solution to each problem presented.

Tools may be used by corvids for purposes other than that of obtaining food. Encounters among different species near a common food source, such as a feeding platform, often produce aggression. There is an amazing reported case in which corvids used a stick in a weapon-like way during an aggressive interaction. After repeatedly failing in its attempts to drive an American Crow from a feeding platform by scolding, approaching and diving at it, a Steller's Jay flew into a nearby bush, where it worked vigorously to break off part of a small branch. Having broken off the twig, the jay, holding the stick in its bill, approached the crow and thrust the pointed stick at it. The crow lunged at the jay, which then dropped the stick, whereupon the crow picked it up and flew after the jay.

Confined to the Tumbesian ecoregion, the semi-arid Pacific slopes and lowlands of south-west Ecuador and north-west Peru, the ***White-tailed Jay*** *is associated particularly with mesquite woodland and shrubby cactus steppe. Examinations of its stomach contents have revealed its diet to consist of beetles, ants and other insects and seeds, supplemented by birds' eggs. The bird in the picture appears to be eating the flesh, rather than the seeds, of this prickly pear* (Opuntia). *The fleshy fruit is perhaps a source of moisture in an area which relies on the El Niño Southern Oscillation for its rare and irregular rainfall.*

[*Cyanocorax mystacalis*, Chaparri Ecological Reserve, Peru. Photo: Heinz Plenge]



When dealing with food that needs to be opened, such as conifer seeds, the corvid holds down the item under the inner and middle toes of one or both feet and uses its bill to tear, bite or hammer it. Nutcrackers are the most specialized corvids in opening conifer seeds. Clark's Nutcracker employs two methods of hulling, or dehusking, to open pinyon pine seeds. One method is that of crushing, whereby the bird squeezes and cracks the seed husk and separates it from the endosperm while holding the seed in the bill; the other involves pounding, when it holds a seed between the feet and perch and pounds it forcefully with the bill until the husk cracks. It is reported that seeds that were pounded were significantly wider and had a thicker husk than those crushed. Clark's Nutcracker, a species highly skilled in handling pine seeds, assesses the most appropriate hulling method by testing the seed in its bill; hulling seeds by pounding them usually took 2·5 times longer than the time taken to dehusk them by crushing. Pinyon Jays, which have a relatively narrow bill, do not open the thick-coated pine seeds by the crushing technique, but only by pounding them. It has been stated that the crushing technique could allow birds to remain attentive to their surroundings, which is important for a non-social species such as Clark's Nutcracker; for the social jays such as the Pinyon Jay, with a well-developed sentinel behaviour (see General Habits), crushing is not of such great importance. Sympatric species, but less specialized in exploiting the pinyon pine, Steller's Jay and the Western Scrub-jay do not have a sharp and pointed bill, and consequently, unlike Clark's Nutcracker and the Pinyon Jay, they cannot open the closed cones in which the seeds are set; they obtain the seeds only from previously opened cones or by kleptoparasitizing nutcrackers.

*The **Grey Jay** becomes bold and tame in regular proximity to humans. It will visit bird tables, steal pet food, haunt picnic and camp sites and will even, as shown here, take food from the hand. The long-standing association between many corvid species and humans is partly the result of their ability to accustom themselves to novel, processed foodstuffs, beginning with bread, and extending to modern innovations such as breakfast cereal. The Grey Jay's opportunism was a source of frustration to early trappers, who found that the birds learned to follow them and steal the bait from their traps.*

[*Perisoreus canadensis canadensis*, Ontario, Canada. Photo: Adrian & Jane Binns/VIREO]

Food-storing is a very common aspect of behaviour among corvids, and occurs when an individual has more food available that it is able to consume at the time. It makes use of the store during periods of food scarcity, thereby gaining a fitness advantage. The ability of seeds to remain dormant makes them particularly suitable for storing, but any item can be stored, especially if it is of a kind that will remain edible for some time. Typical crows in the genus *Corvus*, and possibly *Pica* magpies, do not depend on stored food for their survival during the harsher months of the year. Whereas long-term hoarders, such as some species of jay and nutcracker, are dependent on stores because of the seasonal fluctuations in their food abundance, short-term hoarders, for instance several crows and magpies, use food caches to counter fluctuations caused by variable weather or fluctuations in prey availability in the course of the day. Seeds of conifers are an example of food items stored by a long-term hoarder such as the Eurasian Jay, while clams (Mollusca), which are protected by their shells and remain closed for up to two days, are an example of food stored by a short-term hoarder, the Northwestern Crow. In a study investigating the ancestral state of caching behaviour by corvids, it was found that the ancestor was probably a moderate

*Most corvids need to drink regularly, and so provision of artificial water sources in arid areas can help them to extend their ranges. The spread of the **House Crow** into the Middle East has been greatly assisted by the development of irrigated agriculture, and also, in Israel, by the construction of fishponds. In urban areas these aggressively adaptable birds can also be found drinking from garden ponds and even swimming pools.*

[*Corvus splendens*, Oman. Photo: Daniele Occhiato]

Species that spend the winter in snowy climates, such as choughs (Pyrrhocorax) *and* ***Blue Jays****, can satisfy their water requirements when the usual sources are frozen by eating snow. Clark's Nutcracker* (Nucifraga columbiana) *makes a different use of snow, burying its caches of pine seeds in places which lose their snow cover at different times in the spring. This provides it with a steady supply of food which is hidden from competitors such as other jays and rodents until the bird is ready to use it. Its nestlings are raised almost exclusively on pine seeds from these surviving caches.*

[*Cyanocitta cristata bromia*, Quebec, Canada. Photo: Daniel Houx]

cacher. In addition, it was suggested in that study that differences in the degree of adaptation to food-caching are due to a bi-directional evolutionary trajectory in this behaviour.

The storing of conifer seeds during the autumn seems crucial to the winter survival of long-term hoarders, such as the Pinyon Jay and Clark's Nutcracker in the temperate zone and the Siberian Jay in the boreal zone. Unfortunately, there are few quantitative data to show that the stored food really is crucial for the survival of these species during periods of food scarcity. The only evidence is of an indirect nature; for the Pinyon Jay, for example, cached pine seeds make up to 70–90% of the winter diet.

Seeds are often stored in or on the ground, the bird raking or pulling over adjacent soil or vegetation with sideways movements of the bill, concealing the food from sight. It may also place one or more stones, leaves or other objects on top of the stored food, probably in an attempt to camouflage the store. Corvids tend to be reluctant to hide food if conspecifics and/or other species are watching them because newly made caches are more likely to be robbed. In fact, they tend to be fairly secretive when hoarding food, presumably to avoid the attentions of competitors. Clark's Nutcracker uses a number of different cache sites that become free of snow at different times in the spring; this behaviour, supposedly, is designed to protect the stores from competitors such as, for example, rodents, which cannot reach caches buried under deep snow. The Grey Jay uses its own sticky saliva in forming food balls, which it then sticks to various parts of trees; the food becomes securely fixed in position, and requires forceful extraction, a feat beyond the capability of a small pilferer. Corvids

In courtship displays, the male ***Pied Crow*** *struts around the female with the plumage of the nape and throat fluffed out, and the bill lowered. Corvid courtship may also include bowing, accompanied by rattling calls. The female responds with a submissive display, crouching and quivering her wings, a typical invitation to coition among passerines. Among the Corvidae, these displays have been most extensively studied in the Eurasian Jay* (Garrulus glandarius).

[*Corvus albus*, Simien Mountains National Park, Ethiopia. Photo: Elio Della Ferrera/ naturepl.com]

The rolling and tumbling aerial displays of ***Common Ravens*** *have a number of functions, some related to territorial defence and courtship. The elements of the display—including a roll with closed wings directly over the territory—probably convey information to the partner, as well as reinforcing the pair-bond. A pair will also fly in loops over their territory, their turns and wingbeats perfectly synchronized. Sometimes, particularly in snow, the birds tumble to the ground, where they continue to roll and sprawl, their claws extended to one another.*

[*Corvus corax hispanus*, Salamanca, Spain. Photo: Alejandro Torés]

very seldom hide a large number of food items in exactly the same place, but flocks of specialized species use caching sites inside their home range.

In a detailed study in northern Arizona, Marzluff and Balda reported that the Pinyon Jay's activity for 2–3 months in the autumn consists largely of the harvesting of pinyon pine seeds and transporting them to a caching area, which is about 4 ha in size. Flocks can fly up to 7 km to reach the caching area. In each trip, each Pinyon Jay can carry about 38 seeds in its extendable oesophagus. The capacity to carry seeds seems to be proportional to the distance over which a species transports food. Clark's Nutcracker has a special morphological structure known as the sublingual pouch (see Morphological Aspects), which can hold 90 pinyon pine seeds, and this species, being a stronger flier than the Pinyon Jay, may carry the seeds up to 22 km. Steller's Jay, which does not possess any special morphological feature for seed-carrying, transports as many as 18 pine seeds on each flight, which may cover a distance of up to 3 km.

Stored food has to be recovered after a certain period of time. Several corvids have been shown to possess an extraordinary power of spatial memory with regard to the retrieval of cached food; they may hide food in hundreds or thousands of sites for periods of days or months, and then relocate a large proportion of these. Some of the species have been found to have an efficiency rate of 60–90% in recovering stored conifer seeds in excavations made through the snow. In aviary experiments, Pinyon Jays arranged their caches spatially in clumps, which proved to be more efficient for successful retrieval than was the case when the seeds were widely dispersed. In another, similar experiment, however, Clark's Nutcrackers did not clump their caches in this way but, instead, spaced them out, which suggests a more highly developed spatial memory; apparently, the nutcracker remembers the exact place where it stored each seed. This exceptionally well-developed power of spatial memory of food-hoarding species is related to the fact that the hippocampus in the brain is larger than that of non-hoarding birds. Indeed, not only is a larger hippocampus related to the spatial memory but so, too, is a variety of associated brain regions and synaptic connections. The simultaneous evolution of these neural substrates and the behaviour of food-hoarding may result in an increase in size of the entire brain.

Relocation of food by means of olfaction seems unlikely for a bird storing seeds, but data on Northwestern Crows suggest that olfactory cues may help in this process. In the case of both the Rook and the Carrion Crow, the recovery patterns for stored acorns suggest a memory only for the general area of hoarding. These two species were seen to search for caches particularly on cold days in late winter, when the calorific value of recovered acorns exceeded that of other available food, but their efficiency in recovering stored seeds seems less than that of other species, recovery apparently occurring by chance.

In any case, a proportion of seeds hidden in the ground is never recovered, which means that corvids are potential dispersers of seeds. Studies on corvids as seed-dispersers are quite detailed with regard to the relationship between Clark's Nutcracker and various species of pine, between the Pinyon Jay and the common pinyon (*Pinus edulis*), between the Blue Jay and the pin oak (*Quercus palustris*), and between the Eurasian Jay and species in the beech family (Fagaceae). Several authors have suggested that the northward spread of certain tree species after the last glaciation might be due to seed-hoarding corvids. For example, such behaviour by the Blue Jay could help to explain how *Quercus* spread northwards; it is believed that morphological adaptations of the trees facilitate efficient exploitation by birds that act as seed-dispersers. In laboratory experiments in which nuts and acorns of five North American tree species were used, it was suggested that Blue Jays, although showing a preference for small seeds not having a hard outer covering, may exploit a wider variety of seeds according to availability, thereby contributing to the dispersal of all species of the Fagaceae.

In the laboratory, the Blue Jay and the Western Scrub-jay were unable to subsist solely on acorns. This was attributed to the relatively high concentration in acorns of secondary compounds known as tannins, which inhibit protein digestion. It seems, therefore, that jays do not possess physiological adaptations for countering the protein-binding properties of the tannins. It is suggested that, in nature, it is quite important that the jays consume high-protein foods in conjunction with acorns; without sufficient mixing of high-protein foods with the consumption of tannin, dietary protein from acorns and perhaps the digestive enzymes in the bird may be effectively bound, resulting in the near-total negation of nutritional benefit. This mutualistic interaction between corvids and plants, whereby changes in the parties involved act reciprocally as selection pressures on one another and lead to increased fitness for both, has been interpreted as co-evolution.

*This male **White-necked Raven** is feeding the female as part of a courtship ritual. Later he will regularly provision his mate on the nest. During courtship feeding, the female begs by vibrating her wings and tail, while giving prolonged chirring calls similar to the juvenile begging call. In corvids, the male responds by placing the food into her mouth. In some other families, such as finches (Fringillidae), the male regurgitates the food into the female's mouth. Male Herring Gulls* (Larus argentatus) *present the female with the food offering by regurgitating it onto the ground in front of her.*

[*Corvus albicollis*, Virunga National Park, Democratic Republic of Congo.
Photo: Konrad Wothe]

Clark's Nutcracker and the whitebark pine have shared a strong mutualist co-evolutionary history, which has shaped the morphology and mental capacity of the bird and determined the distribution and genetic structure of the pine. As mentioned previously (see Systematics), an ancestor of Clark's Nutcracker crossed the Bering land-bridge from Siberia probably after the ancestor of the New World jays of such genera as *Cyanolyca*, *Cyanocorax*, *Calocitta*, *Psilorhinus*, *Cyanocitta*, *Gymnorhinus* and *Aphelocoma*. This scenario is consistent with the lack of subspecific differentiation in Clark's Nutcracker and genetic evidence that the whitebark pine also crossed into North America recently; the strong co-evolutionary history of the jay and the pine genus *Pinus* facilitated the dispersal of the latter in North America. The earlier colonization of North America by the New World jays, which also contributed strongly to the dispersal of other species of *Pinus*, should have benefited the nutcracker by creating an increased area of available food. Some Neotropical jay and magpies species, namely those in the respective genera *Cyanocorax* and *Calocitta*, are known to hide food on the ground or in the branches of trees, but they do not rely on this stored food in the wild, since the availability of food resources in their environments is much more constant through the year. It is hypothesized that such behaviour could be a relict from their ancestors.

*This **Unicoloured Jay** is collecting rootlets to line its nest. The main bowl of the nest is built from short, relatively thick twigs, commonly oak* (Quercus) *twigs, 2–5 mm in diameter and some 35 mm long. The nest is placed in an oak, pine or madrona* (Arbutus) *tree, either in the crown or where a major limb meets the trunk, at a height of 5·5–13·5 m. Unicoloured Jays live in territorial groups including a female breeder, a primary male, and a number of less dominant males and females. This species is unusual in that the "secondary" birds join the primary ones in nest-building.*

[*Aphelocoma unicolor unicolor*, Guatemala.
Photo: Samuel Hansson]

Pica *magpies are relatively unusual among the Corvidae in building domed nests. These bulky structures consist of a loose outer shell of hefty, often thorny twigs, surrounding a nest bowl made of mud or dung and lined with grass, rootlets, animal hair and feathers. The Black-billed Magpie* (P. hudsonia) *was until very recently treated as a race of the* ***Common Magpie****, but the two forms differ in nest spacing and territoriality. Common Magpies defend territories of about 5 ha, with nests regularly spaced. Black-billed Magpies either exhibit no territorial defence, or defend an area of about 0·3 ha around their nests.*

[*Pica pica pica*, Rhineland-Palatinate, Germany. Photo: Mathias Schäf]

Food-storing behaviour favours sedentary and territorial habits, since the individual should retrieve the stored food. It therefore has implications for the social organization of the species doing the caching. Residency in the breeding area during the winter may confer a reproductive advantage, and food-storing may enable birds to survive the winter in areas in which they would otherwise have succumbed. Nevertheless, there are records of migration by corvids that store food during the winter, such as the Blue Jay and the Spotted Nutcracker; it has been suggested that these corvids retrieve the stored food when they return in spring. The Pinyon Jay is resident when storable food is plentiful, but it migrates when the food crop fails.

The availability of pinyon seeds accelerated gonadal growth in the Pinyon Jay and thus, together with photoperiod, acted as a proximal timer for breeding. Stored food enables Clark's Nutcracker and the Pinyon Jay to begin breeding in winter conditions, earlier than other corvid species such as the Western Scrub-jay and Steller's Jay, which are dependent on animal food for the rearing of a brood. The advantages of early breeding are that there are fewer parasites in the nest during winter, that more time is available for the young to gain weight and develop feeding skills, and that early-fledged young become dominant over late-fledged ones; but early breeding seems also to be a necessity for the hoarding species, since adults must be free from parental du-

Iberian Azure-winged Magpies *are social breeders, their nests forming loose colonies, but rarely with more than one nest in a single tree. The female does most of the nest-building, although the male brings material to the site, and "helpers", presumed to be young from the previous year, often participate. The nest-site is 3–7 m above the ground in a fork in an outer branch, as far as possible from the main trunk. Asian Azure-winged Magpie* (Cyanopica cyanus) *nests, by contrast, are frequently domed, and often placed in tree hollows. They are rarely more than 2 m up, and sometimes actually built on the ground.*

[*Cyanopica cooki*, Portugal. Photo: M. D. England/ Ardea]

The blue magpies include both social breeders like the Taiwan Blue Magpie (Urocissa caerulea)*, and others, like the* ***Sri Lanka Blue Magpie****, which are assumed to be solitary breeders. Information on the breeding of the Sri Lanka Blue Magpie is scant, but like others in its genus, it probably involves helpers, presumably non-breeding young from the previous year. The photographers describe this picture as showing three adults tending recently hatched chicks. Co-operative breeding, which can take many forms, is largely confined to corvids with a southerly distribution. The ancestors of the Corvidae are thought to have been co-operative breeders.*

ties to begin storing food, and juveniles must be able to make their own stores. Food stored before the reproductive season either is used during the breeding period by the parents themselves or is fed to the nestlings. Nestlings are dependent on stored food to different extents. For example, nestlings of Clark's Nutcrackers are raised almost exclusively on pine seeds from the parents' caches, whereas only 9% of the nestling food of Pinyon Jays consists of conifer seeds, and Eurasian Jay nestlings are fed with hoarded acorns either occasionally or not at all. It is thought that stored food represents a positive benefit for reproduction; in studies of the Northwestern Crow, there was a drastic reduction in the female's nest attendance when the cached food was removed, and this may lead to lower breeding success.

Breeding

There are some reasonably long-term studies of the breeding behaviour of several species of corvid, and these have revealed great variation in social organization within the family, sometimes with strong variations within a single genus, or even within the same species in different regions. Such a wide variety of breeding sys-

The ***Australian Raven*** *is a solitary and non-co-operative breeder, on a continent with more than its share of co-operatively breeding bird families related to the Corvidae. Its nest, a large bowl of sticks lined with fibrous bark, animal hair and wool, is placed at the top of the highest tree or artificial structure (telegraph pole, windmill or pylon) in its territory. In the absence of even a large shrub, it may build on the ground, usually leaning its nest against an object such as a fence post.*

[*Corvus coronoides coronoides*,

tems is frequently explained as being an influence of habitat, although recent studies seem not to corroborate this for some species. In fact, studies of the breeding systems of corvids have become quite detailed, and this has been important in the development of theories on the evolution of altruism and co-operative breeding by birds, and an additional stimulus for researchers since the 1970s. On the other hand, knowledge of the reproductive behaviour of some tropical corvid species is based mainly on sporadic reports.

Corvids tend to be monogamous, with a strong pair-bond usually sustained during the year, and frequently during the life of the individuals concerned. For the Florida Scrub-jay the "divorce" rate is only about 5%, and the bond is broken primarily when one partner becomes temporarily or permanently incapacitated and is replaced. It has been demonstrated that long periods of fidelity lead to increased breeding success. The Mexican Jay, in its extremely complex breeding system, exhibits variations from monogamy, the system used in most situations, to polygynandry, with multiple breeding males and breeding females in one social group.

A detailed study of a Pinyon Jay population revealed some pairing patterns. Within the pair, partners were of the same age but were not necessarily comparable in terms of bill length and body weight. Assortative pairing for age may be favoured because similar-aged partners produced slightly more young than dissimilar-aged ones, and their young survived for longer than those from dissimilar-aged pairings. It is possible that similarity in age may promote increased fecundity by ensuring that the partners are compatible. Pairs consisting of a heavy female and a light male lived for longer and were more successful in producing offspring compared with partners of other size categories. This may have been due to the fact that small males did not completely dominate large females, so that aggressive encounters were less frequent.

The social organization of corvids includes defence of an all-purpose territory by a pair or by a flock. In the latter case co-operative breeding may occur, an area then being defended by a flock, usually a familial flock, in which non-breeding helpers are present. Helpers may assist in nest-building, in feeding the incubating female, and in caring for the young. Habitat use and the concept of ecological constraints have played a major role in the development of theories concerning the evolution and maintenance of co-operative breeding by birds. In the Corvidae, co-operative breeding is strongly correlated to latitude, and its predominance in species with a southerly distribution indicates a secondary evolution of co-operative breeding in the lineage leading away from the basal corvids. Some species of corvid are colonial breeders, pairs placing their nests very close to one another, sometimes in one large tree, and even with several nests on the same branch; the territory is then no more than a tiny area around the nest. Variations of those three basic systems may exist, however, with gradients, for example, between territorial and colonial.

The American jays, in particular, exhibit an impressive variety of social organization, with different levels of sociality. Brown proposed that the origin of sociality in jays is the delayed dispersal in the all-purpose territory. According to Brown, Steller's Jay would represent a first step towards the colonial system. This species maintains an area of dominance around the nest which is not a territory as strictly defined, but which results from aggressive competition; home ranges overlap significantly, individuals extending their foraging range far into the home range of others. This system provides some advantages of flocking, such as the finding of temporary rich food resources and the detecting of predators, without the susceptibility to predation that is typical of clumped nests. Steller's Jay is not colonial, as its nests are spaced by means of the area of dominance, but the circumstances favour the development of coloniality. The Blue Jay presents the same system as Steller's Jay, but its home ranges seem to overlap less. For both of these jays, a dominance rank and good reproductive success may be expected; this is achieved by means of the complete suppression of breeding by subordinates in the home range.

Among the American jays, there is probably only one species, the Pinyon Jay, that is truly colonial. Nests of this jay are clumped, a defended individual distance being apparently non-existent, so there is no defence against other colony-members. In the colonial system of the Pinyon Jay, there are no helpers at the nest for the first two weeks after hatching, but a few adults, although no first-year birds, may sometimes contribute helping activities during the last four or five days of the nestling period; after the young have fledged, helping activities increase. During the autumn, Pinyon Jays are highly gregarious. The long-term study of the Pinyon Jay carried out in Flagstaff, in Arizona, by Marzluff and Balda showed that the rather large autumn flocks, containing an average of 190 individuals, consist of many

Eurasian Jackdaws *are frequently seen taking hair from live animals to line their nests. Sometimes several birds will perch on the same horse (as here), sheep or deer. The mammals, perhaps used to having ticks removed by corvids, appear remarkably tolerant of the often vigorous tugging. Males will continue to bring this and other nest materials after the female has begun to incubate. Jackdaw nests are very variable in size and structure, depending on the nest cavity. In a deep hole, such as a chimney, sticks will be thrown in until enough of them lodge to form a firm foundation.*

[*Corvus monedula monedula*, Scandinavia. Photo: Uno Berggren/ Ardea]

***Rooks** are highly gregarious and colonial, nesting close together in the tops of tall trees, often with numerous nests in the same tree. Each pair defends a very small territory around the nest. Theft of twigs is common, some pairs obtaining up to 30% of their nest material from their temporarily absent neighbours. Although essentially monogamous, at least some male Rooks are promiscuous, and younger females in particular have been found to mate with one or more of them in addition to their partners.*

[*Corvus frugilegus frugilegus*, Germany. Photo: Günter Ziesler]

small clans of related jays; clans are extended families consisting of two or three generations of parents. New genes are brought to the flocks through the immigration of individuals; in a studied flock in Arizona, 36% of individuals were immigrants. In a colonial system such as this, the feeding area is shared with many other individuals; the population expansion occurs mainly through colony growth.

The Florida Scrub-jay is an example of co-operative breeding in which pairs retain ownership and sole breeding privileges in one territory year after year. Detailed findings are available for this species from a long-term study, carried out over several decades by Woolfenden and Fitzpatrick in central Florida, based on hundreds of ringed individuals of a population living in the Archbold Biological Station. Nearly all yearlings remain as helpers in their natal territories; a pair may have up to six helpers, but half of the breeding pairs had no helpers at all. Helpers assist the breeding pair in all territorial and breeding activities except those of nest construction, egg-laying and incubation. The Florida Scrub-jay occupies only the botanically distinct Florida oak scrub, a rare and scattered habitat. All available habitat of this type is constantly occupied by this species, various measures having shown the habitat to be densely crowded with breeding birds. Mature, non-breeding individuals are present in many territories, so that every new breeding space is immediately filled. Working together, members of a pair defend a relatively small territory, of 9 ha on average, throughout the year. With a surplus of jays always competing for breeding space, in a habitat in which physical territorial defence is relatively easy, the benefit-to-cost ratio of strong territorial defence clearly favours its existence among breeding Florida Scrub-jays. A pair without helpers, defending only enough space in which to survive and reproduce, cannot win in competition with pairs that defend sufficient extra land to provide a core for the future generations' territories, particularly when some birds are able to expand their territories through the additional efforts of helpers. In such a system, parents provide for their offspring, including ones yet unborn, by defending a greater area than they themselves need. Offspring improve their own fitness by adding to the landholdings, which increases both their opportunities to inherit space and the ease with which they can safely disperse to a neighbouring territory to fill a vacancy. Helping beyond the age of two years is of infrequent occurrence, especially among females, but a few males have helped for up to six years before beginning themselves to breed. Pairing is commonest at or near the age of two years, females pairing significantly earlier in their lives than males. Florida Scrub-jay helpers obtain breeding space by any one of four methods: through mate replacement in a territory outside their natal one; by what is known as "territorial budding", whereby a male, paired with an immigrant female, inherits a portion of his natal territory; through direct inheritance of the natal territory following the death of a breeder; and by establishing a territory between existing ones. About 56% of breeding males obtain a breeding space by means of some form of territorial inheritance, while some 94% of breeding females pair outside their natal territory. The Florida Scrub-jay's helper system can be viewed as a combination of strategies in which dispersal is delayed until a breeding vacancy can be located outside the natal territory or be created within it; such a system would be suitable in sharply bounded habitats that are saturated with long-lived breeders.

In California, the closely related Island Scrub-jay, confined to Santa Cruz Island, also has to acquire a breeding space, these being similarly in short supply, and young or subordinate individuals must delay reproduction for several years until they are able to acquire a suitable nesting territory. On Santa Cruz, however, the young do not remain on their natal territories or act as helpers, but, instead, they wander along the peripheries of established territories and suboptimal habitats until a breeding space can be acquired. These young individuals, termed "floaters", may survive in areas that are unsuitable for breeding territories, whereas such "marginal" habitats are less available for the Florida Scrub-jay.

Also closely related to the Florida Scrub-jay, the Western Scrub-jay exhibits variations in its breeding system. In California, territories are defended only by the breeding pairs, but in the mountains of northern Oaxaca, in south Mexico, flocks defend territories or help in the defence of them, although non-breeders have not been seen to feed nestlings. The population living in Oaxaca does not corroborate the notion that habitat saturation favours co-operative breeding, as had previously been observed for the Florida Scrub-jay, because available habitat is plentiful in Oaxaca but scarce in California.

In the case of the Mexican Jay, delayed reproduction and reduced dispersal are carried to an extreme. The young remain with

Jackdaws differ from all other species in the genus Corvus *by nesting in cavities. In open wooded country, farmland, parkland and other areas with scattered trees, they use tree holes.* ***Eurasian Jackdaws*** *often take over the nest-holes of Black Woodpeckers* (Dryocopus martius), *though only near woodland edge. Where tree holes are in short supply, jackdaws have been recorded nesting in rabbit burrows. Other suitable sites include cliff faces and old buildings; the ornate roofs of cathedrals are a favourite. One of the few differences in behaviour between the two jackdaw species is that the Daurian Jackdaw* (C. dauuricus) *will sometimes build nests in open sites in the tree canopy, though possibly only when suitable cavity sites are not available. The density of Eurasian Jackdaw colonies depends on the availability of holes. To avoid nest predation, jackdaws prefer holes with small entrances, and holes which have been predated are less likely to be used in subsequent years. Resident pairs defend their nest-site throughout the year, but will move if a better one becomes available. However, a large, successful breeding colony on a cliff can make use of all the cavities available. As colony size increases, nest predation decreases, because group defence against predators like ravens improves.*

[*Corvus monedula*, Germany. Photo: Konrad Wothe]

their parents and, when mature, they breed in pairs in their home flock at separate nests; the majority of individuals probably live their entire life within their home-flock territory. Territories, which can have several active nests, are therefore the exclusive property of the flocks and are stable in size and location for decades; variation in social structure, correlated with habitat structure and composition, was recently detected at a study site in Sierra del Carmen, in Mexico. Both the parents and other individuals care for a single brood. Pair territories appear not to exist for the Mexican Jay, and it is suggested that any behaviour that could be termed territorial aggression likewise is non-existent. The Mexican Jay presents the highest level of communal breeding known among jays.

Among the Neotropical jays for which the relevant details are known, co-operative breeding seems to be frequent, although the documentation for some species is based on only one or a few studied sites, as for the Azure Jay, the Curl-crested Jay and the Plush-crested Jay. In both subspecies groups of the Green Jay, the young stay with the parents for one year; young of the Middle American subspecies, however, are driven from their parental groups after one year and do not provide benefits for the siblings, whereas those of the South American races stay for longer, usually for two years, and help at the nest. The San Blas Jay has a large number of breeders per flock and extensive mutual helping among breeders. In the Brown Jay, the co-operative breeding system varies. In a population in Monteverde, in Costa Rica, studied over a period of 13 years, this species exhibited the complete spectrum of co-operative breeding, from an adult nuclear pair assisted by non-breeding young birds to the extreme of communal breeding similar to that of the Mexican Jay. In this Costa Rican population, it was possible to identify situations ranging from incomplete habitat saturation, in which the jays maintained moderate group sizes, to more complete saturation, in which they maintained larger group sizes and showed increased aggression at high densities. Sociality has not simply been forced on that population, because even at low densities, and in the presence of ample unused habitat, the Monteverde Brown Jays bred only in flocks. Similar variation of the breeding system was detected for the White-throated Magpie-jay: singular breeding, involving a single breeding pair within a given group range, to true plural breeding, with multiple breeding pairs within a given range, and partial range-sharing among related females. In contrast to most corvids, an extremely male-biased natal dispersal is a feature of the Brown Jay and the White-throated Magpie-jay. Recent study at the Monteverde site suggests that Brown Jay males invest less in nesting activities compared with other well-studied New World jays.

In the Old World, the Iberian Azure-winged Magpie has helpers in family flocks. A study in south-eastern Portugal, however, suggests that helpers are more frequent in years with more severe weather conditions, and helper presence significantly increases provisioning rates and breeding success of the breeders. Each flock defends an extensive territory throughout the year against other flocks, although the species sometimes roosts communally. Helpers participate in the delivering of nest material and in nest-building, in the feeding of the incubating or brooding female, in feeding the nestlings and fledglings, and in the removing of the chicks' faecal sacs; they were found not to participate in incubation, or the brooding of the young.

Reproduction by the Common Magpie, the Black-billed Magpie and the Yellow-billed Magpie has been extensively studied, providing a tremendous body of information. As pointed out by T. R. Birkhead in his 1991 monograph of this group, the three species differ fairly constantly in terms of nest spacing. In northern Europe, the Common Magpie defends territories of 5 ha on average, with its nests regularly spaced; some territories are occupied throughout the year. In the territories of the Common Magpie both breeding and feeding activities take place. Yellow-billed Magpies breed in small, loose colonies, in which each pair defends a territory of about 1 ha during the breeding season; foraging occurs either within the territory or in communal feeding areas outside it. The Black-billed Magpie has an intermediate system, its nests being aggregated, but generally less so than those of Yellow-billed Magpies. The Black-billed Magpie either performs no territorial defence or defends a relatively small area of only about 0·3 ha around its nest during the breeding season; breeding individuals forage mainly outside their territories, and usually in pairs. Interestingly, Common Magpie nests in Spain and north Africa are clumped, like those of the Black-billed Magpie, but unlike Common Magpie nests farther north in Europe. Although ecological reasons for these geographical differences are not clear, variations in food supply are probably associated. In an experimental study conducted by J. J. Soler and M. Soler at Hoya de Guadix, in south Spain, the effects of food supplemen-

*The **Black Magpie**, considered to be one of the most primitive members of the Corvidae, assembles a crudely constructed platform of twigs with a shallow cup in which it lays two to three whitish, finely speckled eggs. The rim of the nest may be decorated with flowers or mosses. Eggs have been reported in Borneo, where the race* aterrimus *occurs, rather later in the year than in the nominate race of the Malay Peninsula. The two races are well differentiated and may represent separate species. To date, these birds have received remarkably little study.*

[*Platysmurus leucopterus leucopterus*,
Taman Negara, Malaysia.
Photo: Ong Kiem Sian]

*The female **Eurasian Jackdaw** incubates the eggs alone, and is fed at the nest by the male. Clutch size in both jackdaw species is typically around four, but can vary from two to eight. Eggs laid later in the sequence tend to be progressively smaller, and less likely to result in fledged young. Average incubation periods within the genus* Corvus *seem to be related to the size of the species, being 17–18 days in the Eurasian Jackdaw, 18–19 days in the Carrion Crow* (C. corone)*, and 20–21 days in the Common Raven* (C. corax)*. However, these figures can vary; and a period of up to 23 days has been recorded in the Eurasian Jackdaw.*

[*Corvus monedula spermologus*, near Logroño, La Rioja, Spain. Photo: Joseba del Villar]

tation on a population of Common Magpies were found to be that males built significantly larger nests and females laid significantly larger eggs.

During the spring, the Eurasian Jay is territorial and it no longer tolerates the presence of one-year-old jays. Its territories, covering 6·7–14 ha and in which occur courtship, breeding, feeding and food-caching, do not overlap; sometimes, individuals leave the territory in order to collect food for caching. Outside the breeding season, territoriality seems weak or non-existent and other one-year-olds are tolerated in the home range, which has an average size of 12·7 ha. In Toscany, in western Italy, the social system of the Eurasian Jay is possibly different from that in north Europe: individuals in Italy shifted their home range from areas with pine woods in summer to areas with scrub and olive (*Olea*) in autumn, and thence lived at a higher density of 484 individuals per km². In some years, failure of the acorn crop results in mass evacuation of the breeding areas in autumn and sometimes large eruptive flocks. The Spotted Nutcracker is also solitary and territorial; in a study in Austria, this species was found to be basically resident, within a home range of 5–10 ha, and to have much smaller territories with a radius of 25–40 m from the nest.

*High ledges in old buildings sometimes provide **Red-billed Choughs** with a convenient substitute for natural sites in the roofs of caves or rock chimneys. The female alone broods the nestlings, a duty which tails off after the first ten days. Otherwise, the parents share equally in tasks like feeding the nestlings, and removing faecal sacs. They are occasionally assisted at the nest by a helper, probably from a previous brood. The young remain in the nest for 36–41 days, and stay with the family group for up to 50 days after fledging. Choughs pair for life, but first-year and second-year pairings can be short-term until each bird finds the right partner.*

[*Pyrrhocorax pyrrhocorax erythroramphos*, Erla, Zaragoza, Spain. Photo: Ricardo Vila]

The Siberian Jay maintains territorial flocks during all months of the year, a territory containing a pair and 3–6 further individuals. The offspring may continue to share the territory with the adults and are tolerated at resources for extended periods; indeed, their assistance in feeding the fledgings may extend well into the time when the chicks become independent. This tolerance of the young is viewed as a case of prolonged parental care, suggesting co-operation. There is, however, no evidence that retained offspring help at the nest. Dominant brood-members may act to expel subordinates, forcing them to disperse. The social unit is then disrupted, contact between the territorial pair and juvenile group-members decreasing; the juveniles are then chased by the adults. With the Grey Jay, a single additional individual will mob potential predators and defend the territory, but it is aggressively excluded from the nest by the breeding male, although it may sometimes feed the fledglings.

Although the genus *Corvus* is essentially territorial, several species may tend towards the colonial system in some situations. The Rook is one of the few members of the genus that is a truly colonial breeder, its nests densely clustered in treetops. In regions with very high numbers of individuals, these rookeries may be connected by scattered nests to such an extent that most of the tall trees of the area seem to comprise part of an enormous far-flung rookery. Each nest is tended by a single pair, which defends a territory consisting of a tiny area around the nest. The area around the colony is used for feeding, and no aggressive interactions among the individuals have been observed. The Rook is gregarious also outside the breeding season when feeding, roosting and on migration, although the pair is the chief constituent unit. The Eurasian Jackdaw is another example of a true colonial breeder, although solitary pairs are not uncommon. This species often has a high density of nests in one site, even in one large tree or along a short section of a cliff; sometimes, because of the way in which suitable nesting sites are arranged, pairs may nest at a considerable distance from their nearest neighbours. Outside the breeding period the Eurasian Jackdaw lives in flocks, pairs again being the basic unit, and at certain periods very large flocks, often associated with Rooks, can be observed. The Carrion Crow is essentially territorial, each pair defending a territory of about 0·14–0·46 km², and these territories can be either partly overlapping or discrete, but not necessarily contiguous. This species' territory serves for nesting, and the adults cover most of it every day in the search for food; territorial individuals are rarely seen outside the territory in the breeding season. Sometimes, where suitable nest-sites are few and concentrated in extensive feeding areas, Carrion Crow nests are so close together as to form a loose colony and, exceptionally, colonial nesting has been reported, as in north-east Germany. Helpers at Carrion Crow nests have been recorded in Switzerland and northern Spain. A recent study, in which supplementary food was placed in the territories of Carrion Crows, suggested that the availability of food resources positively affected the tendency of the young to remain in the natal territory and promoted helping behaviour.

The *Corvus* species in North America exhibit differences in their breeding systems, even within the same species. A population of the Chihuahuan Raven studied in New Mexico did not show any sign of co-operative breeding, but this species is reported as co-operating in defence against predators. The American Crow varies in its reproduction system, populations living in California showing tendencies to nest in colonies, those in Florida to defend territories during the breeding season, and those in Massachusetts to defend territories throughout the year. The core areas around the nests occupied by pairs and families of western populations are small, overlap extensively with those of neighbours, and are not defended against conspecifics. Average territory sizes are 42 ha in Massachusetts, while in the western USA there are on average 0·8 pairs per hectare. Helpers at the nest were recorded in several studies of the American Crow. In Florida, three or four yearlings participated in all phases of nesting, including nest-building, the feeding of the female during incubation and brooding, caring for the nestlings, and defending the nest and territory. In California, delayed breeding and dispersal were also recorded, which suggests similarities to the co-operative breeding of the American jays. The Northwestern Crow likewise has helpers, but there is only one helper per nest and, moreover, not all nests of this species have a helper. Helpers feed and cache food in the territory, which represents a cost for the breeding pair; in addition, the breeding male sometimes feeds the helper. In the case of the Northwestern Crow, however, helpers participate to varying degrees in territory and nest defence, and feed the nestlings and the fledglings; it was found that pairs with helpers laid larger clutches and produced

*The endemic **Taiwan Blue Magpie** is the only species in Taiwan known to breed co-operatively. It is generally found in groups of six or more. All flock members take part in nest-building and defence, but the female alone incubates the 5–6 eggs. In the various blue magpie species in which co-operative breeding has been observed, the breeding pair alone appears to feed the nestlings, the female doing most of the work. The helpers, assumed to be the young of the previous year, then assist in feeding the fledglings.*

[*Urocissa caerulea*, Kinmen, Taiwan. Photo: Yung-Fu Chen]

White-necked Ravens *choose inaccessible sites on cliffs where possible, although exceptionally they have been found nesting in trees. A typical clutch is of four eggs, but as few as one and as many as seven have been recorded. The chicks are mostly fed by the female, by regurgitation. Ravens and other corvids begin to incubate before the clutch is complete, so that eggs hatch asynchronously. The first eggs laid tend to be larger, and produce larger hatchlings. As in this picture, the parent gives most attention to the larger, more vigorous birds. If food is limited, the young tend to starve to death in reverse order of hatching, and resources are concentrated on those with the best chance of survival.*

[*Corvus albicollis*, Domboshawa, Harare, Zimbabwe. Photo: Alan S. Weaving/ Ardea]

more fledglings per nest than pairs without helpers. It is possible that the strategy of co-operative breeding by the Northwestern Crow is of recent origin. This species defends a territory only during breeding season, the territory's average size of 0·49 ha and the average inter-nest distance of 17·8 m being relatively small when compared with those of European *Corvus* species. The Fish Crow forms small colonies, but the number of nests in a colony seems smaller than that in colonies of the American Crow in California.

The Common Raven is generally seen solitarily, in pairs, or in flocks outside the breeding season. In his monograph on this species, D. Ratcliffe mentioned that territory-holders commonly remain in the territory, which ranges in size from 2·8 km² to 66·7 km², throughout the year, even in severe weather. Typically, nesting places are traditional, occupied for as long as anyone locally can remember, and sometimes with a history of use going back well over a century. The nesting places are the central and fixed point in a Common Raven's life, becoming the roosting sites outside the breeding season; as the time for breeding approaches, each pair can be seen more constantly in the vicinity of the nest.

Although the Red-billed Chough is territorial, it will occasionally form small loose colonies. In places where this species is numerous or where suitable nest-sites are few and concentrated, as in parts of Spain, several pairs may breed close together and apparently defend as a territory only the area around the nest.

Corvids usually build their nests on trees, generally at the fork of a branch, where they can fix them firmly. They may use shrubs, instead of a tree, or even nest on the ground, among shrubby thickets; the Carrion Crow has been found breeding in *Phragmites* reedbeds in western Mongolia. Other sites commonly utilized include cliffs, as in the case of the Common Raven and the choughs. Artificial structures, such as roof supports, outbuilding walls, telegraph poles and electricity pylons, are also commonly used. Nest-site selection may be linked to the reduction of nest predation, as with the Carrion Crow and the Siberian Jay, to reduction of the negative effects of the weather, as with the Pinyon Jay, and to both of those selective pressures, as with the Brown Jay. The Asian Azure-winged Magpie, however, uses nest-sites that are more concealed by leaf cover in the absence of the Japanese Sparrowhawk (*Accipiter gularis*) that they are when the latter is present; it may be supposed that this magpie species avoids nest predation by exploiting the defence behaviour of the hawks.

Nests of the Corvidae consist typically of an open cup, with a platform of sticks or large stems and an inner lining of softer substances. The clutch size varies from one to nine eggs, but is commonly from two to four. Corvid eggs are usually a shade of blue or green with darker grey or lilac underlying markings. In-

For the first ten days after hatching, ***Rook*** *nestlings are dependent on food brought to the nest by the male, which also feeds the female while she is incubating and brooding. But as the young become larger and more demanding, the female too brings them food. The parenting skills of Rooks seem to improve with age. Young females lay smaller clutches than older ones, whereas older males are more successful in raising young to fledging.*

[*Corvus frugilegus frugilegus*, Le Meillard, France. Photo: Cyril Ruoso/Bios]

Near Granada, in southern Spain, nest parasitism by the Great Spotted Cuckoo (Clamator glandarius) *has a strong adverse effect on populations of the* ***Common Magpie****. The Great Spotted Cuckoo parasitizes four corvid species in this area, but cuckoo eggs laid in magpie nests are twice as likely to succeed as those laid in nests of the Carrion Crow* (Corvus corone)*. The cuckoo's gape stimulates the magpie to feed it at a higher rate than its own offspring.*

[*Pica pica melanotos*, Pinto, Madrid, Spain. Photo: Luis Miguel Ruiz Gordón]

cubation is undertaken by the female alone. The nestling period can be relatively short, being no more than twelve days in the case of the Florida Scrub-jay, or relatively long, that of the Pied Crow lasting for 45 days. Young corvids may require rather a long time before they are able to fly strongly. The Brown-necked Raven, for example, takes 42–45 days to reach the stage when it can fly really efficiently.

Large corvids, when they have reached adulthood, seem to have few natural predators, or, at least, fewer than other passerines. Nevertheless, adult Common Ravens have been reported as being killed by Golden Eagles (*Aquila chrysaetos*) and Peregrine Falcons (*Falco peregrinus*), and by terrestrial predators including coyotes and wolves. Several species of crow have been recorded as falling prey to the Northern Goshawk (*Accipiter gentilis*) and the Eurasian Eagle-owl (*Bubo bubo*), and even smaller birds of prey, such as the Tawny Owl (*Strix aluco*), will sometimes kill larger corvids. The Eurasian Jay, which lives in forest and frequently seeks the security of the trees, is preyed on by specialized hawks such as the Eurasian Sparrowhawk (*Accipiter nisus*).

In the Neotropics, the eggs and young are vulnerable to a great range of predators, from monkeys to toucans (Ramphastidae). There are also records of corvids being killed by other members of their family, such as Common Magpies killing, and being killed by, Carrion Crows. In southern Spain, the Great Spotted Cuckoo (*Clamator glandarius*) used the nests of four corvid species, especially the Common Magpie and the Carrion Crow, in which to lay its eggs; this nest parasitism had a strong adverse impact on the populations of the Common Magpie.

Movements

Populations of several corvid species in the Northern Hemisphere are partially migratory, while corvids living in the Southern Hemisphere are, so far as is known, sedentary. Migratory distances are highly variable from one species to another, and even among populations of a single species living in different localities. Short movements during the winter are made by some species living at higher altitudes, such as the Yellow-billed Chough. Among migratory populations of the Eurasian Jackdaw, those from Scandinavia reach the Low Countries and Denmark, and sometimes also France and Britain, and these could be considered to be examples of a short-distance migrant when compared with birds of this species living in Finland, which reach France; numerous recoveries of ringed individuals indicate many distances exceeding 1000 km. Data on the Eurasian Jackdaw, the Daurian Jackdaw and the Rook indicate that juveniles migrate more, and for longer distances, than adults.

Data on the Rook in Russia suggest a recent tendency towards a progressively shorter migration route. The average distance of movement was 2200 km in 1929–1938, 1900 km in 1950, and 1400 km in 1971–1985. It is possible that an increase in food resources in urban areas, such as in the Moscow region, is related to this reduction in migratory distance. Winter recoveries of Finnish nestlings and juveniles of the Carrion Crow reveal a reduction in the proportion of individuals migrating and in the mean distances covered. It is thought that the reduction in the extent of migration of north European birds is probably due chiefly

Young ***Hooded Crows*** *fledge at 3–5 weeks, but continue to be fed by the parents for 2–3 weeks more, and often throughout their first winter. Rapid weight gain is a good indicator of survival to independence, and future fitness. In a study in Switzerland, chicks of the closely related Carrion Crow* (Corvus corone) *in an urban environment were found to take longer to reach fledging weight than a nearby population on agricultural land, and they weighed less at fledging. The urban birds also had shorter tarsi on fledging. Tarsus length is fixed at the time of fledging, and 79% of the urban fledglings were deemed to have fallen below the minimum size for territory acquisition, and to be excluded from breeding.*

[*Corvus cornix cornix*, Colonsay, Scotland. Photo: Ian Fisher]

to increasing supplies of winter food at rubbish dumps within the breeding range, and perhaps also to climatic amelioration.

Northern populations of the Common Raven are mainly sedentary, but are more prone to make southward movements in winter than the southern populations. Nevertheless, immatures of southern populations do make extensive movements. The Carrion Crow varies from being migratory in the north of its range to being sedentary in the south and west; many of its populations are only partially migratory.

The Rook populations of northern Europe migrate southwards to wintering grounds in temperate Europe, thus leaving their rookeries. Abandonment of the rookery area in winter occurs also in some Scottish Highland valleys. A study in Deeside, in east Scotland, showed that the local Rooks, and also the Eurasian Jackdaws, were mostly dependent on stubble grain for food in the autumn and early winter; this food resource was depleted earlier in the upper parts of the valley than in the lower ones, which led the populations in higher areas to descend to lower areas from autumn until mid-winter. During the second half of the winter, when weather conditions had worsened, the Rooks made regular diurnal visits to their breeding areas, involving round trips of 90 km, to spend, at times, only two-and-a-half hours there. It is supposed that, after the Rooks have accumulated fat, the principal motivation for their return to the rookery in the upper valley during the coldest period of winter is that of defending the sites that they chose in the autumn.

Flocks of Blue Jays are seen flying in numbers that can reach 100 or more. These flocks typically avoid crossing large open stretches of water. The Rook migrates by day in flocks, often following leading lines such as coastlines and river valleys, and often in company of Eurasian Jackdaws or Daurian Jackdaws.

Periodic eruptive migration is a characteristic of some species, and is the result chiefly of the failure of seeds of conifer crops. The production of seeds of conifers is clearly synchronized, irregular and unpredictable. In the case of, for example, the pinyon pine, the production of seeds, the principal food resource of the Pinyon Jay, is highly variable from year to year, large crops occurring every four to seven years in any one area; this means that huge areas of the pinyon woodland produce a large seed crop, but neighbouring areas are barren. In one year a single tree can bear hundreds or thousands of seeds, and in the next year no seeds are found for miles around that area. There is a report that, in Arizona, one year of quite low production of pinyon pine seeds was followed by one with the maximum production ever recorded there. Years with low seed production force Pinyon Jay flocks to converge on the areas of remaining available seeds, which are sometimes well away from the species' normal range and habitat; such areas then become temporary "hot spots" for that corvid. A similar scenario applies to the largely sympatric Clark's Nutcracker. If the crops of the pinyon pine and whitebark pine, this species' principal food resources, fail, swarms of Clark's Nutcracker may leave the mountain forest and spread all the way down the Pacific coastlands of North America. Such events are sparse in the life of this nutcracker, occurring once every 15 years. Less dependent on conifer seeds, but overlapping in distribution with the Pinyon Jay and Clark's Nutcracker, Steller's Jay occasionally invades areas where it is normally absent.

In Europe, eruptions of the Eurasian Jay populations living in the eastern and northern regions, which take the birds well into the west and south of the continent, are probably associated with failure of the acorn crop. The numbers involved and the extent of the movement vary greatly; the longest distance recorded is 3000 km, by one ringed individual that was recaptured. Years with low production of acorns generally follow years with high acorn production, as with the case of the pinyon pine. At times when seed production is very poor, many hundreds or even thousands of jays may be seen flying in search of more productive regions, visiting areas where they are not normally encountered. In Scandinavia, seasonal movements occur each year, especially from north of the distribution of the oak, with eruptions every few years. A famous eruption of Eurasian Jays occurred in 1983, when a massive influx into Britain was recorded; involving many thousands of individuals, this huge invasion began in mid-September and continued to the beginning of November. Several reports of unusually high numbers of jays in the spring of 1984 probably related to the return passage of these jays. Most of the migrants are juveniles, and a considerable proportion of them returns to the area of origin.

The Spotted Nutcracker subspecies *macrorhynchos* is a true eruptive migrant, while the other races of this species are more sedentary. Failure of the seed crop of the Siberian stone pine (*Pinus sibirica*) is associated with the movements of this species, such eruptions having been recorded in Europe on some 25 occasions in the past 250 years. Individual numbers during these

*Having delivered food, this parent **Eurasian Jay** is waiting patiently for the young bird to produce a faecal sac. The nest is noticeably clean, despite the advanced age of the young. Adult corvids carry the faecal sacs away, rather than eating them. Young Eurasian Jays remain in the nest until about 21–22 days, and become independent of their parents at 7–8 weeks. After this, their parents may become aggressive towards them. By the following spring, parent birds will not tolerate their own yearlings within the territory.*

[*Garrulus glandarius fasciatus*, Burgos, Spain. Photo: José Luis Gómez de Francisco]

*Adult **Plush-crested Jays** continue to feed juveniles for around 90 days after they have left the nest. Studies at a few sites indicate that this species is a co-operative breeder, and so some young may stay on to help their parents raise the next year's brood. But the nature of co-operative breeding in Neotropical jays can vary, even within the same species. Although all subspecies of Green Jay* (Cyanocorax yncas) *keep their young with them for a year, the Middle American races drive them away before breeding commences, whereas in the South American races, they stay on for two years.*

[*Cyanocorax chrysops chrysops*, Río Pilcomayo National Park, Argentina. Photos: José Calo]

eruptive movements may reach more than 10,000, as recorded in Germany. Although some of the nutcrackers return towards the areas of their origin, little return movement is witnessed in the following spring.

Daily movements from roosting areas to feeding areas are a common phenomenon for several corvid species, such as the Carrion Crow, the Common Raven, the American Crow and the Torresian Crow, among others. These movements are over short distances, because, in order to minimize travelling costs, the roosting areas are always close to the foraging areas that will be explored on the next day. This is the "patch-sitting" hypothesis, which predicts that birds will roost close to their diurnal activity centre or to the current superabundant food supply, and will use that feeding area in the morning, when their energy needs are the greatest. Both the Red-billed Chough and the Yellow-billed Chough often make daily altitudinal movements of up to several kilometres between roosting and feeding sites.

Relationship with Man

The fact that corvids are common and conspicuous birds in many parts of the world, including in urban areas, makes them quite popular in human culture, and they feature in, for example, folklore, legend, literature, and a large variety of artistic expressions. In films, the image and/or the voices of crows have been frequently used, being associated mostly with situations of terror, suspense or death or feelings of human isolation. In literature, crows are constantly used as a symbol of death, as in the famous poem by Edgar Allan Poe *The Raven*. Crows also served as symbols of death and misfortune in paintings by Hieronymus Bosch, Giovanni Bellini, Pieter Brueghel, and Vincent Van Gogh.

Species in the genus *Corvus* are featured in many myths. The Common Raven, in particular, has held a notable place in the minds of people in the Northern Hemisphere, playing a powerful role as a symbol of supernatural forces. As Ratcliffe wrote in his monograph on the species, people could see human attributes or meaning in the Common Raven's appearance, and its significance in these human associations was as a bearer of omens, which could be good or bad; ravens deliver messages from on high to foretell the outcome of important events. The black plumage, the raucous and sepulchral voice, the species' ability to mimic human speech, and its carrion-eating habits were seen as proof of the connection between the bird and dark forces and death. Ravens were regarded as prophets, soothsayers and magicians, with supernatural powers, including the ability to transmutate into human form. There is a superstitious belief in the talismanic powers of raven relics, such as bones or beaks, and the mythical "Raven stone" was supposedly brought by the bird from the sea to its nest. In various cultures the Common Raven appears in a prominent position. The association with Norsemen is very well known. Their war-god Odin had two Common Ravens named Hugin and Munin, or "Thought" and "Memory". According to legend, Hugin and Munin flew all over the world to gather information and returned in the evening, when they sat on the shoulder of Odin and whispered in his ears what they had seen. Another famous association of ravens, this time in England, is with the Tower of London; there must always be six individual Common Ravens in residence in this medieval fortress, because otherwise the Crown would be at risk of demise. On the Bayeux Tapestry of the Battle of Hastings, William the Conqueror has a Common Raven painted on a standard behind him. Some native North Americans honour ravens by placing them at the top of huge totems.

Among native Americans and ancient Asian peoples, and in traditional European cultures, crows produce similar feelings to those evoked by ravens. Some cultures seem not to distinguish between crows and ravens. Others have joined the two together in their stories, possibly because, in nature, crows routinely mob ravens to keep them from raiding their nests or stealing their food. Immortality is another quality attributed to both crows and ravens, and is due, most likely, to the tendency of these birds to persist from generation to generation in stable territories.

The North American Indians of the plains associated *Pica* magpies with war or death, because the carrion-eating habits of these birds were frequently in evidence on the battlefields. Indians regularly used the feathers and the carcasses of magpies as ornaments. The symbolism associated with magpies and jays, however, is, in general, different from that attributed to crows and ravens. In Portugal, magpies are associated with people who talk too much. The Portuguese king John the First is said to have ordered his workers to paint magpies all over the roof of a room at the Sintra's Palace so as to advise his court against gossiping; this room can be visited nowadays on tourist excursions into the palace, and is known as the "Room of the Magpies". In La Fontaine's *Fables*, magpies were used as examples of beautiful colour but poor voice in order to illustrate that good looks can

*Young **Mexican Jays** remain with their parents and, when mature, breed within the natal territory. Most individuals probably live their entire lives within their home-flock territory, which can remain stable for decades. Juveniles differ from adults in being smaller and duller, with brown rather than black legs, and a paler bill, until they attain adult plumage about 12 months after hatching. Mexican Jays have an extremely complex breeding system, which varies from monogamy to polygynandry (several breeding males and breeding females in one social group). Exclusive pair-bonds are rare. Each female is guarded by a dominant male, which sires most or all young in her nest. However, the female also mates with subordinate males, and a clutch frequently has several fathers. While incubating, the female is fed by the guarding male and most other group members; similarly, the young are fed by the entire group throughout their time in the nest, and for several weeks afterwards. In their turn, the young of the semi-colonial, non-co-operative **Little Raven** fledge at around 37 days, and join flocks of adults soon afterwards. They then move away from the breeding area, part of a number of strategies, including flexibility over the breeding "season", which enable this species to avoid competition with the sedentary and dominant Australian Raven* (Corvus coronoides). *The irides of young Little Ravens change from blue-grey while they are in the nest, to dark brown at fledging, and attain the white colour of the adult iris in the bird's second year.*

[Above: *Aphelocoma ultramarina arizonae*, Arizona, USA. Photo: Mary McDonald/ naturepl.com

Below: *Corvus mellori*, Geelong, Victoria, Australia. Photo: Peter Fuller]

*Young **Clark's Nutcrackers** remain dependent on their parents until they are 3–4 months old. Throughout this period, they are fed with the pine seeds their parents cached during the previous year, along with some insects. They become independent when they learn to locate their parents' caches for themselves, by recognizing germinating conifer seeds. The use of cached seeds means breeding can start before other foods become available, from as early as mid-February, despite harsh winter conditions. Finishing breeding early gives both adults and juveniles time to build their food hoards. The young birds are ready to breed in their second winter.*

[*Nucifraga columbiana*, Banff National Park, Rocky Mountains, Alberta, Canada. Photo: Oriol Alamany]

indicate a lack of deeper or more endearing qualities. Jays, too, are associated with people who talk too much, and both they and magpies are linked with thievery, probably because of their nest-predation habits. In north-eastern Brazil, the finding of a nest of the White-naped Jay is an omen of good luck for all life; in contrast, for some native American peoples, the finding of a Grey Jay's nest brings with it serious bad fortune.

It is not just the close physical association of corvids and humans that has made these birds so popular in human culture. Rather, there is a real interaction between humans and corvids, as shown by Heinrich, Marzluff and Angel. Such interactions began a long time ago, when the nomad ancestors of modern man searched for game and fish. The earliest expression of human kind, recorded some 30,000 years ago in the caves of Lascaux, in western France, feature a crow-headed man and a totemic bird form thought to represent the external soul. There is evidence that ancient hunters and fishermen may have benefited from interacting with corvids; the Hän people of Yukon, in Canada, mimicked the raven's call to attract bears to their hunting areas, and Inuit hunters in Greenland noted an association between ravens passing overhead and nearby caribou (*Rangifer*). Heinrich argued that the close relationship between ravens and wolves has been replaced by a bond with humans, the new dominant drive-hunting predator.

Numerous opportunities exist for corvids to watch humans and to learn about new foods, new threats, and new habitats in urban and rural areas. Crows have learned to recognize a variety of food types, from those dating back to early human history through to the extraordinary variety in a flourishing modern city, including fruits and vegetables from around the world, cooked meats of all shapes, sizes and colours, bread, pastry, noodles, ice cream, potato chips, sauces and cheese puffs, among others. Goodwin highlighted the ability of crows around the world to recognize bread as food. The capacity of corvids to memorize what they see does not make social learning a complex process; observation and imitation of others is a simple form of learning that allows culture to develop. Marzluff and Angel suggested that corvids, in particular crows and ravens, have a culture, and that cultural evolution is an important reason why they live so successfully with humans. In Wisconsin, in the northern USA, R. L. Knight noticed that in rural areas, where crows are accustomed to being shot at, these birds call loudly as people come near their nest trees, but they stay out of shooting range, even if a person climbs to the nest; in contrast, in Madison city, where it is illegal to discharge a gun, crows are quiet, even if a person stands at the base of their nest tree. There are numerous examples that show how corvids learn local tradition and modify their behaviour through a rudimentary form of cultural learning.

Some aspects of crow and raven behaviour and human culture appear to evolve together in a mutually reinforcing way. Marzluff and Angel argued that such situations, where interactions among species lead to social learning and evolution of each species' culture, may be interpreted as culture co-evolution. The

*The pale eyes of the restricted-range **Long-billed Crow** suggest an affinity with the Australian white-eyed crows and ravens. This species is confined to the northern Moluccas, in Indonesia, where it overlaps with the Torresian Crow* (Corvus orru)*, the only Australian corvid also found outside of Australia. It may, however, be more closely related to the Slender-billed Crow* (C. enca)*, which is widespread on Indonesian islands to the east, and which has a bewildering array of bill shapes among its races, though none approaching the length of the Long-billed Crow's. A forest-dwelling species, it still seems to be common and widespread on the large island of Halmahera.*

[*Corvus validus*, Halmahera, Indonesia. Photo: Morten Strange]

Endemic to Santa Cruz Island, the largest of the California Channel Islands at 250 km², the ***Island Scrub-jay*** *is found in oak-dominated chaparral. This habitat is recovering following efforts to control introduced sheep and pigs. In 2003, the population was conservatively estimated at 9000, of which 7000 were reckoned to be breeders. The 2000 non-breeders include "floaters", young birds forced to delay reproduction, possibly for several years, until a territory becomes available. Although the Island Scrub-jay seems at only limited immediate risk, its tiny range and the historical degradation of its habitat have led to its listing as Near-threatened.*

[*Aphelocoma insularis*, Santa Cruz Island, California, USA. Photo: Stefan Oscarsson]

nut-cracking behaviour of Carrion Crows in Japan is perhaps the best example of such cultural co-evolution. In Sendai, in northern Japan, Carrion Crows have learnt another method of cracking hard-shelled nuts, besides simply using gravity; the crows placed seeds on roadways and waited for automobiles to run over them. This behaviour was observed first in the 1960s, but was documented only some years later, by researchers such as H. Higuchi, who reported this first for the cracking of walnuts (*Juglans*). Photographs clearly show that the crows, holding walnuts, first wait for traffic to stop at an intersection, and then fly down in front of stopped cars to position nuts in front of tyres; once the cars have moved on, they return to eat the nuts from the cracked shells. This behaviour has spread slowly, so that other crows in surrounding areas learned this way of cracking nuts; it represents an example of the cultural transmission of behaviour initially learnt through trial and error. The innovative crows' offspring and neighbours would certainly observe and could easily acquire the nut-cracking habit. A new element developed after the "smart activity" of crows had been divulged; car-drivers began to help the crows by intentionally driving over nuts placed on roadways. Higuchi mentioned that, because people enjoyed cracking nuts for the crows, this behaviour has been reinforced in the crow culture and nowadays is well developed over a large area.

It took time, however, for such modern perceptions of wildlife to be reached. In the Middle Ages, ravens, crows and magpies were common inhabitants of towns and villages in Europe, living on the refuse and discarded food that was, because of the lack of concern about hygiene, so freely available. At that time, corvids were welcomed in urban areas because of their scavenging habits; they were seen as friendly cleaners. There are some indications that it was forbidden to shoot ravens because they were considered to drive away bad air. Situations changed dramatically, however, when towns and villages became cleaner and their residents more conscious of hygiene. Corvids then lost their function and were no longer welcomed, and they moved to the surrounding agricultural areas. Here, livestock management was widespread, yet primitive by the standards of today, with high mortality rates of animals old and young, which must have supplied the scavenger corvids with a rich source of food. The association with agriculture created further problems. By feeding on crops, corvids caused damage to agriculture in the early sixteenth century in Europe; the well-known figure of the scarecrow is emblematic of the strange feelings of humans towards crows that eat man's food. Reinforcing these feelings, crows acquired a reputation as killers of domestic animals. At poultry farms with open-top pens, magpies learned to steal eggs, food and young chicks. This problem could be easily solved by covering the top of the pens, but people preferred, instead, an inexpensive campaign of poisoning. Corvids in general were then shot, trapped or poisoned. In the case of magpies, the most effective method, albeit illegal, involved poison baits; these were usually a chicken or pheasant egg laced with the highly toxic insecticide phosdrin, which kills very rapidly, or with alpha-chloralose, which does

Extremely sensitive to human disturbance, the ***Beautiful Jay*** *is found only in a narrow band of wet foothill and premontane forest in west Colombia and north-west Ecuador. As well as suffering extensive logging, this forest has been penetrated by roads, leading to clearance for grazing, plantation crops and human settlement. The Beautiful Jay is also one of a growing number of Neotropical species threatened by coca cultivation for drug trafficking. Its exact population is unknown, but it is rare and patchily distributed, and has been declining since the 1970s. It is listed as Near-threatened.*

[*Cyanolyca pulchra*, Bellavista Cloud Forest Reserve, Ecuador. Photo: Greg & Yvonne Dean/ WorldWildlifeImages.com]

*The **Azure Jay** has already become extinct in some areas where it was previously recorded, such as near Porto Alegre in the south of Brazil. It may also be suffering from over-harvesting of araucaria seeds for human consumption, since it depends on these seeds during the winter. Unexpectedly, in view of its apparent dependence on primary forest, it is increasing on the Brazilian island of Santa Catarina, where it is now common in urban areas and secondary forest. But because of its moderate decline elsewhere, it is listed as Near-threatened.*

[*Cyanocorax caeruleus*, Florianópolis, Santa Catarina, Brazil. Photo: Edson Endrigo]

not kill birds directly but renders them unconscious and they eventually die of hypothermia.

Ratcliffe mentioned that the Common Raven's fall from grace began around 1650. By the eighteenth century, the raven was evidently an object of general dislike in Britain, with a price on its head in many areas. The persecution of the Common Magpie in Britain has changed the habits of this corvid; so confident prior to the eighteenth century that it was called the "cherished neighbour of every farmer", it became quite secretive in its behaviour, "the suspicious thief", "knowing that danger may lurk in every bush". Nowadays, since the persecution is covert and illegal, numbers of corvids have recovered, as in the case of the magpie in many districts of Britain and Ireland.

The rate of increase of Common Magpie populations in suburban England is twice that in rural habits. This can be explained by the fact that conditions in urban areas must be better for magpies than they are in more rural areas. The main problem associated with large populations of magpies in cities is their effect on suburban songbirds, through predation on the latter's eggs and young. Birkhead pointed out two ways in which humans react to

*Still fairly common on the Pacific slope of the Sierra Madre Occidental in northwest Mexico, the **Tufted Jay** lives in relatively inaccessible canyon forest. The threat from logging and clearance is limited, but it is often hunted for fun by schoolboys. Birds confined to small ranges, especially those dependent on forest, are at potential future risk, so this species is listed as Near-threatened. The lack of protected areas in its range has led some to call for it to be listed as globally threatened.*

[*Cyanocorax dickeyi*, Durango, Mexico. Photo: Pete Morris]

the predation of songbird eggs and young by magpies, and these apply also to other corvids. First, there is the emotional reaction, as a magpie kills young while the parents fly noisily and helplessly around; humans do not feel the same way about birds of prey capturing the same young while performing marvellous aerobatics. Secondly, there is the potential impact on the populations of passerines, a subject of recent studies. In Germany, for example, the influence of the Common Magpie on urban bird populations in the city of Osnabrück was analysed; although the population of the magpie increased by 280% from 1986 to 1993, this did not result in a corresponding decrease in the breeding populations of urban songbirds. Similarly, in Berlin, data suggest that magpies have had no effect on the populations of small passerines; even simulated effects of predation by corvids on Whinchats (*Saxicola rubetra*) did not cause a population decline of this passerine.

The tendency of corvids to explore urban areas continues, as illustrated by the well-documented invasion by the Eurasian Jackdaw of the cities of northern Italy, beginning in 1950, or by the Carrion Crow in Milan, in the same region. It is important to mention that, in parts of southern Asia, the Large-billed Crow and the House Crow still play an important role in helping to keep cities clean and sanitary by scavenging on animal and vegetable materials, and mixed flocks of 25–110 crows, scrambling through a fresh pile of refuse on the street, are a not uncommon sight in some places. The House Crow is, perhaps, the best example of urban dependence, as it is not known to live away from human settlement. This species has a great ecological flexibility, having colonized several places, such as Elat, in south Israel, Aden, in Yemen, Medan, in north Sumatra, and Ujung Kulon and Krakatau, both off west Java; it has reached some of them by ship, and become one of the most abundant birds, even at a newly colonized site in the temperate zone, namely The Hague, in the Netherlands. Applying an ecological-niche model, A. Nyári and collaborators predicted the potential future colonization by House Crows of Central America, the Caribbean, equatorial Africa, and mainland and insular South-east Asia.

Corvids have been considered, recently, to be keystone species in restored ecosystems. The consequences of human activities have been the increase of forest fragmentation all over the world; a continuous natural ecosystem becomes a landscape of forest remnants surrounded by agricultural land and urban areas. With simultaneous invasion of the forest remnants by both plant and animal species, the decline of biotic diversity is expected in such landscapes. The corvid habit of storing seeds (see Food and Feeding) may facilitate the regeneration of conifer species, and such constant seed dispersal is quite important, particularly in fragmented forest landscapes, preventing the extinction of those tree species in forest remnants. This has been demonstrated, for example, for the Blue Jay with regard to its habit of storing seeds of Fagaceae tree species in south-eastern Wisconsin. Data suggest that the Blue Jay is a keystone species in deciduous-forest ecosystems because it positively influences populations of nut-bearing trees and also, indirectly, the many species that depend on them. It is the only known organism that transports nuts across dispersal barriers such as cropland. In one studied case, the Blue Jays collected and dispersed only sound, healthy nuts, resulting in dispersal of seeds of the highest quality and viability in terms of future germination; it was estimated that more than half of the acorn crop, some 133,000 nuts, might be transported 1 km or more away from the seed trees by Blue Jays.

Besides the importance of the Corvidae in ecosystem restoration, another page in the relationship between corvids and humans has been written since the end of the twentieth century. The West Nile virus first appeared in the Western Hemisphere in 1999, near New York city, where it caused substantial mortality among corvids, with a few infections in humans. By 2004, it had reached all the states in the USA, as well as other countries in the Americas, including some in South America. It is believed that this virus is transmitted primarily between mosquitoes (Culicidae) and birds. The three bird species that are the most competent hosts are all corvids, namely the Blue Jay, the Western Scrub-jay and the American Crow; the Black-billed Magpie and the Fish Crow are among the 15 most competent

*The smallest of the treepies, the **Andaman Treepie**, is endemic to the Andaman Islands. A recent surge in human population, partly due to settlers from the parent country, India, is putting pressure on the forests on which the treepie depends. Along with most of the other Andaman endemics, it is listed as Near-threatened, but still remains relatively common where forests are intact. A number of national parks and sanctuaries have been established, particularly on smaller islands, but there are concerns that protection may not be sufficient, and uncontrolled tourism is an increasing problem.*

[*Dendrocitta bayleii*, South Andaman Island. Photo: Jon Hornbuckle]

species. This new situation has brought an additional ambivalence towards corvids once again.

Status and Conservation

Owing to their remarkable ability to survive in a variety of abiotic and biotic conditions, corvids are present in reasonable numbers in their various habitats. The fact that most of the 123 species live in open areas or at forest edges makes them more

Along with the White-throated Babbler (Turdoides gularis), *the **Hooded Treepie** is endemic to the Irrawaddy plains of central Myanmar. The dry deciduous forests of these plains have been almost entirely cleared for agriculture, and the treepie has been classified as Near-threatened because of the sharp decline in its population. More recent information suggests that it is still locally common where extensive habitat remains, and that it may be tolerant of degraded habitat such as secondary forest and even scrub-jungle.*

[*Crypsirina cucullata*, Pyay, Myanmar. Photo: Jimmy Chew]

The Cuban race minutus *of the* ***Palm Crow*** *seems never to have been common, but clearance for agriculture is forcing this forest-dwelling bird to retreat, while the more adaptable Cuban Crow* (Corvus nasicus) *takes its place. The Palm Crow is now confined to stands of palms in the cultivated lowlands. The Hispaniolan race has also declined because of forest clearance, but this bird is also hunted for sport and as a delicacy. It occurs in national parks in both Cuba and the Dominican Republic.*

[*Corvus palmarum palmarum*, Dominican Republic. Photo: Roland Seitre]

tolerant of changes in their natural habitats, and corvids may, sometimes, benefit from disturbances of habitat. Documented densities of the Common Magpie, the Carrion Crow, the Eurasian Jay and the Eurasian Jackdaw in Britain increased on farmland over the period 1964–1993.

Nevertheless, several species of corvid that are specialized for life in particular habitats and/or have a restricted range have decreased in number and are threatened to varying degrees. The situation is worrying because some of those habitat specialists have a restricted natural geographical distribution. Of the 123 members of the family currently recognized, twelve species are listed as globally threatened, and a further twelve are considered Near-threatened. In addition, what was presumed to be the last wild individual of the Hawaiian Crow was seen in 2002, and this species appears to be Extinct in the wild. This corvid, together with the Robust Crow (*Corvus viriosus*) and the High-billed Crow (*Corvus impluviatus*), may have become extinct on the island of Maui, in the eastern Hawaiian Group, some hundreds of years ago as a result of the activities of early Polynesians. Captive-breeding of Hawaiian Crows was successful, but, of 27 individuals released in Hawaii, 21 died from predation or disease. The population decline of this species was caused by several factors, including habitat destruction, not only through logging and agriculture, but also through feral ungulates, which

Historically, the ***Collared Crow*** *was fairly common across southern China, Hong Kong, Taiwan and northern Vietnam. It is now only a vagrant in Taiwan, and there are just three recent records from Vietnam. In other places where the birds were once counted in hundreds, single figures are the norm. The only place where counts still exceed 100 appears to be the Deep Bay area of Hong Kong. Rapid agricultural intensification, with over-use of pesticides and rodenticides, is blamed for wiping out its prey. In 2008 it was uplisted to Near-threatened, with an estimated population of 10,000–20,000, based largely on poor-quality data; its true status may be worse.*

[*Corvus pectoralis*, Changbin, Taitung, Taiwan. Photo: Yung-Fu Chen]

destroy the understorey foodplants that are important for this crow. In addition, habitat degradation may have favoured the Hawaiian Hawk (*Buteo solitarius*), which is a crow predator. The impact of shooting, diseases and introduced mammals, including rats (*Rattus*) and a small mongoose (Herpestinae), have also been cited.

Four species in the genus *Corvus* are globally threatened. The White-necked Crow is intolerant of degraded habitats or areas opened up by forest clearance, and it was extirpated from Puerto Rico, where it was once abundant, in about 1963. It is now found only on the neighbouring Caribbean island of Hispaniola. This species was formerly killed by the local people for food. Owing to the fact that its population and range are now small and fragmented, and its numbers continuing to decline, the White-necked Crow is listed as Vulnerable. The Flores Crow is confined to the island of Flores, in the Lesser Sundas, where it is now found mostly as single individuals in the extreme west of the island. Forest fragmentation seems the principal cause of its population decline. High rates of forest destruction on Flores are a cause for alarm over the status and future prospects of this species, which is listed as Endangered.

The decline of the Mariana Crow in Guam has been attributed to predation by the introduced brown tree-snake (*Boiga irregularis*), which spread over the island after the Second World War. Similarly, predation by introduced rats and mangrove monitor lizards (*Varanus indicus*), as well as habitat destruction, disease, and competition with introduced Black Drongos (*Dicrurus macrocercus*), has been suggested as the main cause of the decline in the only other locality where this crow species is found, the small island of Rota, in the Northern Mariana Islands. This population has declined rapidly, and in 2006 it was likely fewer than 500 individuals. A recent study on Rota suggests that the reduction in the population of the crow is not related to predation, but to ectoparasites. The Mariana Crow is considered Critically Endangered.

Another Critically Endangered *Corvus* is the Banggai Crow. This poorly known species was initially discovered in the 1880s, when two specimens were obtained in the Banggai Archipelago, immediately east of Sulawesi. It was not subsequently detected for more than a century. Then, in 1991, an individual was found on the mountain slopes of Peleng, the largest island of the group, suggesting that this species survived on the western side of this island. Concerted follow-up searches conducted in 2004, 2006 and 2007 confirmed that this species did, indeed, survive in the archipelago, but only in forest on the mountain slopes of the western half of Peleng and, in small numbers, at lower levels in the centre of the island. The total numbers present are not known, but very rough estimates suggest that the global population may be between 30 and 200 individuals. Since these observations were made, local conservationists have worked in conjunction with local communities to devise ways in which the crow and its forest habitat can be protected and conserved. It was concluded that assistance should be provided to enable the communities to practise more sustainable agriculture; more efficient methods would mean that the local farmers would not need to clear areas of forest for shifting agriculture. In addition, birds and mammals are hunted for food and other purposes, and it was suggested that the development of ecotourism, a new concept with regard to the forests of this archipelago, might help. The Banggai Archipelago, which consists mainly of small islands and mountains, holds an important range of forest types and reef diversity, which should provide further justification for integrated conservation strategies.

Owing to habitat alteration in its quite small range and a dramatic decrease in its population over recent decades, Stresemann's Bushcrow, the sole representative of the genus *Zavattariornis*, is considered an Endangered species. It is found in an area around Yabello and Mega, in southern Ethiopia, where it inhabits open semi-arid areas of short-grass savanna with scattered low acacia bushes. It is unclear why this species has so restricted a range. Roadside counts carried out in 1989, 1995 and 2003 revealed that the bushcrow's population has decreased by 80% during this period in the Yabello Wildlife Sanctuary. Acacias, important for nest-sites and for foraging, have recently been cut for use as firewood, or to enable the rich soil to be exploited in agriculture, which could explain the population decline of this rare species.

Lidth's Jay occurs only on the islands of Amami-oshima and the nearby tiny island of Kakeroma-jima, in the northern Ryukyu Islands of Japan. This species, known also as the Amami Jay, is considered Vulnerable because its small global population, estimated at about 5800 individuals in the 1970s, is inferred to be declining, possibly as a result of increased levels of predation by the introduced small Indian mongoose (*Herpestes auropunctatus*) and increasing numbers of the Large-billed Crow. In the past, Lidth's Jay was persecuted by local inhabitants through uncontrolled shooting and trapping.

In the 1940s the US Forest Service declared the pinyon-juniper habitat of the ***Pinyon Jay*** *"non-commercial", and set out to eradicate it. Misguided fire suppression policies, disease and drought have taken further toll on this habitat. In consequence, the Pinyon Jay is listed as Vulnerable, because it is thought to have undergone rapid population decline throughout its range. But survey data may be unreliable; the bird is accustomed to irrupting out of its territories when pine nut crops fail, and travelling far beyond its normal range. Some satellite populations are associated with other, less threatened pine species.*

[*Gymnorhinus cyanocephalus*, USA. Photo: Mike Read]

*The habitat of the **Florida Scrub-jay** is being replaced by housing developments and citrus groves, while changes to the natural fire regime have led to overgrowth of scrub and pines, rendering much of the remaining habitat unsuitable. The species is now listed as Vulnerable, with the best estimate for the sum of its fragmented populations being some 6500 birds. Populations along the Atlantic coast of Florida declined at 4% per year between 1992 and 2002, and if the current rate of habitat loss continues, the Florida Scrub-jay could be uplisted to Endangered. Large reserves are needed, with regular fires to ensure that each jay territory has at least 1 ha of low scrub.*

[*Aphelocoma coerulescens*, Florida, USA. Photo: Brian E. Small]

The Pinyon Jay has suffered rapid population declines, apparently as a direct result of the conversion and degradation of its pinyon–juniper woodland habitat, and it is now listed as Vulnerable. It occupies the foothills and lower mountain slopes of the western and south-western USA from central Oregon east to western South Dakota and west Oklahoma, and extends south to northern Baja California, in extreme north-west Mexico. Since the woodland type on which this species depends was classified by the US Forest Service as "non-commercial" and as having "no value", land-managers have followed a policy to eradicate such woodland and to turn the land into cattle pasture. In addition, uncontrolled wildfires have destroyed large areas of suitable habitat for this species in the late 1990s.

Two Middle American jay species are considered Vulnerable by BirdLife, although Mexican conservationists have recently suggested that they should be upgraded to the category of Endangered. The Dwarf Jay is confined to southern Mexico, and is known historically from Veracruz, adjacent to the border with Puebla, and the Sierra Juárez, Aloapaneca and Zempoaltepec, in Oaxaca, where it is particularly abundant in pine–oak–fir forests at 1400–3200 m. Logging for different land uses is leading to widespread habitat destruction or fragmentation and, consequently, the decline of the population of this rare jay. Also with a restricted range in southern Mexico, this time limited to the Sierra Madre del Sur of Guerrero and Oaxaca, the White-throated Jay is locally fairly common to common in tracts of humid montane forest, favouring cloudforest and oak and pine–oak forests at 1525–3500 m. Many of the remaining forests within its range are being cleared for timber and large-scale agricultural expansion, and this is resulting in a decrease in the jay's range and population size, although it has been found in disturbed areas. A third Mexican species with a restricted range is the Tufted Jay, which lives on the Pacific slope of the Sierra Madre Occidental from Sinaloa and Durango south to north Nayarit, where it is fairly common; its known north–south range was recently extended from 210 km to 295 km by records north of Río Presidio. The Tufted Jay lives in canyon forest, which seems not to be susceptible to logging or conversion to agriculture, but, because of its small range, a decline or a fluctuation in its population is possible. It is currently considered Near-threatened.

A further three corvid species are globally threatened and eleven others are considered Near-threatened. The Florida Scrub-jay is entirely restricted to scrub and shrubby areas in Florida, which are being replaced by housing developments and citrus groves. Fire suppression causes scrub to overgrow and the density of pines to increase, rendering the habitat unsuitable for this jay, which is an additional problem. This species is considered Vulnerable because it has a small and fragmented population and range, which is rapidly declining; if the current rate of urban development continues, the consequent loss of range will soon put this species in the category of Endangered. On the other side of the southern USA, the Island Scrub-jay is confined to Santa Cruz, the largest of the California Channel Islands; it has a total population conservatively estimated at 9000 individuals, of which some 7000 are thought to be breeders. It appears not to be under any specific threat, but, because of its tiny global range and the fact

*Little is known about the **White-throated Jay**, and little is likely to be known, unless drastic measures are taken to pull it back from extinction. Already listed as Vulnerable, the population of this restricted-range species from the Sierra Madre del Sur Endemic Bird Area is declining rapidly, as its humid montane forest habitat is cleared for timber and agriculture. The species is found in one protected area, the Omiltemi State Ecological Park, but this needs to be extended, and others established, if this stunning small jay is to survive much longer.*

[*Cyanolyca mirabilis*, Sierra de Atoyac, Guerrero, Mexico. Photo: Manuel Grosselet]

The rich plumage of ***Lidth's Jay*** *once made it a favourite adornment of ladies' hats. More recently it has suffered the depredations of the small Indian mongoose* (Herpestes auropunctatus), *which was introduced to kill Okinawa pit-vipers* (Trimeresurus flavoviridis). *Ironically enough, Lidth's Jay itself eats the young of this aggressive and venomous snake. Lidth's Jay is now fully protected by Japanese law, having been declared a National Monument, and its numbers are rising again, thanks to natural forest regeneration and efforts to control the mongooses. But with a population of less than 6000 and such a tiny range, it is listed as Vulnerable.*

[*Garrulus lidthi*, Amami-Ô-shima, Kagoshima, Japan. Photo: Hirozo Maki]

that the island has been severely degraded by introduced sheep and pigs, the Island Scrub-jay is considered Near-threatened.

The Palm Crow has a moderately small range in the Caribbean, where it is confined to the islands of Cuba and Hispaniola, on both of which it has declined. The cause of its population decrease on Cuba is uncertain, but competition from the Cuban Crow is a possibility; the ranges of the two species have overlapped only since the destruction of the forest habitat. On Hispaniola, widespread forest clearance and also, probably, hunting for food and for sport appear to be the principal causes of its decline. The Palm Crow is currently placed in the category of Near-threatened.

Two Neotropical jays, the Beautiful and Azure Jays, live in forest areas and are sensitive to deforestation. With a decline in their populations, both are considered Near-threatened. The Beautiful Jay occurs along a narrow elevational band of extremely wet foothill and premontane forest on the Pacific slope of west Colombia, south from extreme south Chocó, and north-west Ecuador, south to Pichincha; it is rare and extremely sensitive to human disturbance, and it appears almost exclusively dependent upon primary forest. The Azure Jay is rare to locally common at up to 1000 m in lowland evergreen and southern-temperate (mixed ombrophilous) forests in south-east Brazil from São Paulo south to Rio Grande do Sul, and in north-east Argentina, and there is at least one record from Paraguay; observations suggest that this species is declining substantially, particularly in the west of its range.

In southern Asia, the Sichuan Jay occurs in a comparatively small area of central China, where it is considered rare; it is listed as Vulnerable. It lives in dry coniferous forest of mature spruce (*Picea*) and in mixed fir and rhododendron (*Rhododendron*) forest, often with a poorly developed understorey, at high altitudes of 3000–4270 m; its population is small and severely fragmented as a result of extensive deforestation throughout its range. Forest cover may also be declining on the Qinghai-Tibetan Plateau, because the climate is becoming progressively drier. Biddulph's Ground-jay lives in sandy desert, scrub and areas of desert poplars (*Populus*) in the Taklimakan Desert, in north-west China. This ground-jay was reported as being common in 1929–1930, but was scarce and difficult to locate in the same areas in 1988; this could suggest a population decline, although ground-jays can be very hard to find, even in areas where they are breeding. Nevertheless, degradation of desert habitats through the intensive grazing of goats and camels, extraction of fuelwood and the conversion of huge areas to irrigated land would be possible reasons for this species to have declined. It is currently considered Near-threatened.

The Sri Lanka Blue Magpie, endemic in Sri Lanka, inhabits areas of tall, undisturbed primary forest, a habitat which is under pressure from human activities. It is probable that hunting contributed to its historical decline, but this activity is unlikely to represent a serious threat today. Although many forests within its range are protected, some of these are still subject to degradation and further fragmentation, and forest die-back in the montane region, perhaps a result of air pollution, is also a potential threat. In addition, brood parasitism by the Common Koel (*Eudynamys scolopacea*) is a factor that has possibly contributed to the decline of this magpie species, which is now listed as Vulnerable.

The Andaman Treepie is restricted to the Andaman Islands, where it inhabits areas of dense broadleaf evergreen forest. Although forests in its range remain relatively intact, indications of an increase in human activities in the archipelago may lead rapidly to habitat fragmentation. Clearly, the future of this forest species depends on the enforcing of logging restrictions. It is currently listed as Near-threatened.

Several corvids of south-eastern Asia are Near-threatened. The Crested Jay and the Black Magpie occur in parts of Thailand, Malaysia and Indonesia, the former being found in evergreen forest to 1500 m and the latter in evergreen forest and mangrove to 800 m. Extensive habitat destruction such as that in the Sundaic lowlands, which is so severe that all primary formations are expected to have disappeared by 2010, may cause declines in the populations of both species; the fact that the Crested Jay uses submontane forest and the Black Magpie uses hill forest and forest edge implies, however, that these species are not at immediate risk. Living in a quite restricted area in central Myanmar, the Hooded Treepie is commonly found in dry dipterocarp forest, dry thorn-scrub, secondary growth and the edges of cultivations in the lowlands to 1000 m. Areas of this species' range are now largely cleared for agriculture and the treepie was thought to have suffered a sharp decline, but recent surveys indicate that it remains locally common. As with the previous two species, it is classed as Near-threatened. Placed in the same category, the Brown-headed Crow is confined to the New Guinea region, where its known distribution is highly fragmented, presumably as a result of some unknown habitat specialization; it lives in primary forest and mangroves, occasionally

*The nomadic ways of local pastoralists maintained an ideal habitat for **Stresemann's Bushcrow**, leaving behind them loose, well-dunged soil rich in beetle larvae. Settlement in permanent villages with private land ownership has led to overgrazing and soil compaction. In the Yabello Wildlife Sanctuary the acacias it needs for nesting are being cleared for firewood. Formerly relatively common within its 5000-km² range in southern Ethiopia, roadside counts indicate an 80% decline between 1999 and 2003 alone, and Stresemann's Bushcrow is now listed as Endangered.*

[*Zavattariornis stresemanni*, Yabello Wildlife Sanctuary, Ethiopia. Photo: Ketil Knudsen]

in second growth, but rarely in open areas. Habitat destruction caused by a number of human activities may have led to a decline in the species' population, although it is judged to be reasonably secure in the large areas of forest, with no immediate threats within its range.

Once reasonably common over a fairly wide range in southern Asia, the Collared Crow has recently suffered a contraction in its range and a decrease in its population. This is believed to be due to a loss of food supplies owing to agricultural intensification and the consequent over-use of pesticides, including rodenticides. Moreover, the decline appears to be continuing, and is only made worse in some areas by human persecution, including the use of this crow by children for target practice. The Collared Crow is currently listed as Near-threatened, but it needs to be monitored in case its situation worsens.

Finally, it is important to mention that some corvids, although not listed as threatened or at potential risk, have suffered decreases in their populations as a result primarily of habitat loss and damage caused in particular by agricultural practices. One such example is that of the Red-billed Chough. Many studies have highlighted the ecological needs of this species in low-intensity farmland habitats, such as undisturbed rough grass and short-grazed pasture; data have showed long-term declines with increasing agriculture, and this species is now considered to be vulnerable in parts of its range.

The Arabian Magpie is restricted to juniper forest and well-vegetated wadis in south-west Arabia, where such habitat is under threat from development for tourism, as well as from climatic change, which is producing hotter and drier weather, forcing the remaining population of the magpie into smaller pockets of suitable habitat.

*There were no confirmed sightings of the **Banggai Crow** for more than a century after the species was described from two specimens in the 1880s. Recent surveys indicate that it survives at least on the forested mountain slopes of western Peleng, the largest island in Indonesia's Banggai archipelago. Numbers are likely to be tiny, no more than 200 individuals, and possibly as few as 30. It is listed as Critically Endangered. Conservationists are working with local communities to devise sustainable livelihoods which will protect the bird and its habitat.*

[*Corvus unicolor*, Peleng Island, Indonesia. Photo: Filip Verbelen]

By 1992, there were no more than twelve ***Hawaiian Crows*** *left in the wild. Four years later only three could be found, and the last two failed to return to their traditional nesting site in 2003. The Hawaiian Crow is now considered Extinct in the Wild. The first attempt at a reintroduction of captive-reared birds was abandoned when 21 of the 27 died of predation or disease. Further reintroductions are planned, although the captive group is inbred, which may reduce reproductive success.*

[*Corvus hawaiiensis*, McCandless Ranch, Kealakelua, Hawaii Island. Photo: Jack Jeffrey]

In south-eastern Asia, both the Ratchet-tailed Treepie and the Racquet-tailed Treepie could be at some risk in the near future because of their reliance on lowland forest, a habitat that is becoming increasingly vulnerable. The three species of green magpie in the genus *Cissa* are likewise considered potentially vulnerable; the Common Green and the Indochinese Green Magpies are subject to continued habitat loss due to clearance of lowland forests, and the Short-tailed Green Magpie has a limited range in north Borneo and west Java, where it appears to be uncommon. The Taiwan Blue Magpie, another species with a very restricted range, in this case limited to Taiwan, could also become vulnerable through increased fragmentation of its forest habitat.

Genus *PLATYLOPHUS* Swainson, 1832

1. Crested Jay

Platylophus galericulatus

French: Geai longup **German**: Haubenhäher **Spanish**: Arrendajo Crestado
Other common names: Malay Jay, Crested Shrike-jay; Malay Crested Jay (*malaccensis*); Sumatran Crested Jay (*coronatus*); Javan Crested Jay (*galericulatus*)

Taxonomy. *Corvus galericulatus* Cuvier, 1816, Java.
Affiliations uncertain, and molecular-genetic studies have not yet shed light on its relationships. Originally allied with shrikes (Laniidae), and has been suggested as being closest to the helmet-shrikes (Prionopidae) and perhaps better placed within that family or with bush-shrikes (Malaconotidae). Unlike other members of present family, has distinctive very long crest, lacks obvious nasal tuft but has long rictal bristles (leaving nostrils exposed), and has spotted and barred juvenile and immature plumages. Until further information becomes available, however, probably best treated as a primitive member of current family. Some confusion has existed over names applied to races; proposed names *scapulatus* and *ardesiacus* (both with vague type localities restricted to Java) are junior synonyms of nominate. Race *lemprieri* possibly part of a cline and perhaps of doubtful validity. Four subspecies recognized.
Subspecies and Distribution.
P. g. malaccensis Cabanis, 1866 – Malay Peninsula.
P. g. coronatus (Raffles, 1822) – Sumatra and most of Borneo (except N).
P. g. lemprieri Nicholson, 1883 – N Borneo.
P. g. galericulatus (Cuvier, 1816) – Java.
Descriptive notes. 31–33 cm; 78–114 g. An unmistakable dark bird with remarkable long crest formed chiefly by two elongated central feathers, tips of which are slightly broader and commonly "nod" forwards, medium-short slightly graduated tail, rather small bill with pronounced hook at tip of upper mandible; nasal tuft vestigial but rictal bristles long and prominent. Nominate race is virtually wholly blackish, apart from conspicuous long white crescent on side of neck and broken small white mark at rear of eye (latter giving white-eyed appearance); tail slightly glossy; iris

reddish to brownish; bill and legs black. Sexes similar. Juvenile is very different from adult, being rufous overall, with head and neck (including short crest) orange-brown, rear crown and upperparts dark rufous-brown, pale buff tips on primary coverts, greater coverts and tertials, chin and throat orange-buff, becoming browner on breast, paling to whitish on lower underparts, iris brown; immature more like adult, but retains small whitish spots at tips of greater coverts and tertials, and dark underparts are finely marked with narrow whitish barring and pale shaft streaks. Races differ mainly in depth of plumage coloration: *malaccensis* is very like nominate but head colour often more sooty, upperparts, including wing and tail, blackish olive-brown, underparts dark slate-grey, nape patches almost joining on nape; *coronatus* is rich tawny-rufous overall, with blackish only around the white of neck crescent; *lemprieri* is similar to last, but slightly paler overall. Voice. Noisy. Contact call (often first indication of species' presence) an excited, almost explosive, staccato chattering rattle, bearing some resemblance to chatter of an excited squirrel (Sciuridae); given in varying degrees of intensity and speed of delivery, and uttered constantly during foraging in forest shrubbery. Also a short "chip" and a reeling note. Presumed song a short, fluty phrase followed by a shrill high-pitched whistle, repeated constantly as the birds move through foraging territory.

Habitat. Lowland broadleaf forest; in hill forest reaches to 750 m in Thailand, 1000 m in Sumatra, and 1800 m in Kelabit highlands of Borneo.

Food and Feeding. Surprisingly poorly known. Diet a variety of invertebrates, including large hairy caterpillars (Lepidoptera), millipedes (Diplopoda), cicadas (Cicadidae), beetles (Coleoptera), grasshoppers and crickets (Orthoptera), wasps (Hymenoptera) and cockroaches (Blattodea). Usually seen singly or in small parties, latter presumably mostly family-based groups; in gloom of dark undergrowth, white neck and eye markings striking and no doubt useful for keeping family close together. Fearless, and will approach humans to within a few metres while uttering shrieking calls, bobbing and weaving, and raising and lowering crest. Otherwise feeds almost entirely inside foliage of bushy growth and in lower to middle canopy of trees.

Breeding. Poorly studied. Season Jun–Jul and Oct–Feb in Java; eggs laid early Feb in Malay Peninsula. Solitary breeder. Well-made nest has foundation and exterior of curly wooden tendrils, with shallow cup, built across lateral branches, close to trunk of major sapling, c. 2–3 m from ground. Clutch usually 2 eggs; no information on incubation and fledging periods.

Movements. Sedentary, as far as is known. May possibly be nomadic to a certain extent, as suggested by trapping at Pasoh research forest (Negeri Semblan), in Peninsular Malaysia, where none was retrapped over 25-month period.

Status and Conservation. Not globally threatened. Currently considerd Near-threatened. Locally not uncommon. Reliance on lowland forest makes it vulnerable to habitat destruction. Although it survives mainly in secondary growth in Malay Peninsula, populations there have dropped considerably; numbers at Pasoh research station had not recovered more than 50% of original loss, even after 25 years of regeneration. Generally uncommon in adjacent Thailand, and not uncommon in Java, Sumatra and Borneo, but forest destruction must have had adverse affect on these populations, too, bearing in mind this species' low tolerance of secondary forest growth.

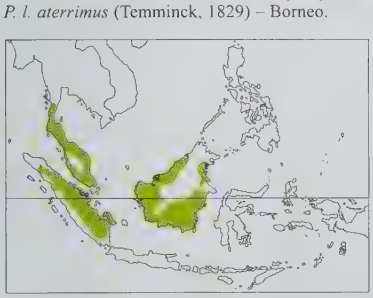
Bibliography. Anon. (2008p), Butchart & Stattersfield (2004), Dickinson *et al.* (2004), Glenister (1951), Goodwin (1986), Lekagul & Round (1991), MacKinnon & Phillipps (1993), Madge & Burn (1994), Robinson & Chasen (1936), Robson (2000), Sheldon *et al.* (2001), Smythies & Cranbrook (1981), Stattersfield & Capper (2000), Steinheimer (2009), Vaurie (1958a), Wells (2007).

Genus *PLATYSMURUS* Reichenbach, 1850

2. Black Magpie

Platysmurus leucopterus

French: Geai à ailes blanches **German**: Trauerelster **Spanish**: Urraca Negra
Other common names: White-winged Magpie(!)/Jay; Black Jay, Black Crested Magpie (*aterrimus*)



Taxonomy. *Glaucopis leucopterus* Temminck, 1824, Sumatra.

Affinities uncertain; probably one of the most primitive members of the family, but has received remarkably little study. Races well differentiated, and may represent two separate species. Research, including comparative molecular studies, required. Two subspecies currently recognized.

Subspecies and Distribution.

P. l. leucopterus (Temminck, 1824) – Malay Peninsula S from extreme S Myanmar (S Tenasserim) and S Thailand, Bintan (in Riau Archipelago), Sumatra and Bangka I.

P. l. aterrimus (Temminck, 1829) – Borneo.

Descriptive notes. 39–41 cm; 178–182 g. Rather heavily built, black "jay" with moderately long and broad tail strongly graduated, rather short but stout bill with curved culmen; feathers of forecrown stiff, short and blunt, merging into nasal tuft of stiff upcurving bristles, which forms short stiff crest on each side of forehead. Nominate race has almost entire plumage black with weak green sheen, forecrown being particularly glossy; large white wing patch formed by white greater coverts, often tips of median coverts, and outer webs of tertials; iris red; bill and legs black. Sexes similar. Juvenile is duller than adult, more greyish or brownish in tone, with softer plumage, shorter and more stubby crest. Race *aterrimus* lacks white wing patch, and has taller bristly crest than nominate. Voice. Rather noisy, voice often first clue to bird's whereabouts; possibly some geographical differences, but varied vocabulary makes this difficult to assess. Calls of nominate race include harsh chattering of 8–12 notes (not unlike that of *Pica pica*), low hoarse repeated "grraah", repeated metallic ringing note, and rapidly repeated monotone bleat; also a resonating "kon-ting-kalongk" like sound of cow-bell, and xylophone-like "tok-tok telingk-klinkg-klingk". In Borneo, chattering phrase tends to be shorter, of 3–8 gruffer notes. Wings produce low throbbing "boobooboo..." sound in flight.

Habitat. Lowland forest, to 200 m in Peninsular Malaysia and Thailand, and to 800 m on Sumatra, thus chiefly in plains. Equally at home in dry forest, freshwater swamp-forest and peatswamp-forest, preferring mature or well-grown secondary growth, including paperbark trees (*Melaleuca*), and fringes of mangroves. Often around village clearings.

Food and Feeding. Omnivorous. Few details of diet, but species known to be fond of caterpillars (Lepidoptera) and beetles (Coleoptera), and doubtless takes a variety of other invertebrates; seen to dismantle small nests of bees (Apidae) in tree canopy (strongly cushioned forecrown feathering perhaps offers protection against stings). Also takes fruits, and two species of fig (*Ficus*) recorded as eaten. Feeding on small mammals reported. Often in small parties, usually of five or six individuals, keeping inside canopy, usually feeding at middle-canopy level. Very active, seemingly constantly on the move; even when perched has habit of bowing head. Flies between trees in follow-my-leader fashion; often flies over open country to get to next forest area, but does not fly high, preferring to keep within confines of canopy. Often with mixed feeding flocks of smaller birds.

Breeding. Poorly studied. Season Dec and Feb–May in Malay Peninsula; eggs reported in Jun in Borneo. Solitary breeder. Nest a relatively large platform of twigs, with shallow cup lined with finer tendrils, strips of bark and rootlets, rim area sometimes decorated with mosses and flowers, placed 1–8 m above ground inside shrubby cover or in low tree. Clutch 2–3 eggs. No further information.

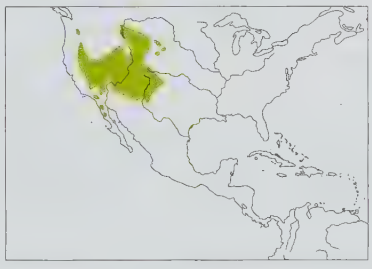
Movements. Sedentary, as far as is known.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Uncommon throughout range; extinct in Singapore. Reliance on lowland forest makes this species vulnerable to habitat destruction and distributional fragmentation. Nevertheless, its tolerance of secondary growth and the fact that it is often seen around forest clearings with human habitation suggest that prospects for its future survival must be positive.

Bibliography. Anon. (2008p), Butchart & Stattersfield (2004), Dickinson *et al.* (2004), Ericson *et al.* (2005), Glenister (1951), Goodwin (1986), Irham & Kawaji (2007), Lekagul & Round (1991), MacKinnon & Phillipps (1993), Madge & Burn (1994), Mees (1986), Robson (2000), Sheldon *et al.* (2001), Stattersfield & Capper (2000), Vaurie (1958a), Wells (2007).

Genus *GYMNORHINUS* Wied, 1841

3. Pinyon Jay



Gymnorhinus cyanocephalus

French: Geai des pinèdes **German**: Nacktschnabelhäher **Spanish**: Chara Piñonera

Taxonomy. *Gymnorhinus cyanocephalus*, Wied, 1841, Maria-River = between Marias River and Yellowstone River, Montana, USA.

Birds from Big Bear Valley (San Bernardino Mts), in California, described as race *rostratus*, but appear inseparable from those in rest of species' range. Monotypic.

Distribution. W USA from C Oregon S along arid mountain slopes of E California to extreme NW Mexico (Baja California), E to Montana and Black Hills of South Dakota, Wyoming, W Nebraska, W Oklahoma and New Mexico.

Descriptive notes. 26–29 cm; male 111 g, female 99 g. A dull blue jay with long sharply pointed bill and short tail. Male is dusty blue above, brighter blue on head, with greyer flight-feathers and black inner webs of primaries; whitish chin and throat slightly mottled darker, underparts like upperparts or slightly paler; iris dark brown; bill and legs black. Female is very like male, but smaller, with crown and cheek duller and paler blue. Juvenile has uniformly mouse-grey body feathers, blue-grey wing and tail feathers, clove-brown inner webs of primaries; immature similar to female but generally duller, and primary inner webs clove-brown. Voice. Well-studied repertoire of at least 15 calls, enabling co-ordination of activities and recognition of individuals; "near-er" calls and juvenile begging calls individually unique, and allow individual recognition of mates, parents and young, and flock-members. "Multiple racks" are graded alarm calls that shift up in pitch frequency with caller's motivation; alarm-call length does not appear to code predator identity, but combination of other calls ("near-er", "racka", "chirr") with alarm "racks" is most frequent in response to aerial predators. Only females "rattle" and "trill"; females and juveniles "chirr" when begging from mates or parents; males give nasal "ran" calls in response to female "rattle". Rambling song can last for 20 or more minutes, and given especially commonly by isolated individuals.

Habitat. Woodlands and forest where pinyon–juniper (*Pinus–Juniperus*), sagebrush (*Artemisia*), scrub oak (*Quercus*) and chaparral dominate; in C Arizona and S California, inhabits areas of ponderosa pine (*Pinus ponderosa*) and Jeffrey pine (*Pinus jeffreyi*). Also enters gardens in cities and towns.

Food and Feeding. An omnivore that specializes on pine seeds for much of year. Adults also eat variety of arthropods, including grasshoppers (Orthoptera), spiders (Araneae), Lepidoptera, beetles (Coleoptera), flies (Diptera), true bugs (Hemiptera) and small lizards. Forages in pine trees on green and ripening cones, harvesting thousands of seeds each autumn; stores seeds up to 11 km away, in small caches a few centimetres below ground; memory of cache sites well developed, allowing birds to feed on seeds throughout autumn, winter and spring. Utilizes seed feeders in gardens. Animal items obtained by feeding on the ground. Often forages in flocks in rolling waves,

On following pages: 4. Blue Jay (*Cyanocitta cristata*); 5. Steller's Jay (*Cyanocitta stelleri*).

walking and flying short distances through woodland, individuals in rear of flock "leap-frogging" to the front. Highly social, living in large co-operative, synchronized flocks of up to 500 individuals throughout year.
Breeding. Season begins early spring, from mid-Feb (even at high elevations), earliest in suburban settings, and may breed in autumn if green cones abundant. Forms socially monogamous permanent pair-bond; bonds lasting for ten years observed in the wild. Nesting colonial and highly synchronized. Co-operative breeding regular, but at low frequency; helping, by sons, apparently confined to a few, very successful family lineages; helpers do not increase reproductive success of parents, but may benefit from extended parental care. Nest built by both sexes, average size c. 111 mm wide × 65 mm deep, an outer platform of sticks, with middle layer of woven coarse grasses, and thick (46 mm) inner cup of finely shredded plant parts, feathers, horsehair and discarded human rubbish, placed in upper half of pine tree. Clutch 2–5 eggs, average 3·7–4·1; incubation by female, period 17 days; chicks fed by both adults, nestling period 21–22 days; fledglings gather in creches, guarded by a few sentries throughout day as adults forage as a flock, parents return approximately every hour to feed young synchronously; young dependent on parents for 2–3 months after fledging. In a well-studied flock, pairs produced 2–3 offspring during their four-year reproductive lifespan; nests fail during early spring snowstorms and are destroyed by variety of mammalian, avian and reptilian nest predators; pairs renest following failure and avoid locations associated with past failure (e.g. exposed sites destroyed by predators or shaded sites destroyed by snow). Females usually begin breeding when 2 years old, males at 3 years. In a well-studied suburban flock, individuals long-lived and fecund; maximum lifespan was 16 years (and male concerned sired ten yearlings).
Movements. Flocks roam widely over large areas (up to 64 km²) and each autumn travel extensively, even nomadically, in search of cone crops. When local cone crops fail, may abandon traditional ranges, settle tens of kilometres away for a year, or wander hundreds of kilometres during autumn and winter; wanders from core range NW to Washington, N to SW Saskatchewan (Canada), E to Kansas and Iowa, S to Texas, and W to coastal California and Santa Catalina I. Most individuals remain in natal flock throughout life, but females and some males disperse to adjacent flocks (3–30 km distant), especially when sex ratio in natal flock skewed in favour of own sex; dispersal of more than 600 km recorded. After nest failure, pairs may move 3–5 km and nest in smaller satellite colonies.
Status and Conservation. VULNERABLE. Locally common. Thought to have undergone rapid population decline throughout its range, apparently as a result of loss of and degradation of its pinyon–juniper woodland habitat; currently, habitat in some areas is dying from disease and drought. Because of the species' nomadic and social lifestyle, however, long-term surveys are unreliable indicators of population size. Ability to exploit bird-feeders in suburban and urban landscapes may allow jays to survive moderate loss of pinyon pine woodland. Various satellite populations exist beyond pinyon pine range in association with small-seeded pines (ponderosa pine; higher elevations of Rocky Mts and Coast Ranges) and agriculture (Idaho, Montana).

Genus *CYANOCITTA* Strickland, 1845

4. Blue Jay

Cyanocitta cristata

French: Geai bleu **German**: Blauhäher **Spanish**: Chara Azul

Taxonomy. *Corvus cristatus* Linnaeus, 1758, in America septentrionali = south-eastern South Carolina, USA.
Genus closest to *Gymnorhinus* and *Aphelocoma*. Analyses of mitochondrial DNA suggest that this species and *C. stelleri* likely split from a common ancestor over 5 million years ago (cytochrome *b* gene divergence of 10·7%). Known to hybridize with *C. stelleri*, and also with *Aphelocoma coerulescens* and *Cyanocorax yncas*. Geographical variation rather weak and clinal, and *semplei* perhaps better subsumed in nominate; review desirable. Four subspecies currently recognized.
Subspecies and Distribution.
C. c. bromia Oberholser, 1921 – S Canada from E British Columbia E to Newfoundland, S in USA from North Dakota to NE Nebraska and C Missouri and, in E, to SC Illinois, C Indiana, NE Kentucky, NE Tennessee and SC Virginia.
C. c. cyanotephra Sutton, 1935 – from SE Wyoming and Nebraska (except NE) S through E Colorado, W Kansas and Oklahoma to N Texas.
C. c. cristata (Linnaeus, 1758) – from S Missouri, S Illinois, SW Indiana, W Kentucky, Tennessee (except extreme NE), SW Virginia and North Carolina S to SE Texas, coastal Gulf of Mexico and C Florida.
C. c. semplei Todd, 1928 – S half of Florida (S from Hillsborough and Osceola counties).

Descriptive notes. 25–30 cm; 70–100 g. Small jay, blue, white and black with distinctive but short erectile crest, medium-long graduated tail, and grey to blue rictal bristles covering nostrils. Nominate race is dull blue above, often with purplish wash, crest purple-blue; facial area and throat grey to white, narrow black collar extends upwards to form black band on nape, black eyestripe joining black lores to black nape; bluish-white nasal tuft; upperwing and tail bright sky-blue, marked with narrow black bars and white tips (especially prominent white tip of tail in flight); breast and flanks grey, fading to white on vent; iris dark brown; bill and legs black. Sexes similar, male slightly larger than female. Juvenile has blue areas of plumage greyer, especially on back, nape and crest, white tips of tail more restricted, black markings browner than those of adult, barring on wing-coverts less distinct, bars on secondaries and tail less regular, and legs and feet paler and greyer. Race *bromia* is largest, is darker and brighter blue above than nominate, more extensive white markings on wing and tail; *cyanotephra* is intermediate in size between previous and nominate, with dull pale blue upperparts without purplish wash, extensive white in wing and tail; *semplei* is small, and said to be more white than grey on breast and flanks, less blue on lower throat, and paler, duller and less purple above than nominate, with soles yellow (not black). VOICE. Large vocabulary of graded calls, divided into five broad categories. (1) "Jeers" are harsh, loud, harmonically structured calls used for assembly, mobbing and perhaps as contact; extensive gradation in intensity, higher-pitched and louder calls probably associated with increasing degree of alarm. (2) "Pump-handle" calls are clear, musical, multisyllabic whistles like sounds made by handpumps, pulleys and squeaky gates, and often used to indicate low-intensity alarm. (3) Contact calls between mates are soft, guttural clucks, "chuck" notes, and, when excited, "whines"; begging calls included in this group. (4) "Rattle" calls are series of rapid, dry, raspy clicks, often given by excited females. (5) Other calls include noises made when swallowing food, "squacks", soft song, and "peeps". Extensive mimicry, especially of raptors.
Habitat. Forest and woodland, whether coniferous, deciduous or mixed, with openings and extensive edge. Closely associated with mast-bearing trees, especially oaks (*Quercus*); common in towns where mast trees planted. Utilizes shelter-belts and human settlements across Great Plains.
Food and Feeding. Omnivorous, but seasonal specialist on mast crops. Large sample of stomach contents from 1920s contained 22% insects, 43% hard mast (mostly acorns, but also beechnuts, hickory nuts and hazelnuts), 7% wild fruits, and traces of cultivated grain, fruit, and bird eggs and nestlings. Other small vertebrates known to be taken are mice (Muridae), bats (Chiroptera), frogs, lizards; carrion eaten, especially in winter. Each individual caches thousands of nuts each autumn from areas within 4 km of breeding site; small groups of nuts (2–5 acorns, 15 beechnuts) transported in throat, oesophagus and bill from harvest site to cache area, where individually buried within a few metres of each other; spatial memory of this corvid well developed, and likely an important adaptation allowing efficient cache recovery. Sophisticated forager, known to form search images and to use vegetative characteristics to aid detection of cryptic prey, to switch foraging patches after prey locally depleted, and to make tools to obtain items otherwise out of reach (in the laboratory). Found mostly in pairs or family groups in spring and summer, but often in small flocks (up to 30 individuals) at reliable food sources or when harvesting mast during autumn and winter.
Breeding. Nest-building begins in mid-Mar, and laying from early Apr in S to mid-May in N of range. Long-term socially monogamous pair-bond. Solitary breeder, non-territorial; dominance interactions between neighbours subtle. Male collects most of nest material, but female does most of building work and may select nest-site; nest a bulky structure with coarse outer platform (17–21 cm diameter, 10–12 cm deep) of fresh twigs, lichens, moss and, when available, bits of rubbish and debris (including paper, plastic, string, cloth), layer of mud on coarse sticks is lined with rootlets and sometimes partially decomposed leaves, inner cup 8·5–10·5 cm wide and 6 cm deep; placed 1–30 m or more above ground in tree or, rarely, in shrubs or on building. Clutch 2–7 eggs, typically 4–6 in N range and 3–4 in Florida; incubation by female, fed on nest by male, period 17–18 days; chicks brooded by females for 8–12 days, nestling period 17–21 days; juveniles disperse from family group c. 2 months after fledging, dispersal behaviour poorly known, but confirmed natal dispersal of 2–3 km. Recorded longevity 18 years in the wild and 26 years in captivity; annual survival rates c. 50%.
Movements. At least some individuals resident in all parts of range. Except in extreme S, up to probably not more than 20% of population migratory; N race *bromia* makes post-breeding movement S through Oregon, E Texas, S Louisiana, C Alabama and NE Georgia. Autumn migration primarily from mid-Sept to late Oct and often concentrated along major rivers; one instance of offshore migration along barrier islands of Gulf Coast resulted in large mortality. Spring passage primarily from late Apr to late May, less conspicuous and less concentrated along major rivers than autumn migration. Migrates in small groups or loose strings mainly along SW–NE axis, during day, and from treetop level to 300 m above ground; sometimes forms large flocks of hundreds of individuals during migration. In winter some vagrants or migrants seen irregularly outside normal range, especially during "invasion" years when acorn crops fail, e.g. in 1976–1977 and 1990–1991 recorded W to S British Columbia, W Washington, W Oregon and N California; irregular Montana, Idaho, WC Nevada, Utah, Arizona, New Mexico and W Texas. Two reports from Bermuda.
Status and Conservation. Not globally threatened. Common throughout range. Density variable with habitat, 7–28 pairs/100 ha; densities in towns may exceed those in forested areas. Has bred once in Oregon (Union County). Range extensions to W increasingly common since 1970s, and often associated with small towns, cities and other human activities. Slight decline (1·7% from 1966 to 1996) in E of range. Susceptible to West Nile Virus, which locally depleted some E populations during 1999–2002 and resulted in a region-wide decline of up to 26%, before numbers recovered in 2005. Ability of most yearlings to breed when local population density is low may allow this species to recover rapidly from years of exceptionally high mortality.

5. Steller's Jay

Cyanocitta stelleri

French: Geai de Steller **German**: Diademhäher **Spanish**: Chara de Steller

Taxonomy. *Corvus stelleri* J. F. Gmelin, 1788, in Sinu Natka Americae borealis = Nootka Sound, Vancouver Island, British Columbia, Canada.
Genus closest to *Gymnorhinus* and *Aphelocoma*. Analyses of mitochondrial DNA suggest that this species and *C. cristata* likely split from a common ancestor over 5 million years ago (cytochrome *b* gene divergence of 10·7%). Occasionally hybridizes with *C. cristata*. Race *suavis* intergrades with *lazula*; latter poorly differentiated, possibly better merged with *ridgwayi*; also, *teotepecensis* and *ridgwayi* subsumed in *coronata* by some taxonomists. Sixteen subspecies currently recognized.
Subspecies and Distribution.
C. s. stelleri (J. F. Gmelin, 1788) – S Alaska and coastal British Columbia S to NW Oregon.
C. s. carlottae Osgood, 1901 – Queen Charlotte Is (off British Columbia).
C. s. annectens (S. F. Baird, 1874) – Rocky Mts of interior British Columbia and SW Alberta (Canada) S in USA to E Washington, Idaho, Montana, E Oregon and Wyoming.

C. s. frontalis (Ridgway, 1873) – C Oregon S through mountains to E California and WC Nevada.
C. s. carbonacea Grinnell, 1900 – N California (counties of Marin, Contra Costa and Monterey).
C. s. macrolopha S. F. Baird, 1854 – S Rocky Mts from SW South Dakota S to Utah, Nevada, Arizona and New Mexico, E to Nebraska and W Texas, and S to N Mexico (N Sonora and Chihuahua).
C. s. diademata (Bonaparte, 1850) – Sierra Madre Occidental from SE Sonora and SW Chihuahua S to Durango and Jalisco; also E Nuevo León.
C. s. phillipsi Browning, 1993 – C Mexico (SC San Luis Potosí).
C. s. purpurea Aldrich, 1944 – SC Mexico (N & C Michoacán).
C. s. coronata (Swainson, 1827) – E Mexico (SE San Luis Potosí and N Veracruz S to Puebla).
C. s. azteca Ridgway, 1899 – WC Veracruz S to México, Morelos and W Puebla.
C. s. teotepecensis R. T. Moore, 1954 – high mountains of C & S Guerrero, in S Mexico.
C. s. restricta A. R. Phillips, 1966 – Oaxaca, in S Mexico.
C. s. ridgwayi W. deW. Miller & Griscom, 1925 – highlands of SE Mexico (Chiapas) and adjacent Guatemala.
C. s. lazula van Rossem, 1928 – El Salvador and SW Honduras.
C. s. suavis W. deW. Miller & Griscom, 1925 – highlands of E El Salvador, Honduras and N Nicaragua.

Descriptive notes. 30–34 cm; 100–142 g. A robust, vibrant blue-and-black jay with flashy crest that is erected to convey dominance and aggression; short, stout bill slightly hooked at tip. Male nominate race has dark bluish-black head and crest, small light blue streaks on forehead; neck and mantle bluish-black, upperwing dark blue with thin black barring, tail indigo with narrow black barring; throat paler blue and grey-streaked; upper breast dark blue-grey, rest of underparts blue; iris dark brown; bill and legs black. Female is similar to male but slightly smaller, with narrower and less prominent barring on wing and tail. Juvenile differs from adult in having shorter crest which lacks stripes, pale blue wings and tail, greyer underparts, and pale bill. Races differ mainly in size and coloration, N races with head, crest and back black, most S races with these areas blue, S races also smaller: *carlottae* is largest and darkest, head and crest jet-black, mantle and back also black, body colour variable, mostly light to dull blue or purple, distinct barring on wing and tail; *annectens* is similar to nominate, but has silvery spot above eye, greater contrast between blue mantle and back and black-blue head and crest; *frontalis* has greyish-black head to back, crest with blue-tinged top, blue streaks on forehead extend over crown; *macrolopha* has jet-black face and long glossy black crest contrasting sharply with grey mantle and back, large grey throat patch extending to upper breast, distinct white stripe over eye and white spot below eye; *carbonacea* has black crest, no white spot over eye, blackish-grey upperparts, contrasting sky-blue underparts; *diademata* has white to blue-white forehead spots, grey back, long jet-black crest, sky-blue underparts; *phillipsi* has blue crest with long pale stripes at front, dull blue upperpart and underparts; *purpurea* has deep blue crest, blue to ultramarine-blue mantle and back, small grey throat patch, grey ventral area blending to dark blue undertail; *coronata* has long blue crest, whitish-purple marks on front of crest and crown, black cheeks and face contrasting with ultramarine-blue upper throat, and greyish-blue back with light blue rump; *azteca* has black crest, cheeks and throat contrasting with grey-blue mantle, extensive white above and below eye, purplish-blue wings and tail; *teotepecensis* resembles *purpurea* but is less purple, with crest richer blue, and has conspicuous white throat patch; *restricta* has short blue crest with pale blue at front, and light blue body; *ridgwayi* has ultramarine-blue crest, purplish-white forehead streaks, distinct grey-white throat, white patches above and below eye, and mostly dull blue body; *lazula* closely resembles previous, from which possibly not distinct; *suavis* has ultramarine-blue crest and back, pale blue throat and underparts, small greyish throat patch. Voice. At least twelve distinct calls, along with flock-specific calls and frequent mimicked sounds (e.g. of other animals, especially raptors). Many guttural notes given at close range. "Aap" calls are given in variety of social contexts and vary in intensity, likely indicating caller motivation; at highest intensity, associated with agonistic wing-spreading behaviour. "Wek" calls are strung together in sequences of up to five per second, call rate graded to indicate aggression and alarm. "Wah" calls and "growls" indicate aggression and may be used during mobbing. Only male gives "creak" note, often in association with female-specific "rattle" call. Whistles, gurgles, snaps, pops, and harsh notes are combined into songs often lasting several minutes, and rendered mostly by males.

Habitat. Forests and woodlands, including deciduous forest, temperate rainforest and humid coastal forest with Sitka spruce (*Picea sitchensis*), western red cedar (*Thuja plicata*), redwood (Cupressaceae), fir (*Abies*) and hemlock (*Tsuga canadensis*) from Alaska S to W California; dry ponderosa pine (*Pinus ponderosa*) and lodgepole pine (*Pinus contorta*) forests and pinyon–juniper (*Pinus–Juniperus*) woodlands of Rocky Mts and isolated western ranges; mixed conifer, oak (Quercus), and eucalypt (*Eucalyptus*) forests in coastal California; pine–oak woodlands from SW USA S to Central America. Common around homes in wild and suburban settings; frequents picnic and camping areas in forested landscapes. Most abundant in fragmented, patchy forested landscapes including rich mosaics of variously aged forests with little or no human settlement; at lower densities in settled landscapes, even those with small towns and suburbs.

Food and Feeding. Omnivorous. Takes fruits, seeds, berries, arthropods, small vertebrates, and discarded household scraps (e.g. bread, meat); preys on nestlings and eggs of other birds incidentally while foraging for common food items (arthropods and plant material), eggs may be especially important early in nesting season. Routinely takes offerings at feeders, especially during autumn and winter. Caches surplus food and, where available, harvests large seeds of pinyon and whitebark pine (*Pinus albicaulis*), which it transports up to 3 km and stores mostly as single seeds; pine seeds and acorns likely recovered during late autumn and winter. Finds own caches by using spatial memory; pilfers caches made by other birds and mammals by observing them when they cache and remembering the location. Forages on ground and in vegetation. Lives mostly in pairs, or in family groups for a few months, but may form flocks at locally abundant food sources outside breeding season. Associates with *Aphelocoma* jays and *Gymnorhinus cyanocephalus* during autumn and winter in SW USA.

Breeding. Nest-building begins in Mar and reaches peak in Apr throughout C of range, eggs mid-Mar to mid-Jul. Pair-bond appears stable and permanent, but not studied in depth. Defends small area of dominance near nest. Nest built by both sexes, a bulky structure with coarse twig outer platform 25–43 cm wide and 15–18 cm tall, middle layer of mud and plant material, and lining of pine needles, rootlets and hair (11–13 cm in diameter, 6–9 cm deep), placed 2–25 m above ground in central, dense part of tree, or on artificial structure e.g. roof support or outbuilding wall; may interrupt nest-building if mud unavailable. Clutch 2–6 eggs, mean 3 (often 4 in first nest of season); incubation by female only, fed on and off nest by male, period 16 days; chicks fed by both parents, nestling period 16 days; young fed by both adults for 1–2 months after fledging. Success rate in mostly forested landscapes high, e.g. 16 of 25 pairs fledged 1–5 offspring (mean 2·9 fledglings) in Washington temperate rainforests, but in nearby suburban landscapes low (1 of 9 nests fledged young). Age of first breeding likely 2–3 years. Maximum recorded lifespan in wild 16 years.

Movements. Resident. May make eruptive movement in poor food years or migrate seasonally from high to lower elevations. Movements of 50 km unusual, but occasionally recorded E into Saskatchewan and Quebec (Canada), South Dakota, Illinois, Kansas and Texas, and S into Baja California (NW Mexico).

Status and Conservation. Not globally threatened. Common. Most populations appear locally stable or increasing slightly. Lives in variety of human-dominated landscapes, including those with urbanization and where lands used for forestry, where it thrives in mature forest as well as edges and patchy regenerating forest. Routinely visits bird-feeders, but density and reproduction lower in suburban areas than in nearby mostly forested areas. Threatened with extirpation in El Salvador owing to habitat loss. In temperate portions of range may pose a conservation threat to other, rarer birds by preying on eggs and nestlings, e.g. those of Marbled Murrelet (*Brachyramphus marmoratus*) in far NW of range.

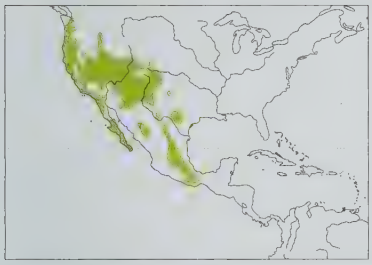
Genus *APHELOCOMA* Cabanis, 1851



6. Western Scrub-jay

Aphelocoma californica

French: Geai buissonnier **German**: Kalifornienhäher **Spanish**: Chara Californiana
Other common names: Scrub/California Jay; California Scrub-jay ("nominate group"); Woodhouse's Scrub-jay ("*woodhouseii* group"); Sumichrast's Scrub-jay (*sumichrasti*, *remota*)

Taxonomy. *Garrulus californicus* Vigors, 1839, Monterey = Monterey County, California, USA. May form a superspecies with *A. insularis* and *A. coerulescens*, and the three previously treated as conspecific. Relationships of this group with *A. ultramarina* and *A. unicolor* yet to be resolved, as recent studies indicate that divergence of these three major lineages within the genus was apparently rapid, leading to conflict among genetic markers. Present species hybridizes with *A. coerulescens* in captivity and may perhaps hybridize with *Cyanocitta stelleri* in the wild. Subspecies fall into three fairly well-defined groups, "nominate group" (incorporating also *immanis*, *caurina*, *oocleptica*, *obscura*, *cana* and *hypoleuca*), "*woodhouseii* group" (incorporating also *nevadae*, *texana*, *grisea* and *cyanotis*), and "*sumichrasti* group" (with *remota*); these possibly represent three distinct species. Race *cana* is possibly merely a hybrid between nominate race and *obscura*; *immanis*, *caurina* and *oocleptica* sometimes subsumed in nominate. Proposed race *cactophila* (from C Baja California, in NW Mexico) synonymized with *hypoleuca*; birds from SC USA and NC Mexico described as *suttoni*, but considered inseparable from *nevadae*. Fourteen subspecies currently recognized.

Subspecies and Distribution.
A. c. immanis Grinnell, 1901 – NW USA (W Washington, coastal and interior Oregon).
A. c. caurina Pitelka, 1951 – from coastal S Oregon S to California (Napa and Sonoma Counties, and E to inner Coast Ranges).
A. c. oocleptica Swarth, 1918 – SC Oregon S to interior C California (including Sacramento and San Joaquin Valleys and adjacent Coast Ranges S to San Francisco peninsula), Sierra Nevada foothills and E to W Nevada.
A. c. californica (Vigors, 1839) – Coast Range of C California (from San Mateo County and SE Alameda County S to SW Ventura County).
A. c. obscura Anthony, 1889 – SW California (highlands of Mojave Desert) and extreme NW Mexico (N Baja California).
A. c. cana Pitelka, 1951 – Eagle Mt, in Joshua Tree National Park (SE California).
A. c. hypoleuca Ridgway, 1887 – C & S Baja California.
A. c. nevadae Pitelka, 1945 – interior SW USA (throughout Great Basin, mountains in Death Valley and Mojave Desert, and SW New Mexico) S to N Mexico (NE Sonora and NW Chihuahua).
A. c. woodhouseii (S. F. Baird, 1858) – foothills of Rocky Mts from Utah and S Wyoming S to N Arizona and Colorado, E to W Oklahoma and Texas (including Big Bend), and N Mexico (N Chihuahua).
A. c. texana Ridgway, 1902 – Edwards Plateau (WC Texas).
A. c. grisea Nelson, 1899 – NW Mexico (Sierra Madre Occidental, mostly in Chihuahua).
A. c. cyanotis Ridgway, 1887 – E Mexico (lower Sierra Madre Oriental).
A. c. sumichrasti (Ridgway, 1874) – S Mexico (Distrito Federal E to Veracruz, Oaxaca and Isthmus of Tehuantepec).
A. c. remota Griscom, 1934 – SW Oaxaca and C Guerrero, in S Mexico.

Descriptive notes. 28–30 cm; 70–100 g. Small, crestless jay with long tail, plumage blue, grey and white; bill varies from stout, short and hooked (where populations rely on acorns) to long, tapered and sharp (where seeds of pinyon pine consumed). Nominate race has crown and neck deep violet-blue, ear-coverts dark grey suffused with blue, narrow white supercilium, grey-streaked white throat, nearly complete blue collar below throat; mantle dull greyish-brown, rest of upperparts bright blue, upperwing and tail dark dull blue; breast grey, rest of underparts white, undertail-coverts (especially longest ones) tinged with blue; iris brown; bill heavy and hooked (acorn-eater), black; legs black. Sexes similar, female slightly paler and duller than male. Juvenile differs from adult in having grey to brown head with only slight superciliary stripe, less pronounced white throat, barely discernible collar, and shorter bill. Races differ mainly in depth of coloration, "nominate group" (nominate and first six below) generally brightest and darkest, with most distinct supercilium, "*woodhouseii* group" duller and lighter blue with less distinct collar and less contrast between dull blue hood and grey-brown back, also generally larger but bill smaller, and "*sumichrasti* group" (last two below) largest and palest, with supercilium and breastband barely discernible: *immanis* is larger than nominate, but with proportionately shorter wing and tail, less purple overall and back brown more than grey, dark blue dorsal plumage contrasts strongly with ventral white, undertail-coverts of most males tinged pale blue or grey; *caurina* is similar to nominate in size and plumage, but more purple (especially on head), darker grey back, and darker smoke-grey breast; *oocleptica* is larger than nominate, dark in W of range, paler in E (where purple less pronounced, especially around head), undertail-coverts mostly white, only few individuals having blue tinge; *obscura* is smaller and darker (with more purple) than nominate, throat more heavily streaked, undertail-coverts often tinged with blue, and wing and tail brighter blue; *cana* is smaller and duller than nominate, with bill less heavy (exploits small pine seeds); *hypoleuca* is smaller and lighter coloured (with less purple) than nominate, with paler back, whiter belly, bill proportionately longer than that of others in group; *woodhouseii* has head and neck dull blue, back brownish-grey, abdomen grey, undertail-coverts bluish-grey, tapered, pointed bill; *nevadae* has head and neck duller blue than last, long narrow bill with little or no hook (reliance on pinyon pine seeds); *texana* has slightly darker blue plumage than *woodhouseii*, with narrow but contrasting collar between white throat and upper breast, browner breast, whiter belly, large white area around cloacal region, bill heavier and more hooked, juvenile paler than *woodhouseii*; *grisea* is lighter overall and larger, with longer wing and shorter bill than *woodhouseii*, slight collar, white undertail-coverts; *cyanotis* is similar in size to previous, has blue duller and less purple than *woodhouseii*, back mostly brown and supercilium faint, undertail-coverts white, sometimes tinged grey, wing longer and bill shorter and heavier than *woodhouseii*, juvenile pale and browner on breast than *texana*; *sumichrasti* is very large, has bright blue head and neck, velvety black auriculars, reduced white supercilium, dark grey-blue wings and tail, bright blue uppertail-coverts, chin to mid-breast streaked pale grey, faint collar, heavy bill with short hook; *remota* is similar to last but slightly larger, with duller and lighter blue plumage, greyer and lighter back, and even less evident collar. Voice. Large repertoire of at least 15 call notes, begging, and soft song. Courting and solitary individuals sing. Territory defended with "weep", "screlch", "shlenk" and "nhyuk" calls. Predators mobbed with "scold", "zeep", "zraanh" and "shlank" calls. At high intensity, "distress screech" used in mobbing. Males give "chuk" and females "rattle" during territorial interactions. Partners communicate with "wheeze", "snarl", "kuk", "poit" and "wah" calls. Further study required, including details of geographical, motivational, contextual and individual variation.

Habitat. Mixed oak (*Quercus*), pine (*Pinus*) and juniper (*Juniperus*) woodlands, scrublands, chaparral, and brushlands; reliant on acorns or large seeds of pinyon pine that occur throughout these habitat types. Exceptions to close association with pines and oaks are notable: pure mountain mahogany (*Cercocarpus*) shrubland and chaparral in California, Nevada and Oregon; pure juniper in S Wyoming, Oregon and Idaho; high montane pine–spruce (*Pinus–Picea*) forests in N Baja California (Sierra San Pedro Mártir); desert riparian and cactus forest in S Chihuahuan Desert; palmetto and thorn-scrub in Oaxaca; and mangrove (*Rhizophora mangle*, *Laguncularia racemosa*, *Avicennia germinans*) swamps in Bahía de Magdalena region of S Baja California. Able to thrive in human-dominated areas if shrubs or trees available, and if feeders, cultivated grains and fruits, poultry eggs or household scraps provided.

Food and Feeding. Omnivorous, but seasonal specialist on pine and oak crops throughout most of range. Takes fruits, seeds, invertebrates, small vertebrates including mice (Muridae), lizards, snakes, small birds and nest contents, also carrion and, where available, discarded scraps and other household fare. Large sample of stomach contents from early 1900s in agricultural area of California contained 38% acorns, 23·5% insects, 22% fruit including cultivated cherry and plum (*Prunus*) and wild elderberry (*Sambucus*), 12% grain (mostly oats and corn), 3·5% small vertebrates (small mammals, reptiles, amphibians, bird eggs and nestlings). Stomach analyses and observational studies in Arizona and California confirm importance of acorns in diet. Stores acorns and pine seeds within territory, or in home range (of non-territory-holding "floaters"), for use throughout winter and early spring, caching 5000–7000 seeds each autumn; on each trip from harvest to caching grounds transports a few seeds (1–5) in mouth or bill 1–500 m, and usually one seed at a time cached in ground. Uses spatial memory to recover seeds, but landmarks and sun-compass may be used to orient to caches. Experienced cachers, which have pilfered caches of others, avoid possible loss of own caches by moving them when observed; when storing perishable and non-perishable items, recovers perishable items first. Forages on the ground and in shrubs. Mostly in pairs or, for brief post-fledging period, in family groups. Floaters may form small aggregations of 5–15 individuals (in Arizona) or up to 30 (California), within moderate-sized home range (average 21 ha), but membership of these flocks changes frequently.

Breeding. Nest-site selection and start of nest-building in late Feb to early Mar in N California, and laying from late Mar to early Apr; repeated nesting after failure, occasionally second broods, or possible late nests (when acorn crops superabundant) can result in active nests as late as Sept. Long-term socially monogamous pair-bond. Single pair defends all-purpose territory, using combination of flight and vocal displays; territory size varies, but generally small, 0·7–6·5 ha. In N Oaxaca (S Mexico), more than 60% of territories (mean size 1·5 ha) defended by groups of 2–6 adults, which exhibit co-operative behaviour, including feeding of fledglings; helpers at nest rare in this co-operative population, in which singular breeding the norm. Bulky nest has coarse outer platform 15 cm in diameter and 9 cm deep, of twigs and rootlets, lined with plant fibre, rootlets and animal hair, inner cup 10 cm wide and 5 cm deep, placed 2–4 m above ground in tree, vines or shrub. Clutch 1–5 eggs (typically 4–5 in N of range, 2–3 in Baja California); incubation by female, fed by male, period 16–18 days; chicks brooded by female, nestling period 17–24 days; juveniles disperse from family group c. 6–9 weeks after fledging. Success rate in California typically high, and older breeders more successful than naive ones, but average productivity of 0·84 independent young per pair per year. Longevity in wild at least 15 years 9 months; average annual survival rates in California 83% for males and 78% for females.

Movements. Resident throughout range. Pairs may wander to harvest nuts and other food bonanzas; floaters may generally move to more productive feeding locations or lower elevations during autumn and winter. In N Arizona and New Mexico, large numbers may move to lower-elevation desert shrublands and riparian areas during winter; in California, some territories abandoned after mast-crop failure (half are then reoccupied by previous owners during breeding season). Irruptive movements following poor acorn and pine-seed production occasional, coincident with those of other seed-eating corvids. Dispersal of ringed and radio-tagged individuals studied in N California: males disperse farther than females, and many birds breed within 6 km of natal territory; others traverse longer distances (at least 40 km) before settling to breed.

Status and Conservation. Not globally threatened. Common throughout range; rare in Eagle Mts of California, where race *cana* listed as a California species of special concern. Populations stable to slightly increasing where annually assessed, i.e. 1% annual increase from 1966 to 2000 in N of Mexico. Distribution on W coast has been moving gradually northwards. Vulnerable to exotic diseases, which are increasingly common within this species' range; these include West Nile Virus, which is deadly to most corvids. Vulnerable also to effects of Sudden Oak Death and loss of pinyon woodlands to drought and fungus, which can reduce oak and pine mast.

7. Island Scrub-jay

Aphelocoma insularis

French: Geai de Santa Cruz **German**: Inselhäher **Spanish**: Chara de Santa Cruz
Other common names: Santa Cruz Jay

Taxonomy. *Aphelocoma insularis* Henshaw, 1886, Santa Cruz Island, California, USA.
May form a superspecies with *A. californica* and *A. coerulescens*, and the three previously treated as conspecific; present species derived from coastal clade of former. Relationships of this group with *A. ultramarina* and *A. unicolor* yet to be resolved, as recent studies indicate that divergence of these three major lineages within the genus was apparently rapid, leading to conflict among genetic markers. Monotypic.
Distribution. Santa Cruz I (SW California), in SW USA.

Descriptive notes. 33 cm; male 100–147 g, female 100–117 g. Smallish, crestless, long-tailed jay, primarily grey-blue in colour, with disproportionately large bill, broad head, long legs. Male has dull ultramarine-blue crown, nape, upperwing and tail, contrasting white chin, throat and upper breast, nearly complete blue collar below throat; black face, thin white supercilium; upperparts dark brownish-grey with blue tinge; lower breast and below greyish, bluish undertail-coverts; iris brown; bill and legs black. Differs from *A. coerulescens* mainly in larger size, relatively larger bill, longer legs, deeper blue coloration and darker brown back. Female is is like male, but paler. Juvenile is brownish-grey with blue-tinged crown and dark dull blue wings and tail; immature similar to adult, except that greater primary coverts edged brown, outer primaries and tail feathers rounded or bluntly pointed, feathers of alula sharply pointed. Voice. Extensive repertoire of at least eleven calls. Both sexes defend territory with loud, harsh "shek-shek-shek"; female often responds to male "shek-shek-shek" with staccato clicking and warbling "rattle". Series of "chiop" calls by male in aggressive territorial disputes. When agitated, gives "screech scolds" to mob predators; loud, raspy "distress screech" used for high-intensity mobbing. Female and young beg from mate and parents with "wah" note. Quiet "warble-song" may last 10 seconds, given by territorial males and females. Quiet "vrrt" for contact among adults, and "peep" by nestlings when gaping for food.
Habitat. Preferentially inhabits chaparral dominated by low-growing oak (*Quercus*), and oak woodland; found also in other woodland types, even relict pine (*Pinus*) forest, and shrublands, including sage (*Artemisia*) brushlands; driest areas of island (grasslands) and marine terraces utilized the least, and primarily by non-territorial floaters. Exploits greater diversity of habitats than *A. coerulescens*, but lesser diversity than *A. californica*.
Food and Feeding. Omnivorous. Diet includes acorns, invertebrates, and occasional small vertebrates; takes bird eggs and nestlings. Acorns a very important component of diet, especially in autumn. Caches acorns individually; also caches lizards and small mice (Muridae). Forages by gleaning as it hops on ground and through trees; searches under objects, and flycatches emerging insects. Appears to watch other breeding birds to learn where nests are, prior to preying on their contents. Singly and in pairs; non-breeders may form flocks.
Breeding. Laying from early Mar to early Jun, nestlings Apr to mid-Jun. Socially monogamous, pair-bond mostly permanent (c. 10% of bonds break annually, despite survival of both partners); no helpers at nest. Breeding pair defends all-purpose territory throughout year; territory size 0·6–2·2 ha (smaller than that of scrub-jays on California mainland), largest where least oak woodland present. Aggressive interactions subtle, consist mostly of territorial vocalizations by pair, rapid bobbing of head and torso, and undulating flight. Bulky nest built by both pair-members, of live oak twigs, lined with rootlets or horsehair, outer cup c. 30 cm in diameter and 15 cm tall, inner cup 10 cm in diameter and 7 cm deep, placed 2–3 m above ground in bush or tree. Clutch 2–5 eggs (mode 4); incubation by female, period 18 days; chicks fed by both parents, no information on duration of nestling period; young tended by both parents for 4–7 weeks after fledging. Age of first breeding ranges from 1 to 6 years, mostly 4 years, much later than for *A. californica*.
Movements. Resident. Occasionally moves up to 650 m to local food resources, e.g. fruiting oak trees. Non-breeders roam widely across island.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Global population conservatively estimated in 1997 at 12,500 individuals, with (7000 breeders), but currently at 9000 individuals (7000 breeders). Despite these numbers, species considered potentially at risk because of small range; restricted to Santa Cruz (250 km²), in California Channel Is. Degradation of native oak vegetation by invasive species, overgrazing by introduced sheep and pigs, and erosion threaten to reduce this species' population size. These threats now being managed and overgrazing controlled in order to maintain this and other unique native species.
Bibliography. Anon. (2008p), Atwood (1978, 1980a, 1980b), Atwood & Collins (1990), Atwood *et al.* (1990), Bridge *et al.* (2008), Butchart & Stattersfield (2004), Corey (1994), Curry & Delaney (2002), Curry *et al.* (2002), Delaney *et al.* (2008), Ericson *et al.* (2005), Espinosa de los Monteros & Cracraft (1997), Haemig (1989b), Isitt (1989), Kelsey (1998), Kelsey & Collins (2000), Peterson (1992a), Peterson, Martínez-Meyer & González-Salazar (2004), Pitelka (1951c), Rice *et al.* (2003), Saunders & Edwards (2000), Stattersfield & Capper (2000).

8. Florida Scrub-jay

Aphelocoma coerulescens

French: Geai à gorge blanche **German**: Floridahäher **Spanish**: Chara Floridana
Other common names: Florida Jay

Taxonomy. *Corvus coerulescens* Bosc, 1795, in Amer. septentrionale = Florida, USA.
May form a superspecies with *A. californica* and *A. insularis*, and the three previously treated as conspecific. Relationships of this group with *A. ultramarina* and *A. unicolor* yet to be resolved, as recent studies indicate that divergence of these three major lineages within the genus was apparently rapid, leading to conflict among genetic markers. Present species hybridizes with *A. californica* (in captivity), and recorded as hybridizing once with *Cyanocitta cristata*. Monotypic.
Distribution. Peninsular Florida, in SE USA.
Descriptive notes. 26 cm; male 79·3 g, female average 75 g. A moderate-sized, crestless, long-tailed jay with stout hook-tipped bill. Has dull purplish-blue head with frosty white forecrown blending into superciliary region, white throat finely streaked blue; upperparts pale grey-brown, rump, uppertail-coverts and tail dull blue, upperwing dull blue, primaries tipped dull, dark grey;

blue necklace separating whitish throat from grey breast and belly, flanks faintly streaked brownish, undertail-coverts blue; iris brown; bill and legs black. Differs from other scrub-jays mainly in having white forecrown merging into superciliary area (rather than clearly defined white supercilium), paler back. Sexes similar, female slightly smaller and paler blue than male. Juvenile differs from adult in having dull, dark brown head, duller wings and tail, and dull brown scapulars, median and marginal upperwing-coverts and uppertail-coverts, initially has brownish bill, yellow gape, and brownish-black legs; older juvenile best distinguished from adult by dull brown tips of greater primary coverts. Voice. Large vocabulary of graded calls. Loud "weep", often in series of variable length and cadence, for territory defence. Single "kweep!" may warn group-members of predator near dependent young; series of "kweep!" warns of aerial predators; grating, repeated "screech scold" against ground or perched predators. Aggressor gives short guttural "attack growl" just prior to physical contact with another jay; "snarl" given before predator attacked during nest defence; soft "chiop" may indicate anxiety during territorial defence. Relaxed adults and juveniles combine whistles, chirps and guttural notes into soft "warble-song". Low, raspy "kuk" before food or nest material exchanged. Young nestlings "peep"; older nestlings, dependent young and nesting females utter "waah" while begging. Female gives mechanical series of "hiccup" when agitated, perhaps analogous to rattle of congeners.
Habitat. Isolated patches of oak (*Quercus*) scrub on sandy ridges; avoids pine (*Pinus*) forest, but occurs in housing developments within oak scrub. Unique, fire-dependent habitat dominated by short (less than 3 m) evergreen oak shrubs (five *Quercus* species), rusty lyonia (*Lyonia ferruginea*) and Florida rosemary (*Ceratiola ericoides*), sparse ground cover including palmetto (*Serenoa repens* and *Sabal etonia*); bare sand important for foraging and caching. Good drainage results in habitat that is dry, despite being in areas with more rainfall than environments used by other *Aphelocoma* species.
Food and Feeding. Omnivorous. Variety of plant foods includes berries, acorns, pine seeds; arthropods, including grasshoppers and bush-crickets (Orthoptera), wasps and bees (Hymenoptera), ticks (Ixodoidea), lepidopteran larvae, spiders (Araneae); small vertebrates, e.g. snakes, lizards e.g. green anoles (*Anolis carolinensis*), tree-frogs, nestling birds, eggs including those of conspecifics, mice (Muridae); also takes carrion, and human subsidies (notably peanuts and other seeds at birdtables). Focused on acorn harvest and caching during Aug–Dec. Scatter-caches 6500–8000 acorns mostly within territory each autumn; recovery of stores especially important in late winter and early spring, when arthropods less available. Routinely inspects and moves acorn caches. Caches also animal parts and bird eggs (perhaps only short term), but above ground in vegetation. Searches for food in dry parts of territory, including shrubby oaks, grassy road margins, palmettos; hunts edges of seasonal ponds for reptiles and amphibians, especially during winter. Often listens for prey and creeps under and into vegetation, probing for insects and small vertebrates; will pursue prey by flycatching or attempt to flush prey by beating vegetation with wings and feet. May opportunistically hunt co-operatively for medium-sized snakes.
Breeding. Nest-building Feb to late Apr (most in Mar), and eggs late Mar to May, earlier in suburban settings; normally only one brood per year, but 30–40% of suburban pairs attempt second brood after fledging a first, although very few successful. Forms long-term monogamous pair-bond in permanent all-purpose territory; territory 4–20 ha (average 8–9 ha) in wildlands, suburban territories can be especially small (5 ha) where permanent sources of human-provided food utilized. Solitary or co-operative breeder, with up to six pre-breeding helpers (typically yearling males or females from previous breeding season), occurrence of helping varies annually (27–80% of pairs; average 52% of pairs in optimal habitat); on average, pair helped by a single yearling, which participates in territorial defence, predator-mobbing, sentinel activity, alarm-calling, and usually feeding of nestlings and fledglings; helpers increase reproductive success, thereby gaining indirect fitness benefits, also benefit from reduced mortality and increased ability to obtain nearby breeding space (including some males which inherit or "bud off" portions of their natal territory for exclusive use). Bulky nest of coarse oak twigs, platform 18–20 cm in diameter, with sparse inner layer of fibres (cup diameter 8–9 cm), placed c. 1 m above ground on main stem of scrub oak, generally well hidden in shady portion of shrub; in suburbs and in citrus groves often placed higher in taller shrub or low in tree. Clutch 1–4 eggs, average at Archbold Biological Station 3·3, clutch size significantly larger in suburban settings; incubation by female, period 16–21; female fed on and off nest by male; chicks brooded and shaded by female, fed by both pair-members and by any helpers present, nestling period 12–25 days (average 18 days); fledglings fed by all members of group until c. 85 days old; dispersal usually delayed 1–2 years, and only of short distance, especially for males, with 80% of males and 50% of females breeding within two territories (c. 0·8 km at Archbold Biological Station and Kennedy Space Center) of natal site. Breeding success increases with age and experience for several years; during 1969–1985, at Archbold Biological Station, 200 breeding jays had average lifetime productivity of 7·4 fledglings, 4·2 independent young, and 2·2 yearlings; pairs in suburban sites, having constant supply of supplemental food (e.g. birdseed, peanuts, bread), breed earlier and lay larger clutches than those in wildlands, but suffer greater nest loss to predators, frequent (30% of successful nests) brood reduction, and poor post-fledgling survival of early-hatched nestlings which have limited access to natural foods (especially arthropods); snakes are common nest predators. Maximum recorded lifespan 15·5 years; 8·4% of adults live for 10 or more years.
Movements. Resident. Maximum known dispersal distance 17 km for males and 38 km for females in contiguous habitat, and 35 km for males and 50 km for females in fragmented habitats.
Status and Conservation. VULNERABLE. Locally common; restricted to scrub and shrubby areas in Florida. Has small and fragmented population and range, which are rapidly declining. Global population estimated at 8000 individuals. Habitat being replaced by housing developments and citrus groves; in addition, suppression of natural fire regimes (burn frequencies of 3–15 years) causes overgrowth of scrub and increase in density of pines, rendering habitat unsuitable for this species. Continuing scrub loss and scrub degradation and fragmentation (especially by roads) have reduced quality of many territories, so that source-sink population dynamics becoming evident. Populations along C Atlantic coast of Florida declined by 4% per year during 1992–2002. If current rate of urban development continues, consequent loss of range will soon be sufficient for this species to be listed as Endangered. Large reserves will be important for maintaining this species in short term. These will need frequent fires so that each jay territory has at least 1 ha of scrub 120–170 cm tall, with bare sand patches for acorn-caching and foraging; landscapes surrounding reserves will need attention so that limiting factors in suburban sinks are reduced. The survival of this corvid will depend on maintaining many large population sources, enabling adaptation to future challenges of climate change and exotic disease.

9. Mexican Jay

Aphelocoma ultramarina

French: Geai du Mexique **German**: Graubrusthäher **Spanish**: Chara Mexicana
Other common names: Grey-breasted/Ultramarine Jay

Taxonomy. *Corvus ultramarinus* Bonaparte, 1825, Temascáltepec, Mexico.
Relationships of this species with the *A. coerulescens* group and *A. unicolor* yet to be resolved, as recent studies indicate that divergence of these three major lineages within the genus was apparently rapid, leading to conflict among genetic markers. Races traditionally arranged into three geographical groups, but recent genetic evaluation suggests that isolation among rugged mountains of the region has produced four independently evolving clades: "*wollweberi*" group (includes also *gracilis* and *arizonae*), "nominate group" (with *colimae*), "central group" (*potosina*) and "eastern group" (*couchii*). Race *wollweberi* intergrades gradually with *arizonae* to N and *gracilis* to S. Seven subspecies recognized.
Subspecies and Distribution.
A. u. arizonae (Ridgway, 1874) – S USA (SE Arizona and SW New Mexico) S to N Mexico (N Sonora and NW Chihuahua).
A. u. wollweberi Kaup, 1854 – SE Sonora and SW Chihuahua S in Sierra Madre Occidental to W Zacatecas and N Jalisco.
A. u. gracilis G. S. Miller, 1896 – W Mexico (Nayarit and NW Jalisco).
A. u. couchii (S. F. Baird, 1858) – extreme S USA (Chisos Mts of extreme SW Texas) S in Sierra Madre Oriental to S Nuevo León and N San Luis Potosí.
A. u. potosina Nelson, 1899 – EC Mexico (San Luis Potosí S to C Hidalgo).
A. u. colimae Nelson, 1899 – SW Mexico (most of Jalisco and NE Colima).
A. u. ultramarina (Bonaparte, 1825) – SC Mexico (SE Jalisco and NW Michoacán E in S plateau region to Veracruz).

Descriptive notes. 28–32 cm; male 84–150 g, female 77–137 g. Small, chunky, crestless jay, dull bluish above and dingy below, with fairly heavy, pointed bill; bill length varies significantly with season, shorter in winter. Nominate race has head dark bluish, lores black, upperparts more bluish-purple; brownish-grey below, throat and undertail-coverts paler; iris brown; bill and legs black. Sexes similar, male slightly larger than female. Juvenile differs from adult in being mostly mouse-grey above with hint of dull blue wash, tail grey to blue-green and duller, wings greyer and with distal portions dark brown, legs brown, gradually deepening to black, bill typically pale; first-year in autumn slightly smaller (especially in wing and tail) than adult, with duller plumage, juvenile tail retained until definitive moult complete (c. 12 months after hatching). Races differ mainly in depth of coloration of plumage and in size: *colimae* is smaller and lighter in colour than nominate, with less purplish hint; *potosina* is duller and smaller than nominate; *arizonae* is deep dull blue above, facial region dull but darker blue, back brownish-grey with dull blue, rump more blue than black, uppertail-coverts light dull blue, primaries with dull dark brown tips, chest light brownish-grey with some dull blue cast (obscure broad band from side of neck across upper chest), belly and undertail-coverts white; *wollweberi* is smaller than previous, bluer above, has lighter underparts, juvenile browner-backed; *gracilis* is lighter in colour and smaller than last, strikingly smaller than *arizonae* and with back darker and less blue, underparts lighter with little or no blue wash; *couchii* is smaller than *arizonae*, has darker back, darker and more intensely blue neck and head with stronger contrast between neck and back, lighter throat contrasting more with brown-grey breast, blue (rather than brownish-grey) wash on lower breast and belly, juvenile overall darker and browner with less grey. Voice. Not formally studied. Like other corvids, has soft "whisper-song", begging calls, and "rattle". Whisper-song given by male during courtship and by lone individuals; only female thought to "rattle"; young and subordinate birds, including breeding females, beg from parents, mates and dominant flock-members. "Loud call" by flock-members when encountering trespassing jays, stationary predators, and generally when scolding in agitated manner; softer version, "hawk buzz", given to accipiters and other flying raptors.
Habitat. Montane mixed woodland with oak (*Quercus*) and pine (*Pinus*) or juniper (*Juniperus*); at lower elevations found along creeks and grasslands with oak-dominated riparian woods. Reliant on the acorns or large seeds of piñon pine that occur throughout these habitat types.
Food and Feeding. Omnivorous; seasonal specialist on pine and oak crops. Diet nuts, fruits, seeds, nectar; invertebrates; small vertebrates, e.g. lizards, small birds and nest contents (including those of own species). Takes carrion and, where available, scraps provided by humans. Cached nuts eaten throughout winter and early spring, even by incubating female. Opens acorns and pine seeds by forceful pounding and tearing; bill morphology reflects diet at local scale (those eating pine seeds have long, unhooked bill, acorn-eaters have stouter, hooked bill). Lives in small, permanent flocks of 2–25 individuals. Stores food throughout year, especially Jul–Aug, when acorns and pine seeds harvested and cached singly throughout group's territory. Caches thousands of pine seeds and acorns per autumn, in hundreds of locations; in each trip from harvest to caching grounds, transports up to five seeds in mouth or bill a short distance (1–500 m); individual uses spatial memory to recover seeds cached by itself and those seen cached by others. Feeds primarily on ground for insects and stored nuts, and in shrubs and tree canopy and on trunks for fruits, seeds, nectar and invertebrates.
Breeding. Nest-building begins late Feb and early Mar and laying late Mar to early Apr (rarely through Jun) in S USA (Arizona); repeated nesting after failure. Variety of social bonds formed among males and females, which live together in group and communally defend all-purpose territory; territories exclusive property of group, and stable in size and location for decades; within flock, males compete for mates and females compete over nests. Extremely complex breeding system varies from monogamous (most situations) to polygynandrous (with multiple breeding males and breeding females in one social group), exclusive pair-bond rare; each female guarded by a male, which (if dominant over other males) sires most or all young in her nest, but multiple paternity of a clutch frequent, and ability to obtain extra-pair fertilizations favours subordinate males, which may remain in natal flock as helpers; rarely, two females lay in a single nest and share incubation. Male typically initiates nest construction and may select nest-site, female may also "approve" site, usually only single male and female build nest, but several nests initiated simultaneously by male–female pairs within group; in Arizona, bulky nest had coarse outer platform 33 cm in diameter and 7·6 cm deep, made with dead twigs, rootlets woven into coarse outer sticks, inner cup (12·7 × 5·1 cm) lined with fibres from shredded yucca (*Yucca*) leaves and animal hair (material often stolen from other pairs within territory during building process), placed 3·7–24·4 m above ground and well concealed in leafy tree; entire nests of subordinate pairs may be usurped by dominant pairs. Clutch 1–5 eggs (typically 4–5); incubation by female, fed throughout by the guarding male and most other group-members (excluding other breeding females), period 18 days; chicks brooded by incubating female, fed by all group-members, nestling period 24–28 days; juveniles continue to be fed for several weeks after fledging, and most spend entire life in natal flock, often breeding in company of parents and siblings. In Arizona success typically high, each female produced on average 1·4 fledglings per year (older breeders more successful than inexperienced ones), and lifetime reproductive success of females 8·7 fledglings (range 0–50); females may continue to experience improved pairing and egg-laying success at age of 8 and above; birds nesting early in year in Arizona produced more nestlings, yearlings and three-year-olds. Recorded longevity 21 years in the wild; in Arizona, annual survival rate of individuals at least 1 year old was 81%.
Movements. Resident. Dispersal extremely limited, but rare long-distance movements and wanderings of vagrants to unusually low or high elevations have been documented; one record in S Kansas (SC USA). Some wander from territory in harsh winters.
Status and Conservation. Not globally threatened. Common throughout range. In Arizona, average size of home range 0·36 km². Populations in Arizona fluctuated annually during 1986–1994, but no constant increase or decrease. In Mexico, race *potosina* (in C plateau) and nominate and *colimae* (in Transvolcanic Range) are at risk because they occur in small area undergoing extensive habitat clearance for agriculture and timber. Throughout its range, this species is vulnerable to exotic and increasingly common diseases, including West Nile Virus, which is deadly to most corvids, and Sudden Oak Death; also to loss of pinyon pine woodlands to drought and fungus, which can reduce oak and pine mast.

10. Unicoloured Jay

Aphelocoma unicolor

French: Geai unicolore **German**: Einfarbhäher **Spanish**: Chara Unicolor

Taxonomy. *Cyanocorax unicolor* du Bus de Gisignies, 1847, le Méxique = San Cristóbal de Las Casas, Chiapas, Mexico.
Relationships of this species with the *A. coerulescens* group and *A. ultramarina* yet to be resolved, as recent studies indicate that divergence of these three major lineages within the genus was apparently rapid, leading to conflict among genetic markers. Five subspecies recognized.
Subspecies and Distribution.
A. u. concolor (Cassin, 1848) – E Mexico (E Hidalgo, WC Veracruz, México, Puebla).
A. u. guerrerensis Nelson, 1903 – SW Mexico (near Omilteme, in Guerrero).
A. u. oaxacae Pitelka, 1946 – C highlands of Oaxaca, in S Mexico.
A. u. unicolor (du Bus de Gisignies, 1847) – S Mexico (around San Cristóbal and E along Sierra Madre to Pico de Loro, in Chiapas) and Guatemala (E in Sierra de las Minas to Chilasco).
A. u. griscomi van Rossem, 1928 – El Salvador and W Honduras (from Los Esesmiles and Mt Pucca E to Alto Contoral and Rancho Quemado).

Descriptive notes. 27–32 cm; male 119–153 g, female 113–136 g. A crestless, long-tailed, wholly blue jay of moderate size, with rather heavy hook-tipped bill. Nominate race is mostly uniformly dark blue, with black area around eye, duller back; chin streaked grey, undersurfaces of wing and tail brownish-black; iris brown; bill and legs black. Sexes similar, female smaller than male. Juvenile is faintly bluish-grey, with dull blue wings and tail, dull brownish-black underwing and undertail, and most of lower mandible yellow; immature bluer, entire bill gradually turns from pinkish yellow to black in first 1–2 years. Races differ in tone of plumage and in size: *concolor* is similar in size to nominate (but with smaller feet), plumage intermediate between bluer nominate and purpler *oaxacae*; *guerrerensis* is longer-tailed, darker and more purplish than other races; *oaxacae* is slightly smaller than others, more purplish and darker than nominate, most similar to previous but slightly less purplish; *griscomi* is similar to last, but slightly less purplish and larger (especially bill). Voice. Vocalizations known primarily from single population in Chiapas (nominate race). More than 40 sounds distinguishable; great variety of acoustic components, including wide-band noise, complex combinations of fundamentals and overtones, single pure tones (rare); many calls have overall upward inflection and/or downward terminal flourish. Can sound grating/harsh, musical/resonant, whistled; loud or soft.

Commonest loud long-range calls "weet", "wit", "ralph", "zhreenk", some less common ones as "heup", "cleemp" and "gronk"; commonest soft short-range calls "poit", "kuk" and "wah"; graded variations on all of these and many others. Two kinds of "rattle" call, one slow and one fast, both only by females. Rambling low-volume "whisper-song". Overall, vocabulary most similar to those of *A. ultramarina* and *A. californica*; less similar to that of *A. coerulescens*. Association of particular calls with particular contexts less well known than for *A. californica*. Loud sounds used for long-range contact; in defence of group territory boundary, in mobbing perched or ground predators and in warning of overhead predators; and during enigmatic "calling conventions" in which jays perch and call to other group-members at relatively short range in a way that appears not to serve any of aforementioned functions. Female sometimes calls loudly from nest, and while leaving or approaching it. Soft sounds used in flock movement, courtship, mate-guarding, nest-building; and by juveniles when begging.

Habitat. Locally distributed in wet, mist-covered, tall, luxuriant tropical cloudforest (2135–3050 m) on high mountains or lower (1370–2590 m) but similarly vegetated steep Caribbean slopes. Humid hardwood forests in Sierra Madre del Sur, humid mixed pine (*Pinus*)–deciduous forest, cypress and pine forests in Guatemala, and dense montane mixed forest of pine, evergreen oak (*Quercus*) and hardwoods in El Salvador. In Lagunas de Montebello National Park (Chiapas), inhabits wet forests of pine (*Pinus oocarpa*), oak (*Quercus sapotifolia*, *Q. elliptica*, *Q. candicans*, *Q. segovianensis*, *Q. peduncularis* and *Q. acutifolia*) and sweetgum (*Liquidambar styraciflua*), where trees festooned with *Usnea* lichens, bromeliads (*Tillandsia*), mosses and orchids and bracken (*Pteridium aquilinum*) common on forest floor; dense, dripping fog frequently occurs in morning.

Food and Feeding. Omnivorous. Eats berries of *Rubus* and other species, *Myrica* fruits, moths (Lepidoptera), katydids and crickets (Orthoptera), cicadas (Cicadidae), anole lizards (*Anolis*), nestling birds, and human discards (corn, tortillas, pastry); closely associated with oaks and pines, and known to eat seeds of both. Caches in trees and recovers stored food. Forages mostly in trees among lichens and bromeliads, rarely coming to ground. Found in small flocks of 5–8 individuals.

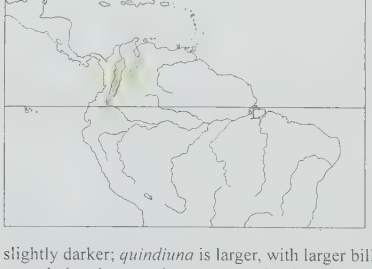
Breeding. Nest-building from as early at 19 Jan in S Mexico (Chiapas). In five-month study of four partially ringed flocks in Lagunas de Montebello National Park (Chiapas), stable groups of adult males and females included a female breeder, a primary male, and secondary (less dominant) males and females; secondary males occasionally copulate with primary female and may share paternity with primary male. All members of flock defended permanent home range of at least 12 ha (Jan–Jun); best-studied flock defended range of 41–45 ha. Unusual in that secondary birds join primary ones in nest-building; nest a bowl 40 cm in diameter and 15 cm deep, made from twigs (commonly oak twigs 2–5 mm in diameter and 35 mm long), lined with rootlets, lichens and a few pine needles, inner cup 11 cm in diameter and 3 cm thick, placed at height of 5·5–13·5 m in fork of crown or on major limb against trunk of pine, oak or madrona tree (*Arbutus menziesii*); nests begun in pine often not completed. Clutch at least 3–4 eggs; only primary female incubates, no information on duration of incubation period; chicks brooded by primary female breeder, nestling period 21–26 days; most group-members feed incubating female and nestlings; fledglings skilled fliers after 10 days out of nest, but continued to depend on parental care for at least 55 days after fledging.

Movements. Resident.

Status and Conservation. Not globally threatened. Relatively common in Guerrero, in S Mexico; nationally threatened in El Salvador. Fragmented and habitat-restricted distribution makes this species vulnerable to extirpation; may already have disappeared from Mexican states of Veracruz, México and Puebla.

Bibliography. Bridge *et al.* (2008), Curry *et al.* (2002), Ericson *et al.* (2005), Espinosa de los Monteros & Cracraft (1997), Goodwin (1986), Komar (1998), Madge & Burn (1994), McCormack *et al.* (2009), Peterson (1991b, 1992a, 1992b), Peterson & Burt (1992), Peterson, Martínez-Meyer & González-Salazar (2004), Pitelka (1945b, 1946, 1951c), Rice *et al.* (2003), Saunders & Edwards (2000), Van Rossem (1928), Webber (2009), Webber & Brown (1994), Zusi (1987).

Genus *CYANOLYCA* Cabanis, 1851



11. **Black-collared Jay**

Cyanolyca armillata

French: Geai à collier **German**: Halsbandhäher **Spanish**: Chara Collareja
Other common names: Collared Jay

Taxonomy. *Cyanocorax armillatus* G. R. Gray, 1846, no locality = Bogotá, Colombia.
Forms a monophyletic group with *C. viridicyanus* and *C. turcosa*; all three formerly considered conspecific, but differ in morphology and probably voice. Three subspecies recognized.

Subspecies and Distribution.
C. a. meridana (P. L. Sclater & Salvin, 1876) – NW Venezuela (Trujillo, Mérida and NW Táchira).
C. a. armillata (G. R. Gray, 1846) – E Andes of SW Venezuela and Colombia (Táchira S along R Chiquito).
C. a. quindiuna (P. L. Sclater & Salvin, 1876) – C Colombia (from Quindío Mts, in C Andes, S to E slope of Andes of Pasto) S to extreme N Ecuador (Carchi, N Napo).

Descriptive notes. 30–34 cm; 190–210 g. Nominate race has forehead, lores and sides of head black, forming a broad mask, crown and nape dull violaceous blue; throat and contiguous part of central upper breast ultramarine, bordered by narrow black line which connects to rear of black ear-coverts; remainder of plumage, including wing and tail, cyan-blue, inner margins of primaries dark brown, underwing and underside of tail blackish; iris brown; bill and legs black. Sexes similar. Juvenile is duller than adult, with greyer throat, body feathers greyish with blue only at tips. Race *meridana* is similar to nominate, but slightly darker; *quindiuna* is larger, with larger bill and longer tail than other races, has crown and nape darker than nominate, contrasting less with back, plumage tinged greenish overall, especially on back, belly, wing and tail. Voice. Large vocal repertoire consisting of variety of short and often musical notes, e.g. a rising, almost twanging "shrwee", various shrill rising and falling notes, a sharp, stuttered "jet-jtjtjtjt", a low guttural "wowr", and soft, liquid "craa".

Habitat. Humid, mossy cloudforest, at 1600–3250 m; frequent at forest edges.

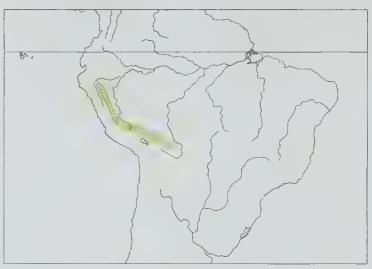
Food and Feeding. Poorly documented. Forages in small flocks in subcanopy and canopy, along branches with epiphytes, hopping along and pausing to peer through foliage. Occasionally descends to gulleys with tree-ferns and bamboo thickets.

Breeding. No information. Seems to occur between Jun and Oct in Colombia.

Movements. Sedentary.

Status and Conservation. Not globally threatened. Poorly known. Quite numerous in W Venezuela; considered uncommon, even rare, in Colombia, and exceptionally rare in Ecuador. Can be rare even in areas of suitable habitat.

Bibliography. Blake & Vaurie (1962), Bonaccorso (2009), Clements (2000), Dickinson (2003), Fjeldså & Krabbe (1990), Goodwin (1976), Hilty & Brown (1986), López-Lanús *et al.* (2000), Madge & Burn (1994), Meyer de Schauensee (1966, 1970), Remsen *et al.* (2009), Restall *et al.* (2006), Ridgely & Tudor (1989), Sibley & Monroe (1990), Stotz *et al.* (1996).



12. **White-collared Jay**

Cyanolyca viridicyanus

French: Geai indigo **German**: Blaukehlhäher **Spanish**: Chara Andina
Other common names: Collared Jay

Taxonomy. *Garrulus viridi-cyanus* d'Orbigny and Lafresnaye, 1838, La Paz, Bolivia.
Forms a monophyletic group with *C. armillata* and *C. turcosa*; all three formerly considered conspecific, but differ in morphology and probably voice. Three subspecies recognized.

Subspecies and Distribution.
C. v. jolyaea (Bonaparte, 1852) – N & C Peru (from Amazonas S to Junín).
C. v. cyanolaema Hellmayr, 1917 – SE Peru (Cuzco and Puno).
C. v. viridicyanus (d'Orbigny & Lafresnaye, 1838) – NW Bolivia (La Paz and Cochabamba).

Descriptive notes. 34 cm; 82–127 g. Nominate race has forehead, lores and side of head black, forecrown and side of crown white, white extending as very narrow stripe over and beyond eye; this white line continues around border of black facial area to connect with a narrow but conspicuous white band bordering lower edge of dark throat and upper breast; throat and adjacent central part of upper breast indigo, hardly contrasting with black facial region; rest of plumage cerulean blue, slightly bluer on crown and nape, underwing and underside of tail blackish; iris dark brown; bill and legs black. Sexes similar. Juvenile is presumed to be duller. Race *cyanolaema* is bluer than nominate, especially on crown and nape, with throat and upper breast ultramarine-blue, contrasting more clearly with black face; *jolyaea* is bluest race, slightly tinged with greenish on wings and tail, the white of crown restricted to forecrown and white collar even narrower than on nominate, throat and adjacent upper breast cobalt-blue, chin paler and clearly contrasting with black facial region. Voice. Large vocal repertoire, much of it atypical of jays, emitted in almost endless combination of components; in addition, 3–5 variations for each call. Some vocalizations resemble those of *Aphelocoma*, others those of *Cyanocorax* (has been suggested that, vocally, this species could be a bridge between those two genera). Typically, two upwardly inflected and nasal (rather harsh) notes, "schree" and "reek!", which resemble vocalizations of *Aphelocoma*. A rapid staccato chatter, which resembles calls of certain woodpeckers (such as genera *Colaptes* or *Dendrocopos*), but never more than two or three times in succession. Also, a soft and uninflected "croooh" (resembling that of *Cyanocorax*), slightly downward-inflected and harsh "craah" (like that of *Cyanocitta stelleri*), high-pitched "peep!" or "cheep!" (reminiscent of notes of domestic fowl hatchling). Sometimes "craah" combined with a mellow disyllablic whistle, "craahs-who-op".

Habitat. Montane forest, from humid luxuriant cloudforest to higher-lying more stunted elfin forest; chiefly between 1600 m and 3000 m, but to 4000 m in Peru. Recorded also at forest edges and older secondary growth, especially with bamboo and tree-ferns. One study site described as a subtropical forest of tall emergent trees (50 m) and closed canopy (30 m).

Food and Feeding. Poorly known. Flocks forage mostly along branches, investigating clumps of epiphytes and crevices at subcanopy and canopy levels.

Breeding. No information.

Movements. Sedentary.

Status and Conservation. Not globally threatened. Common locally, but rare or uncommon in most of its range.

Bibliography. Blake & Vaurie (1962), Bonaccorso (2009), Clements (2000), Clements & Shany (2001), David & Gosselin (2002a), Dickinson (2003), Fjeldså & Krabbe (1990), Goodwin (1976), Hardy (1967, 1984), Hennessey & Gomez (2003), Hilty & Brown (1986), Hornbuckle (1999), Liu Yang & Lei Jinyu (2005), MacLeod *et al.* (2005), Madge & Burn (1994), Meyer de Schauensee (1966, 1970), Meyer de Schauensee & Phelps (1978), Remsen *et al.* (2009), Ridgely & Tudor (1989), Salaman *et al.* (1999), Sibley & Monroe (1990), Stotz *et al.* (1996), Zimmer (1953).

13. **Turquoise Jay**

Cyanolyca turcosa

French: Geai turquoise **German**: Türkishäher **Spanish**: Chara Turquesa

Taxonomy. *Cyanocitta turcosa* Bonaparte, 1853, near Puerres, Nariño, Colombia.
Forms a monophyletic group with *C. armillata* and *C. viridicyanus*; all three formerly considered conspecific, but differ in morphology and probably voice. Monotypic.

Distribution. SW Colombia (Nariño) S in Andes (on both slope in C Ecuador) to N Peru (N Piura and NW Cajamarca).

Descriptive notes. 30–34 cm. Forehead, lores and side of head are black, crown and nape pale turquoise-blue, becoming paler on forecrown, throat very pale, almost turquoise-blue, darkening to purplish-blue towards lower throat; narrow black collar at upper breast; remainder of plumage cerulean blue, underwing and underside of tail blackish; iris probably brown; bill and legs black. Sexes similar. Juvenile is apparently duller. Voice. Most frequently heard are a loud "tsrrrp" and a liquid explosive "kworrr", both of which may be repeated three or four times; other short vocalizations, including clicked snapping sound.

Habitat. Montane humid cloudforest at 1500–3500 m; reaches forest edges into elfin woodland at tree-line. Seems more tolerant of open and secondary forest than *C. armillata*, possibly because

there are extensive stands of alders (*Alnus*), which it favours. One occupied site in NW Ecuador (Otonga), at 1700–2200 m, has been described as a cloudforest with a high diversity and abundance of epiphytic plants, especially bromeliads (Bromeliaceae), aroids (Araceae) and mosses.

Food and Feeding. Poorly documented. Said to forage in small flocks in subcanopy and canopy of forest interior, edges and second growth. Recorded in mixed flocks in a primary cloudforest in Loja Province (Ecuador), although had been considered an irregular member of such flocks.

Breeding. No information.

Movements. Sedentary.

Status and Conservation. Not globally threated. Fairly common in Ecuador, but seemingly not common in Colombia. Fairly common in Peru.

Bibliography. Becker *et al.* (2008), Blake & Vaurie (1962), Bonaccorso (2009), Clements (2000), Clements & Shany (2001), Dickinson (2003), Freile & Chaves (2004), Goodwin (1976), Hardy (1984), Hilty & Brown (1986), Madge & Burn (1994), Meyer de Schauensee (1966, 1970), Poulsen (1996), Remsen *et al.* (2009), Restall *et al.* (2006), Ridgely & Tudor (1989), Sibley & Monroe (1990), Stotz *et al.* (1996), Vellinga *et al.* (2004), Welford (2000), Zimmer (1953).

14. **Beautiful Jay**

Cyanolyca pulchra

French: Geai superbe **German**: Schmuckhäher **Spanish**: Chara Hermosa

Taxonomy. *Cyanocitta pulchra* Lawrence 1875, Quito, Ecuador.

This species and *C. cucullata* are sister-species. Monotypic.

Distribution. Pacific slope of Andes from C Colombia (extreme S of Chocó and Valle) S to NW Ecuador (S to S Pichincha). Monotypic.

Descriptive notes. 27 cm. Feathers of forehead and lores are short, dense and tufted. Male has forehead, lores and side of head black, crown and nape light sky-blue, whitish along upper border of black ear-coverts; upper mantle dull violaceous blue, rest of upperparts, including uppertail-coverts, sepia, upperwing and tail lighter cyan-blue; chin black, throat cyan-blue, becoming darker, almost sepia, on upper breast, and than cyan-blue towards belly; underside of wing and tail blakish; iris brown; bill and legs black. Female is similar to male, but usually with brownish tones on upperparts. Juvenile is drabber and browner than adult; first-year retains brown feathering on mantle and upperwing-coverts, and possible that only older males lose brown more or less completely. Voice. Quickly repeated mellow "chew-chew-chew" (grating call), loosely repeated, or given more continuously when excited; repeated short dry "graasp" and double "click" followed by rising whistle; single "click" and whistle, commonly repeated up to four times.

Habitat. Montane forest at 900–2300 m, mostly 1400–1800 m. Lives in mature humid subtropical forest and cloudforest; recorded infrequently at clearings, secondary growth and edges. Said to favour watercourses and marshy areas.

Food and Feeding. Poorly documented. Forages in understory, more so than do congeners. Forages singly and in pairs; hops, peers, and flies short distances. Generally remains inconspicuous unless calling.

Breeding. No information.

Movements. Sedentary.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Chocó EBA. Uncommon and local in Colombia; rare to locally uncommon in Ecuador. In Colombia, population at Río Ñambí Natural Reserve estimated at just 2–3 pairs in 5 km², but in Tambito Nature Reserve (in SW Colombia) this species is considered fairly common at 1400–1700 m. Generally very sensitive to human disturbance and appears almost exclusively dependent on primary forest. Logging is principal cause of its apparent population decline. Occurs in Cerro Golondrinas Reserve, in Ecuador (Carchi).

Bibliography. Anon. (2008p), Becker *et al.* (2008), Blake & Vaurie (1962), Bonaccorso (2009), Butchart & Stattersfield (2004), Clements (2000), Dickinson (2003), Donegan & Dávalos (1999), Goodwin (1976), Hardy (1984), Hellmayr (1934), Hilty & Brown (1986), Madge & Burn (1994), Meyer de Schauensee (1966, 1970), Orejuela (1987), Pearman (1993), Pitelka (1951a), Remsen *et al.* (2009), Restall *et al.* (2006), Ridgely & Tudor (1989), Sibley & Monroe (1990), Stattersfield & Capper (2000), Stotz *et al.* (1996), Welford (2000).

15. **Azure-hooded Jay**

Cyanolyca cucullata

French: Geai couronné **German**: Blaukappenhäher **Spanish**: Chara Coroniazul
Other common names: Hooded Jay

Taxonomy. *Cyanocorax cucullatus* Ridgway, 1885, Navarro, Costa Rica.

This species and *C. pulcra* are sister-species. Four subspecies recognized.

Subspecies and Distribution.

C. c. mitrata Ridgway, 1899 – E Mexico (extreme SE San Luis Potosí and Veracruz) S to CE Oaxaca).

C. c. guatemalae Pitelka, 1951 – S Mexico (Chiapas) and N Guatemala (Huehuetenango, Alta Vera Paz).

C. c. hondurensis Pitelka, 1951 – W Honduras (Caribbean slopes).

C. c. cucullata (Ridgway, 1885) – Caribbean slope of Costa Rica and Panama, extending locally across to Pacific slope.

Descriptive notes. 26–31 cm; 88–109 g. Feathers of forehead and loral region are short, upstanding, and plush-like. Nominate race has forehead and side of head black, crown and nape sky-blue,

this colour extending slightly in an arc around rear ear-coverts; some individuals have a whitish area above forehead; throat, breast and mantle sepia; rest of plumage, including upperwing and tail, cyan-blue, underwing and undertail blackish; iris dark red; bill and legs black. Sexes similar. Juvenile is duller than adult, has underparts entirely light sepia, iris presumably dull brown, no white on forecrown. Race *mitrata* is larger than nominate, has black of forehead extending farther back onto crown, a narrow white border at front and side of crown, this continuing around lower rear of ear-coverts; *hondurensis* has broader area of white on forecrown and side of crown (in extent intermediate between nominate and previous), and underparts duller, less purplish-blue; *guatemalae* has occipital area and upperparts more cyan-blue. Voice. Most frequent vocalization a clear and loud whistle, "djeek", upwardly inflected, given in rapid series of 3–4 while flock foraging. Also gives single upward-inflected nasal "woyt", which may be alarm call, and a dry, scolding and raucous "raaah"; also a loud snapping, which possibly a non-vocal sound.

Habitat. Interior of cloudforest at 800–2100 m, where vegetation includes tree-ferns of several species, sweet gum (*Liquidambar*), yellow poplar (*Liriodendron*), basswood (*Tilia*) and *Podocarpus*; also in forest borders and oak woodland. Also ranges into tropical forests (often continuous with cloudforests) in foothills and lowlands.

Food and Feeding. Diet includes invertebrates, berries, and small fruits (*Miconia* and Ericaceae). Forages in pairs and in flocks of 3–10 individuals at lower and middle levels of forest, especially in dense vegetation, but found also in canopy. Probes clumps of moss and epiphytes; peers into and gleans invertebrates from foliage and crevices of tree trunks. Recorded as following swarms of ants (Formicidae); three records in total of 17 separate raiding army-ant swarms noted in subtropical forest in Costa Rica (Cordillera de Tilarán at Monteverde). Watched while foraging in trees where flock of *C. pumilo* feeding, but not seen to mix with flock.

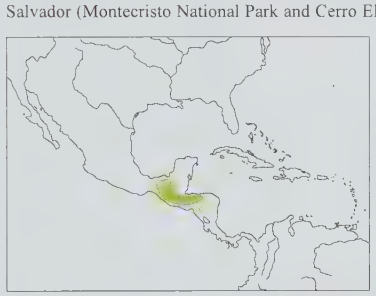
Breeding. Season Apr–Jun in Costa Rica. Solitary nester. Nest a platform of twigs with inner cup (5 cm) of smaller twigs, lined roughly with plant fibres, placed 5–7 m above ground in small tree at forest edge. Two nests each held two young. No further information available.

Movements. Sedentary.

Status and Conservation. Not globally threatened. Fairly common to common in much of range; can appear to be uncommon because of its inconspicuous behaviour. No indication of any threat.

Bibliography. Blake (1953), Blake & Vaurie (1962), Bonaccorso (2009), Clements (2000), Dickinson (2003), Goodwin (1976), Hardy (1964, 1984), Hellmayr (1934), Howell & Webb (1995), Madge & Burn (1994), Peterson *et al.* (2003), Pitelka (1951a), Remsen *et al.* (2009), Rojas Soto & Navarro Sigüenza (1999), Sibley & Monroe (1990), Stiles & Skutch (1989), Stotz *et al.* (1996), Vallely (2001), Van Perlo (2006).

16. **Black-throated Jay**



Cyanolyca pumilo

French: Geai à gorge noire **German**: Schwarzkehlhäher **Spanish**: Chara Gorjinegra
Other common names: Black-throated Dwarf Jay, Strickland's Jay

Taxonomy. *Cyanocorax pumilo* Strickland, 1849, Guatemala (probably Antigua, in Department Sacatepéquez).

This species and *C. nanus*, *C. argentigula* and *C. mirabilis* form a monophyletic group. Monotypic.

Distribution. Mountains of extreme SE Mexico (SE Chiapas), Guatemala, W & C Honduras, N El Salvador (Montecristo National Park and Cerro El Pital) and NW Nicaragua.

Descriptive notes. 25–28 cm; one bird 47 g. Feathers of forehead and lores short, dense and tufted. Forehead and sides of head black, throat sepia; narrow but conspicuous whitish line extends across forehead and over and behind eye, usually so as to create pale border along upper half of black facial area; reminder of plumage tends to cyan-blue, brighter on crown, nape and upperwing, and some individuals have underparts slightly tinged greenish; underwing and underside of tail dark grey; iris brownish; bill and legs black. Sexes similar, female duller than male. Juvenile is duller than adult, with black area of head more greyish-black and shading to blue-grey on throat, lacks whitish border of crown. Voice. Vocalizations resemble some of those of W populations of *Aphelocoma coerulescens*, such as sequence of rapidly repeated "kwesh" notes and a nasal "reek!", latter an alarm call. Other vocalizations, less frequently recorded in the field, are a soft chuckled "cheecheecheecheeche", a repeated squeaky "kirwik-kirwik-kirwik-kirwik", a soft queroulous "shrreee", and a short whining note interspersed with sharper calls.

Habitat. Lives in cloudforest between 1200 m and 3050 m, with tree-ferns of several species, sweet gum (*Liquidambar*), yellow poplar (*Liriodendron*), basswood (*Tilia*) and *Podocarpus*. Seen especially in forest ravines, and several times found in low growth at roadside; field observations indicate, however, that this species only rarely occupies open forests of mixed oaks (*Quercus*), alders (*Alnus*) and pines (*Pinus*). In Mexico considered a "core bird species" in upper cloudforest (above c. 1650–1700 m) in El Triunfo Biosphere Reserve (Chiapas), where *Quercus oocarpa*, *Matudaea trinervia* (Hamamelidaceae), *Hedyosmum mexicanum* (Chloranthaceae) and *Dendropanax populifolius* (Araliaceae) dominate; in Montecristo National Park (El Slavador), 360 km SE of El Triunfo, considered rare in cloudforest.

Food and Feeding. Invertebrates, including insects in both larval and adult stages and spiders (Araneae), and seen to eat large hairy caterpillars; one record of feeding on mulberry (*Morus*) fruits. Flocks of 5–12 individuals forage at all levels of forest, but no observations of feeding on ground. Prefers to forage in dense vegetation in bushes, hanging vines, canopy of tall shrubbery and trees, and dense shrubbery of forested ravines. Probes and pokes among clumps of leaves and lichens along branches and trunks; flock of eight individuals watched as it fed in upper branches of sycamore (*Platanus*) in cutover forest near a road. Sometimes forages with *C. cucullata* in same tree, but flocks not seen to mix.

Breeding. Virtually unknown. Immature seen in Jul and Aug in Mexico (El Triunfo Biosphere Reserve). Nest of twigs, placed in outer branches of tree canopy.

Movements. Sedentary.

Status and Conservation. Not globally threatened. Not uncommon over its restricted range; was considered in danger of being extirpated in El Salvador. Detailed information on populations lacking.
Bibliography. 17. **Dwarf Jay**

Cyanolyca nanus

French: Geai nain **German**: Zwerghäher **Spanish**: Chara Enana

Taxonomy. *Cyanocorax nanus* du Bus de Gisignies, 1847, Mexico.
This species and *C. pumilo*, *C. argentigula* and *C. mirabilis* form a monophyletic group. Monotypic.
Distribution. Mountains in Veracruz and adjacent Puebla and Oaxaca (sierras of Juárez, Aloapaneca and Zempoaltepec), in E Mexico.

Descriptive notes. 20–23 cm; 40–42 g. Forehead is lavender-coloured, crown and rest of upperparts, including upperwing and tail, cyan-blue, lores, malar region and ear-coverts black; very narrow lavender supercilium above black mask and curving down behind rear of ear-coverts; throat lavender, bordered below by very narrow, somewhat diffuse sepia stripe, underparts duller cyan-blue, underwing and underside of tail dull greyish; iris dark red-brown; bill and legs black. Sexes similar, female slightly duller than male. Juvenile is duller than adult, with forehead and supercilium dull greenish-blue and not noticeably paler than crown and with dull greyish-blue throat. Voice. Small vocal repertoire. Most common vocalization a nasal and harsh, but high-pitched double inflected "shreéup", delivered singly or in multiples of two or three, rapidly (almost run together), by undisturbed members of loose foraging flock when [illegible] and out of sight of each other; several variations of this call in different situations; soft version serves as contact/conversational note between two adults close to [illegible]; mid multiple versions heard from moving flock during foraging or when excited [illegible] ator (or human). Other raucous and harsh notes, such as begging call by female [illegible] incitation of food, and intense harsh rasp when humans close to nest.
[illegible] ixed pine–oak–fir (*Pinus–Quercus–Abies*) forests between 1400 m and 3200 m. [illegible] in Oaxaca (Cerro San Felipe), habitat ranged from nearly pure stands of oak, scattered pines and an understorey of subdominant broadleaf trees, to forests of [illegible] ne and oak representation, scattered fir (*Abies religiosa*) and abundant epiphytes; [illegible] eae) and abundant epiphytic growth are characteristic of these associations. Frequent [illegible] d growth, so long as the climax species of trees predominate (if tree cover 70% or [illegible] tracts of mature climax forest are nearby.
Feeding. Arthropods; no records of vegetable items in diet. Foraging individuals inves- [illegible] and around epiphytes, including clumps of bromeliads, ferns and lichens, in branches, and [illegible] ge in very dynamic way, hanging upside-down and hovering in manner of a tit (Paridae); [illegible] onally takes medium-sized flying insects. Also pokes and probes cracks and crevices and [illegible] r loose bark in more typical jay-like manner. Forages at middle level of interior of forest, [illegible] ow canopy; rarely, on the ground or in understorey; seems to visit canopy only when foraging [illegible] across relatively open areas of forest lacking lower vegetation levels. Normally in pairs, but in small flocks of up to twelve individuals after breeding season; flocks can be associated with other bird species, such as Grey-barred Wren (*Campylorhynchus megalopterus*); one recorded in association with *Aphelocoma unicolor*.
Breeding. Laying from late Mar to late Apr, and completely independent young in loose flocks in early Jul. Solitary nester, breeding as simple pair. Nest built by both sexes, usually during morning hours, a bulky compact mass of mosses and lichens, a few twigs (20–30 pieces, 5–15 cm long and 2–5 mm in diameter) incorporated, largely around top (strengthening the rim and cup), cup lined with fine rootlets, pine needles and/or strands of grass; large in relation to size of the jay, external diameter 16–19 cm, height 14–20 cm, internal diameter 7–8 cm and depth 7–7·5 cm; placed 3–15 m above ground near end of branch or in crown of oak. Clutch 2–3 eggs; incubation by female alone, fed at or near nest by male, period 20 days; at one studied nest, chicks brooded by female but fed by both parents, no information on duration of nestling period.
Movements. Sedentary.
Status and Conservation. VULNERABLE. Restricted-range species: present in Southern Sierra Madre Oriental EBA. Fairly common to uncommon and local; recent records from extreme E Querétaro (Tangojó), N Hidalgo, C Veracruz and N Oaxaca (La Chinantla). Has small global population, which is declining rapidly in response to habitat loss. Forest fragmentation and degradation caused by logging, agricultural expansion, firewood-gathering, road and tourist developments, sheep-ranching, intense grazing and intensive urbanization have led to local declines or extinction. Was feared extinct throughout range except for Cerro San Felipe (N Sierra Aloapaneca), where it remains quite common; this site is within the Benito Juárez National Park, but borders of this have never been demarcated and it offers the species little protection. In C & S of range is found only above 1670 m, probably because of habitat alteration. It has recently been suggested that this jay's status should be upgraded to Endangered owing to threats facing the cloudforests in mountains of E & SE Mexico; although it can live in secondary-growth forest if tree cover 70% or more, this habitat type is also under severe pressure.
Bibliography. Anon. (2008p), Blake & Vaurie (1962), Bonaccorso (2009), Butchart & Stattersfield (2004), Clements (2000), Dickinson (2003), Escalante & Néquiz (2004), García-Trejo & Navarro Sigüenza (2004), Goodwin (1976), Hardy (1964, 1971, 1984), Howell & Webb (1995), Madge & Burn (1994), Martínez-Morales (2004), Remsen *et al.* (2009), Sibley & Monroe (1990), Stattersfield & Capper (2000), Stotz *et al.* (1996), Van Perlo (2006).

18. **Silvery-throated Jay**

Cyanolyca argentigula

French: Geai à gorge argentée **German**: Silberhäher **Spanish**: Chara Gorjiplateada
Other common names: Central American Jay

Taxonomy. *Cyanocitta argentigula* Lawrence, 1875, near Pico Blanco, above Sipurio, Costa Rica.
Forms a monophyletic group with *C. pumilo*, *C. nanus* and *C. mirabilis*. Two subspecies recognized.

Subspecies and Distribution.
C. a. albior Pitelka, 1951 – C Costa Rica (Cordillera Central).
C. a. argentigula (Lawrence, 1875) – S Costa Rica (Cordillera de Talamanca) and W Panama (E to Pico Blanco).

Descriptive notes. 25–27 cm; 65 g. Forehead and lores have an inconspicuous tuft of very short stiff feathers. Nominate race has head and neck, including malar region, black, narrow but conspicuous strongly violet-washed whitish band over forecrown and extending back almost as a supercilium; nape and upperparts black, uppertail-coverts slightly tinged cyan, upperwing and tail bright cyan-blue; throat lavender-coloured (tinged with violet in fresh plumage), underparts blackish, belly slightly tinged cyan, underwing and underside of tail blackish; iris dark red; bill and legs black. Sexes similar. Juvenile is duller than adult, with dull greyish-black on head, crown dusky blue, lacks whitish on forecrown and in supercilium, iris presumably duller. Race *albior* has forecrown band and supercilium white and throat pale grey (both areas tinged with violet in fresh plumage). Voice. Most frequent call a harsh, nasal, somewhat scratchy "jew-jeah-jeah" or a single "nyaaaah"; scolding call a harsher "zhraaak"; 2–4 sharper calls, "nyat-nyat-nyat", on taking flight; young give higher and faster "nyaah-nyaah". Said to be quite noisy when going to roost.
Habitat. Montane humid cloudforest, favouring oak (*Quercus*) forest, at 2000–3200 m; occasionally, perhaps seasonally, recorded also down to 1300 m.
Food and Feeding. Invertebrates, small frogs, small lizards, salamanders; also berries and small fruits. Forages in flocks of 4–10 individuals, but after breeding also in larger gatherings of up to 30 individuals. Flock moves through canopy and subcanopy, coming lower at edges and nearby second growth; investigates each tree methodically, inspecting foliage, bromeliads, and tufts of mosses and lichens, before moving on.
Breeding. No information available. Breeding said to occur between Mar and Jun.
Movements. Resident. Possible seasonal descent to lower elevations.
Status and Conservation. Not globally threatened. Restricted-range species: present in Costa Rica and Panama Highlands EBA. Generally rather uncommon. Low-density populations in Costa Rica; appears to be very uncommon in Panama.
Bibliography. Blake & Vaurie (1962), Bonaccorso (2009), Clements (2000), Dickinson (2003), Goodwin (1976), Hardy (1984), Madge & Burn (1994), Pitelka (1951b), Remsen *et al.* (2009), Sibley & Monroe (1990), Stiles & Skutch (1989), Stotz *et al.* (1996), Van Perlo (2006).

19. **White-throated Jay**

Cyanolyca mirabilis

French: Geai masqué **German**: Weißkehlhäher **Spanish**: Chara de Omiltemi
Other common names: Omiltemi/Omilteme Jay

Taxonomy. *Cyanolyca mirabilis* Nelson, 1903, Omilteme, Guerrero, Mexico.
This species and *C. pumilo*, *C. nanus* and *C. argentigula* form a monophyletic group. Monotypic.
Distribution. Guerrero (Sierra Madre del Sur) and Oaxaca (Sierra de Miahuatlan and Sierra de Yucuyacua), in SW Mexico.

Descriptive notes. 23–25 cm; 49·9–54 g. Forehead and lores with inconspicuous tuft of very short stiff feathers. Head and neck black, with white stripe running across forehead, extending back over eye as thin line and continuing around rear ear-coverts to neck side, where it meets white of chin and throat; nape and upper breast black; remainder of plumage duller cerulean blue, underwing and underside of tail dark grey; iris probably brown; bill and legs black. Sexes similar. Juvenile has face duller, with less distinct white borders, whitish throat ill-defined, upperparts dull bluish, underparts sooty greyish. Voice. Vocalizations uttered typically in twos and quickly repeated; resemble calls of *C. nanus*, but less high-pitched, less nasal and somewhat sweeter. Social alarm call a nasal "reek!", very similar to that of *Aphelocoma californica*. Contact call, when in loose foraging flock, a double inflected nasal note; sometimes this call is less nasal, then resembling that of *A. californica*. In mild alarm, a very nasal "chi-eery, cherrup", intensely querulous.
Habitat. Dense humid forest and mixed oak (*Quercus*) and pine (*Pinus*) woodland from 1525 m up to 3500 m; recorded also in disturbed areas. Oak trees may be essential for this species, at least at some period of the year.
Food and Feeding. No information available on diet. Rarely observed in the field; two observations were of pairs, a third was of a group of three or four individuals; one record in mixed flock that included five or six Emerald Toucanets (*Aulacorhynchus prasinus*) as well as 10–15 *Aphelocoma unicolor*.
Breeding. Breeding recorded Apr–Aug. No further information.
Movements. Resident. Suggestion of some local and seasonal movement.
Status and Conservation. VULNERABLE. Restricted-range species: present in Sierra Madre del Sur EBA. Locally fairly common. Has very small range and rapidly declining population as a result of forest fragmentation and degradation; these caused by clearance for timber, agricultural expansion (corn, fruit, coffee), and logging of pine–oak forests. Very little suitable habitat remaining below 1800 m. Although this species occurs in one protected area, the Omiltemi State Ecological Park (in Sierra de Atoyac), most of the area in which it occurs is not protected. It was recently suggested that present species should be considered Endangered, owing to accelerated loss of habitat in past two decades.

Genus *CYANOCORAX* Boie, 1826

20. Bushy-crested Jay

Cyanocorax melanocyaneus

French: Geai houppé **German**: Hartlaubblaurabe **Spanish**: Chara Centroamericana
Other common names: Hartlaub's Jay

Taxonomy. *Garrulus* (*Cyanocorax*) *melanocyaneus* Hartlaub, 1844, Guatemala.
This species and *C. sanblasianus*, *C. yucatanicus* and *C. beecheii* were formerly placed together in a separate genus, *Cissilopha* (the black-and-blue jays of Middle America). Races intergrade in N & E El Salvador and Honduras. Two subspecies recognized.
Subspecies and Distribution.
C. m. melanocyaneus (Hartlaub, 1844) – mountains of Guatemala and S El Salvador (coast range E to Volcán de Vicente).
C. m. chavezi (W. deW. Miller & Griscom, 1925) – mountains of Honduras and NW Nicaragua.

Descriptive notes. 28–33 cm; 80–115 g. Looks bulky-headed when crown feathers erected; feathers of forecrown somewhat stubble-like, but hardly crested. Nominate race has black hood extending down to upper mantle and breast; rest of upperparts, including wing and tail, cerulean blue; underparts below breast variable, from indigo to duller cerulean; underwing and underside of tail greyish; iris bright yellow; bill black; legs blackish. Sexes similar. Juvenile is fuscous brown, with wings and tail cerulean blue, but remiges only a little less bright than those of adult, iris dark brown, bill yellowish-horn (developing brownish tip just before fledging), legs dark grey, quickly (in first few weeks) acquires blackish head and body feathering and bill darkens from tip; first-year has black legs, bicoloured bill and dark brown iris, bill becomes black at c. 10 months; second-year almost like adult, but some whitish areas inside bill (all black in adult). Race *chavezi* is ultramarine-blue on back and tail, but has wings cerulean, underparts dark cyan-blue or, on some, almost blackish. Voice. Cawing call (social call), usually the most often heard vocalization, is short and inflected, and given in several contexts; female on nest emits variation of this call, a soft begging and lower-pitched "caw"; juvenile also has short "caw", which combines elements of begging and location. Contact call "chank chank". Subsong (*sotto voce*), common in this species, is associated with courtship but is also given by isolated birds.
Habitat. Edges of humid woodlands, especially of mixed pine (*Pinus*) and oak (*Quercus*), usually between 1000 m and 2450 m, sometimes lower into foothills; also in clearings and scrubby shrubbery, including coffee plantations. In Montecristo National Park (El Salvador), most frequent in pine–oak forest. In contrast, in a study site in Nicaragua (at 1200 m) seemed to be more abundant in disturbed areas than in undisturbed cloudforest; in one study, 20–50% of home range of one group consisted of coffee plantations, the rest citrus groves, roadside clearings and ecotonal areas.
Food and Feeding. Insects, including beetles (Coleoptera) and grasshoppers (Orthoptera), other invertebrates; also seeds, and fruits e.g. small figs (*Ficus*). Forages in flocks from low levels up to middle canopy, among trees and bushes; also on the ground, where it searches through leaf litter. Observations of a group actively attending swarms of army ants (Formicidae).
Breeding. Eggs recorded late Apr to mid-May, and in El Salvador recently fledged juveniles in mid-Jun; season apparently of two overlapping nesting periods, with either one or two nesting attempts in each. Communal breeder, in group with helpers; only one female lays, and one flock may attend one or two nests simultaneously. Courtship includes display in which pupils are constricted. Nest, built mostly by female, a simple accumulation of sticks lined with finer twigs, very sparsely constructed (may virtually disintegrate by the time when chicks leave), one had external diameter 17–20 cm, height 10 cm, internal diameter 10 cm, depth 5 cm; at one study site in Nicaragua, the nest placed 1·5–6 m above ground and always in coffee tree. Clutch usually 3–4 eggs, but one family group had five recently fledged juveniles; two females share incubation duties and the brooding of chicks, and up to eleven individuals recorded as helping to feed young; no information on duration of incubation and nestling periods.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in North Central American Highlands EBA. Not uncommon. In Montecristo National Park, in El Salvador, estimated density in pine–oak forest (at 1000–1900 m) 0·78 pairs/ha, significantly higher than the 0·26 pairs/ha in a 300-ha Mexican cypress (*Cupressus lusitanica*) plantation (1750–2000 m). Home range 4–5 ha. Lives at forest edges, which has enabled it to become established in areas cleared for agriculture, especially coffee plantations.
Bibliography. Blake & Vaurie (1962), Clements (2000), Dickinson (2003), Goodwin (1976), Hardy (1961, 1969a, 1973, 1974a, 1974b, 1979, 1984), Howell & Webb (1995), Komar (2002), Madge & Burn (1994), Remsen *et al.* (2009), Sibley & Monroe (1990), Skutch (1987), Stotz *et al.* (1996), Van Perlo (2006).

21. San Blas Jay

Cyanocorax sanblasianus

French: Geai de San Blas **German**: Acapulcoblaurabe **Spanish**: Chara de San Blas
Other common names: Black-and-blue Jay

Taxonomy. *Pica San-Blasiana* Lafresnaye, 1842, Acapulco, Mexico.
This species and *C. melanocyaneus*, *C. yucatanicus* and *C. beecheii* were formerly placed together in a separate genus, *Cissilopha* (the black-and-blue jays of Middle America). Has been thought to form a superspecies with *C. yucatanicus*. Two subspecies recognized.
Subspecies and Distribution.
C. s. nelsoni (Bangs & T. E. Penard, 1919) – SW Mexico, from Nayarit, Jalisco and Colima S to W Guerrero.
C. s. sanblasianus (Lafresnaye, 1842) – C coastal region of Guerrero, in SW Mexico.

Descriptive notes. 27–35 cm; 92–122 g. Small frontal crest, length and development varying individually; feathers of loral region plush-like and somewhat stiffened, and continuing posteriorly as broad "eyebrow" of such feathering. Nominate race has head, neck and upper mantle black, rest of upperparts, including upperwing, uppertail-coverts and tail, purplish-blue, remiges edged blue on outer webs, greenish on inner webs; underparts black, undertail-coverts and tibia dark purplish-blue, underwing grey, underside of tail blackish; iris yellow; bill black; legs greenish-yellow. Sexes similar. Juvenile is duller than adult, with elongated wispy frontal crest, iris dark brown, bill yellowish, legs brownish; loses crest at end of first year, after which plumage much as adult, bill becoming black early in first year, iris yellowish generally by third year. Race *nelsoni* is somewhat less bright than nominate, upperparts cobalt-blue, lacking purplish tinge, some individuals tinged greenish, male has iris dull greenish-yellow iris (female pure yellow), juvenile retains crest for longer, to third year, than in nominate race does not acquire yellow iris until fourth year (not third). Voice. Chatter call (social call) of *nelsoni* a rather uniform and short nasal sound, that of nominate more sustained and downwardly inflected; this call the most frequently heard vocalization and included in almost any context, may grade into social alarm call in situation of extreme danger. Contact call a resonant "chank chank", by both races. Begging call a sustained and soft "caah", heard from incubating females and from food-begging juveniles. Nominate race has a rattle call to warn of overhead predator, and a resonant and rarely emitted "clank!" in situations in which high levels of conflict would be predicted. Subsong (*sotto voce*) given during courtship display, also in other situations where probable conflict of motivation.
Habitat. Arid to semi-humid forest, palm groves with native woodland or scrub nearby; avoids interior of forest. Also in mangroves and cultivation mixed with woody scrub.
Food and Feeding. Insects, including katydids (Tettigoniidae), small lizards (*Anolis*) and occasionally larger lizards seem to compose bulk of animal items; eats fruits, especially pericarp of palm nuts. Nestlings fed not only with insects, but also with parts of lizards and pieces of orange fleshy pericarp of coconut fruit (*Cocos nucifera*). Forages high in palm fronds, but captures insects also in herbaceous vegetation; forages also at middle and high levels of broadleaf native vegetation, in hedgerows, and in jungle patches. When foraging for palm nuts, sometimes hangs upside-down or flutters upwards to peer into places difficult to reach. Recorded once as active attendant at swarms of army ants (Formicidae). Forages alone during breeding season and in flocks of up 30 individuals at other times. Foraging home range of group maintained by mutual avoidance, rather than by active defence.
Breeding. Eggs and young recorded in Jun and Jul; groups have at least two partly overlapping nesting periods in breeding season. Communal breeder, living in large groups of 13–26 individuals, of which 6–10 breeding pairs and the others helpers; both breeders and non-breeders of the group assist in feeding and defending young; some nests attended by as many as 14 birds, including parents, and nests begun early in season attract more helpers than do later ones, as helpers have to feed increasing number of fledglings (rather than nestlings) as season progresses. Within extensive foraging territory of a large flock there is a smaller breeding area, where pair (especially male) verges on territoriality towards members of own flock; such individual "core areas" not evident in smaller groups. Courtship includes display in which pupils are constricted. Nest built mostly by female of breeding pair, assisted or accompanied by mate, made with twigs and lined with plant fibres and other soft material, those of nominate 9–15 m above ground and almost exclusively in coconut palm (on bract or cluster of coconuts at base of fronds), nests of race *nelsoni* at height of 3–5·5 m. Clutch 3–4 eggs; incubation period 17–18 days; nestling period c. 18–20 days. Success moderate; 22–38% of eggs result in fledglings. Most birds breed first at 3 years of age, but surprising number of immatures (even first-year birds) also breed.
Movements. Sedentary. Indications of occasional vagrancy N to S USA (Arizona).
Status and Conservation. Not globally threatened. Restricted-range species: present in Balsas Region and Interior Oaxaca EBA and North-west Mexican Pacific Slope EBA. Fairly common to locally common, but rather patchily distributed. Home range of one small flock measured 3·1 ha. May occur in disturbed areas, as in mixed cultivation and in native shrubby wooded habitats, but in more natural conditions seems to be rather patchily distributed.
Bibliography. Blake & Vaurie (1962), Clements (2000), Davis (1960), Dickinson (2003), García-Trejo & Navarro Sigüenza (2004), Goodwin (1976), Gordon & Ornelas (2000), Hardy (1961, 1969a, 1973, 1974a, 1974b, 1979, 1984), Hardy & Raitt (1977), Hardy *et al.* (1981), Howell & Webb (1995), Madge & Burn (1994), Phillips (1950), Raitt & Hardy (1976), Remsen *et al.* (2009), Sibley & Monroe (1990), Skutch (1987), Stotz *et al.* (1996), Van Perlo (2006).

22. Yucatan Jay

Cyanocorax yucatanicus

French: Geai du Yucatan **German**: Yucatanblaurabe **Spanish**: Chara Yucateca

Taxonomy. *Cyanocitta yucatanica* A. J. C. Dubois, 1875, Yucatán, Mexico.
This species and *C. melanocyaneus*, *C. sanblasianus* and *C. beecheii* were formerly placed together in a separate genus, *Cissilopha* (the black-and-blue jays of Middle America). Has been thought to form a superspecies with *C. sanblasianus*. Two subspecies recognized.
Subspecies and Distribution.
C. y. rivularis (Brodkorb, 1940) – Tabasco and SW Campeche, in SE Mexico.
C. y. yucatanicus (A. J. C. Dubois, 1875) – SE Mexico (Yucatán, Campeche except SW, and Quintana Roo) S to N Guatemala (Petén district) and N Belize.
Descriptive notes. 31–33 cm; 105–128 g. Head bulky, with short tufted feathers on forecrown. Nominate race has head, neck and upper mantle black, rest of upperparts, including wing and tail, cerulean blue, some individuals tinged bluish above (particularly on tail); underparts black, undertail-

On following pages: 23. Purplish-backed Jay (*Cyanocorax beecheii*); 24. Violaceous Jay (*Cyanocorax violaceus*); 25. Purplish Jay (*Cyanocorax cyanomelas*); 26. Azure Jay (*Cyanocorax caeruleus*); 27. Curl-crested Jay (*Cyanocorax cristatellus*); 28. Tufted Jay (*Cyanocorax dickeyi*); 29. Black-chested Jay (*Cyanocorax affinis*); 30. White-tailed Jay (*Cyanocorax mystacalis*); 31. Cayenne Jay (*Cyanocorax cayanus*); 32. Azure-naped Jay (*Cyanocorax heilprini*); 33. Plush-crested Jay (*Cyanocorax chrysops*); 34. White-naped Jay (*Cyanocorax cyanopogon*); 35. Green Jay (*Cyanocorax yncas*).

coverts and tibia with scattered blue tipping, underside of tail blackish and underwing grey; iris blackish-brown; bill black; legs bright orange-yellow. Sexes similar. Juvenile is distinctive, has entire head and underparts white, upperparts greyish-blue, undersurfaces of wing and tail dull grey, rectrices (except middle pair) white-tipped, bill and legs flesh-yellow, inside of bill white, iris dark, acquires blackish head and body plumage and brighter leg and bill colour during first moult a few weeks after fledging; through first year like dull adult, but has bright yellow bill and orbital ring and retains whitish tips of tail feathers, by second year bill becomes variably mottled (some are black-billed) and orbital ring broken by black, by third year bill black (some pale areas may persist, and even some fourth-year birds show some whitish inside mandibles). Race *rivularis* is slightly larger, lighter, and more silvery blue above than nominate. Voice. Large vocabulary. Most frequently heard is rapid chatter call, a sequence of harsh notes, lower in pitch, and emitted in staccato, given when potential predator nearby, and causes flock-members to congregate (social call), all individuals of flock joining in chorus; in situation of extreme danger, e.g. predator or human touching nest contents, chatter call may grade to a fear call (social alarm call), thinner and less structured, with notes at faster pace; chatter call may grade to a rattle, an avian-predator alarm, more diffuse, with less staccato quality or a less steep wave front to the successive components. Next most often heard is contact call, "chook chook", a sequence of 2–3 melodic notes lower in pitch, given by birds during foraging or moving slowly in loose group. Begging call by adult female ("caah") on nest or by young birds ("squawk"). Also, a group of resonant and guttural calls, e.g. "pleeop", "yelp" and "clank-clank", supposedly emitted in conflict behavioural contexts; all were heard given by flock attending army-ant swarm, and some could be specialized for that context. One or more members of captive flock gave "peyook" call on discovering new food supply. Subsong (*sotto voce*) rare, this possibly associated with dark iris and consequent lack of constricted-pupil display.

Habitat. Edges and clearings of deciduous forest and dense scrubby woodland, from sea-level to 250 m. In Belize and Guatemala lives in pine (*Pinus*) woodland with scrubby undergrowth; recorded also in marsh in Belize (Lamanai). May benefit from habitat disturbance, which increases edge areas. Breeding flocks appear to prefer forest edge, and optimal habitat a mixture of clearings and patches of forest.

Food and Feeding. Stomachs contents in spring indicated about equal proportions of plant and animal items; seeds (especially corn) accounted for most of vegetable material, and arthropods, mostly beetles (Coleoptera) but also Orthoptera, Lepidoptera larvae and flies (Diptera) were primary animal food, with spiders (Araneae), ants (Formicidae) and a mollusc also recorded. During summer, caterpillars and berries the most frequent food items. Some resources, such as cultivated papayas, reached by means of long flights. Examines foliage and branches of all strata, but observations indicate that food acquired mostly from on or near the ground. Usually in flocks of 6–12 individuals, but in winter months sometimes 45–53 (supposedly amalgamation of neighbouring breeding groups); 40–50% of individuals in each flock first-year birds. Usually the flock moves along near forest edge in loose groups, flying or hopping between branches; parts of group may stop to forage briefly on or near ground while others move ahead. Groups recorded as attending army-ant swarms, but not known if such behaviour sporadic, regular or seasonal.

Breeding. Laying in May and Jun, at least; seemingly two sequential or partially overlapping nesting phases in breeding season. Communal breeder, group size 4–15 individuals, including one or two yearlings and, sometimes, one to three two-year-olds; large groups may have two or more simultaneous nests attended by separate units of the flock. In one study, breeding flock stayed within area of 400 m from nest, although territory defence not documented. Helpers seem to participate in nest-building; nest a flimsy platform with shallow cup, composed mostly of sticks inlaid with a few finer twigs or coarse plant fibres, lining never dense (often permitting contents to be viewed from below), placed 4–9 m up in tree, usually close to edge (within 5 m) in upper forest canopy. Clutch 4–6 eggs; incubation by female breeder, fed by male and by several helpers, period 17 days; chicks fed by all group-members, mostly by adult individuals, in captivity nestling period at one nest 26 days. Infestation of nest by fly larvae common, can have adverse effect on nest success.

Movements. Sedentary; movements of up to 4 km seem rare.

Status and Conservation. Not globally threatened. Common to fairly common throughout range. Habitat disturbance has benefited this species.

Bibliography. Blake & Vaurie (1962), Clements (2000), Dickinson (2003), England (2000), Goodwin (1976), Hardy (1961, 1969a, 1973, 1974a, 1974b, 1976, 1979, 1984), Howell & Webb (1995), Madge & Burn (1994), Raitt & Hardy (1976), Remsen *et al.* (2009), Sibley & Monroe (1990), Skutch (1987), Stotz *et al.* (1996), Van Perlo (2006).

23. Purplish-backed Jay

Cyanocorax beecheii

French: Geai à dos violet **German**: Trauerblaurabe **Spanish**: Chara de Beechey
Other common names: Beechey's Jay

Taxonomy. *Pica Beecheii* Vigors, 1829, Montereale = Mazatlán, Sinaloa or San Blas, Nayarit, Mexico. This species and *C. melanocyaneus*, *C. sanblasianus* and *C. yucatanicus* were formerly placed together in a separate genus, *Cissilopha* (the black-and-blue jays of Middle America). Monotypic.

Distribution. Pacific coastal lowlands of NW Mexico from S Sonora (Alamos) S to N Nayarit (S to Sauta).

Descriptive notes. 35–40 cm; 193 g. Head bulky, with stiffened, plush-like feathers extending from forehead and lores above and, to some extent, under eye, conspicuous only when erected. Head, neck, upper mantle and entire underside are black, throat tending to sepia and tibia to dark purplish-blue; upperparts and upperwing bright ultramarine, outer margins of primaries cerulean blue, inner margins blackish, tail indigo-blue; underwing and underside of tail blackish; iris yellow; bill black; legs yellow. Sexes similar. Juvenile has dark grey head and body, distinctly darker hood and almost blackish breast, bluish wings and tail, bill yellowish-horn with white inside, legs dull horn, iris dark brown; at c. 3·5 months resembles adult, legs become yellow in first year, bill acquires some black (starting from base) during second year, becoming completely black (pale patches remain on inside) in third year, iris becomes gradually greenish-yellow in second year and yellow in third year. Voice. Seems to have limited vocal repertoire. Frequently utters a *Corvus*-like vocalization, a harsh cawing call (social call), "ahhr" or "ehrrr", variable in cadence, amplitude and configuration, variations supposedly related to motivation level of individual (intriguingly, sympatric *Corvus sinaloae* said to have a call similar to that of several species in present genus); in extreme alarm, as when predator too close to eggs, gives a variation of cawing call (social alarm call), with more frequency modulation. Subsong (*sotto voce*) complex, given during courtship. Other vocalizations, rarely recorded in the field and of unknown context, "clok clok clok", "peep!", "pook", and a longer so-called "crying call".

Habitat. Lowland and foothill dry deciduous forests, especially secondary growth, from sea-level to 600 m; also coastal scrub and mangroves. Seems to be associated with interior of forests more than are its congeners in Middle America.

Food and Feeding. Variety of invertebrates, including mosquitoes (Culicidae), winged termites (Isoptera) and ants (Formicidae), cockroaches (Blattodea), cicadas (Cicadidae), larval and adult Lepidoptera, beetles (Coleoptera) and spiders (Araneae); also small lizards (*Anolis*) and small rodents; also fruits, especially mangoes (*Mangifera*), berries, and grain (both from growing corn and that spilt on roadside and railway lines). Recorded as taking discarded tortillas from refuse dumps. Appears to be more omnivorous than congeners in Middle America, e.g. *C. yucatanicus* (hypothesized that more varied diet combined with larger body size would be an adaptation to seasonally low food supply). Several foraging techniques used, from gleaning foliage, probing bark and searching among leaf litter on forest floor to brief bouts of hawking for flying insects. Forages in small flocks of 2–6 individuals (breeding pair and helpers), preferring forest interior over forest edge; forages from ground up to canopy, with approximately equal numbers of observations of birds foraging on ground and in trees. Flock mobility high, individuals seldom spending long periods at one site; flights of more than 100 m recorded.

Breeding. Laying recorded in first half May; one brood per year. Social breeder, occasional solitary nesting recorded (perhaps when low population density); each group has only one active nest at one time, parenthood within group confined to adult of each sex 3 years or more old; all members of group assist in nest defence and in feeding of chicks and fledglings; helpers can be yearlings, 2-years-old or adults. Hostile interactions between birds of different groups, suggesting territorial defence. All members of group contribute to nest construction, mated female doing bulk of work; nest a rather untidy platform of twigs, sparingly lined with finer twigs, built 4–7·6 m up in tree that retains leaves throughout dry season (e.g. *Zizyphus*, *Trichilia trifolia*). Clutch 3–6 eggs, average 5; incubation solely by breeding female, fed by mate, period c. 18–19 days; male "guards" nest in short absences of female, but rarely waits for her return; estimated nestling period 22–25 days. Most important nest predators are Mexican beaded lizards (*Heloderma horridum*), snakes, and *Callocitta colliei*; lesser predators include squirrels (Sciuridae), hawks (Accipitridae), owls (Strigidae), *Corvus* species, and possibly jaguarundi (*Puma yagouaroundi*).

Movements. Sedentary.

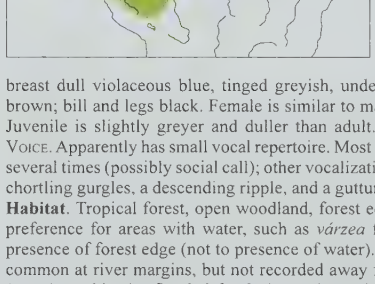
Status and Conservation. Not globally threatened. Restricted-range species: present in Northwest Mexican Pacific Slope EBA. Fairly common, but local. Has low population density, flocks appear to occupy home ranges of 25–43 ha; few nests per group, and high number of nest predators. Requires primary forest; although it forages in secondary growth, has disappeared from clear-cut areas. Extensive areas of native deciduous forest in Sonora and N Sinaloa have been destroyed in recent years. Has been suggested that this species could become threatened in coming decades because it is restricted to dry lowland forest and its habitat has no protection at all.

Bibliography. Blake & Vaurie (1962), Clements (2000), Dickinson (2003), Escalante & Néquiz (2004), García-Trejo & Navarro Sigüenza (2004), Goodwin (1976), Gordon & Ornelas (2000), Hardy (1961, 1969a, 1973, 1974a, 1979, 1984), Howell & Webb (1995), Madge & Burn (1994), Peterson & Navarro Sigüenza (2000), Raitt & Hardy (1979), Raitt *et al.* (1984), Remsen *et al.* (2009), Sibley & Monroe (1990), Skutch (1987), Stotz *et al.* (1996), Van Perlo (2006), Winterstein & Raitt (1983).

24. Violaceous Jay

Cyanocorax violaceus

French: Geai violacé **German**: Hyazinthblaurabe **Spanish**: Chara Violácea



Taxonomy. *Cyanocorax violaceus* du Bus de Gisignies, 1847, Pebas, River Marañón, Loreto, eastern Peru.

Has been thought to form a superspecies with *C. cyanomelas*, *C. caeruleus* and *C. cristatellus*. Two subspecies recognized.

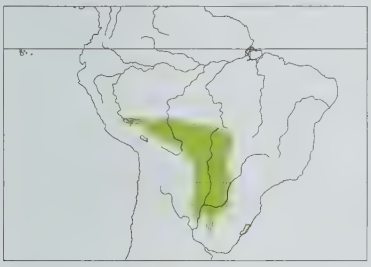
Subspecies and Distribution.

C. v. pallidus J. T. Zimmer & Phelps, Sr, 1944 – N Venezuela (coast of Anzoátegui).

C. v. violaceus du Bus de Gisignies, 1847 – SW & S Venezuela and SW Guyana S to E Peru (S to Madre de Dios and Puno), N Bolivia (Panda and La Paz) and N Brazil (E to upper R Negro and lower R Purús).

Descriptive notes. 33–37 cm; 262 g. Slight frontal crest of erect but short nasal plumes and forehead feathers, and feathers of lores, malar region and eye stiffened; some have longer feathers on crown. Male nominate race has forecrown blackish, crown, side of head, side of neck, throat and upper breast sepia, nape mauvish-white, shading to pale bluish-mauve on hindneck; upper mantle white, heavily tinged dull violaceous blue, rest of upperparts pure dull violaceous blue, tail indigo-blue; upperwing bright dull violaceous blue, primaries blackish with have dull violaceous blue on outer margins; underparts below upper breast dull violaceous blue, tinged greyish, underwing and underside of tail blackish; iris dark brown; bill and legs black. Female is similar to male, but underparts more heavily tinged greyish. Juvenile is slightly greyer and duller than adult. Race *pallidus* is paler overall than nominate. Voice. Apparently has small vocal repertoire. Most frequent call a loud "jyeeeer!" or "jeeer", emitted several times (possibly social call); other vocalizations include "clop-clop-clop-clop", various quiet chortling gurgles, a descending ripple, and a guttural clicking. Harsh note as juvenile begging call.

Habitat. Tropical forest, open woodland, forest edge, and secondary growth. Reported as having preference for areas with water, such as *várzea* forest and mangrove, but this presumed due to presence of forest edge (not to presence of water). In study site of 800 ha in Brazil (W Amazonas) common at river margins, but not recorded away from river in high forest; forest at river margins (*igapó*) at this site flooded for 3–4 months each year and strip-width 50–250 m. Ventures into



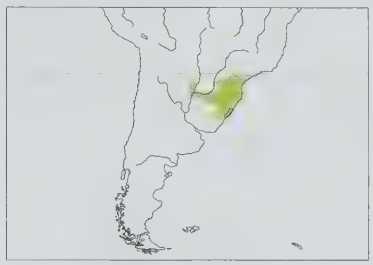
plantations. Lowlands to 1350 m; in Serranía de los Churumbelos (S Colombia) recorded at 350–1100 m, and in Tinigua National Park (N Colombia) at 350–400 m.
Food and Feeding. Insects and fruits. Forages through middle and upper canopy; detailed study in Venezuela showed strong association with canopy (above 18 m). Takes items by hopping and picking. Seen to perch frequently in *Cecropia* along rivers in noisy and active groups of 6–12 individuals; flock-members move one by one across forest clearings and rivers. Sometimes associates with large mixed foraging flocks of oropendolas (*Psarocolius*) and caciques (*Cacicus*).
Breeding. In Venezuela, one nest with eggs in early Apr in Orinoco basin and two large young observed in Jul in *llanos*. Lives in flocks throughout year; presumably a social breeder, but documentation not available. One nest found, a bulky structure of sticks and twigs, lined with plant fibres, c. 9 m up at top of edge tree in mangrove. One clutch of 5 eggs, laid on consecutive days. No other information.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Common to fairly common in much of range; uncommon to locally fairly common in Venezuela.
Bibliography. Blake & Vaurie (1962), Cadena *et al.* (2000), Clements (2000), Clements & Shany (2001), Davis *et al.* (1994), Dickinson (2003), Goodwin (1976), Haffer (1975, 1992), Hardy (1961, 1969a, 1969b, 1984), Hilty & Brown (1986), Hornbuckle (1999), von Ihering & von Ihering (1907), Madge & Burn (1994), Meyer de Schauensee (1966, 1970), Meyer de Schauensee & Phelps (1978), Moscovits *et al.* (1985), Naka *et al.* (2006), Parker & Remsen (1987), Parker *et al.* (1991), Peres & Whittaker (1991), Pinto (1944), Remsen *et al.* (2009), Restall *et al.* (2006), Ridgely & Tudor (1989), Ruschi (1979), Salaman *et al.* (1999), Sibley & Monroe (1990), Sick (1985, 1986, 1997), Sigrist (2006), da Silva (1998), Snethlage (1914), Souza (2004), Stotz (1997), Stotz *et al.* (1996), Walther (2002).

25. **Purplish Jay**

Cyanocorax cyanomelas

French: Geai bleu-noir **German**: Purpurblaurabe **Spanish**: Chara Morada

Taxonomy. *Pica cyanomelas* Vieillot, 1818, Paraguay.
Possibly forms a superspecies with *C. caeruleus*; has been suggested that *C. violaceus* and *C. cristatellus* could be members of same superspecies. Monotypic.
Distribution. Extreme SE Peru (Cuzco and Madre de Dios), N & E Bolivia, Paraguay, SW Brazil (S Rondônia, Mato Grosso, Mato Grosso do Sul, SW Goiás, extreme W São Paulo and extreme W Paraná), N Argentina (E Formosa, E Chaco, N Corrientes, N Santa Fé and Misiones) and extreme NW Uruguay (Artigas). One recent and isolated record in C São Paulo.



Descriptive notes. 37 cm; 185–210 g. Short black frontal crest and nasal tuft, and stiff feathers on lores, malar region and around eye. Has anterior half of crown and side of head sepia, posterior half of crown, nape and hindneck dark drab brown, hindneck slightly tinged violet, side of neck, throat and breast brownish-black; rest of body dull bluish-purple with brownish wash; upperwing violet, inner margin of primaries brownish, tail dark violet; underwing brownish, undertail blackish; iris dark brown; bill and legs black. Sexes similar. Juvenile is paler and duller than adult. Voice. Vocal repertoire seems small, primarily of harsh sounds. Repeated harsh "jar-jar-jar-jar" or "craa-craa-craa-craa" the loudest call (audible to 150 m) and the most common vocalization heard (social call); highly motivated individuals tend to emit shorter notes at faster rhythm. Other shorter harsh notes, with variations, given usually during foraging (contact call), not audible beyond 30 m; this call resembles to some extent those of *Corvus*.
Habitat. Deciduous forest, gallery forest and adjacent areas of scrub and secondary forest, with xerophytic features; mainly lowlands, but has been recorded to 2000 m. Commonly in areas with sparse trees and isolated patches of forest in the Pantanal region (Brazil) and *cerrado* (Brazil, Bolivia and Paraguay). Was considered among the five most abundant bird species in *chiquitano* (xeric forest similar to *chaco* but with stratification rivalling that of the Amazonian forest) at a study site at W Bolivia.
Food and Feeding. Invertebrates, fruits and berries; probably takes contents of other birds' nests; probably feeds also on carrion. Group of six individuals observed to prey on nest of social wasps (Vespidae) in Pantanal; seen to be chased by Hyacinth Macaw (*Anodorhynchus hyacinthinus*) from latter's nest. Forages in small flocks of 6–8 individuals in all forest strata, but prefers canopy; frequently seen on the ground; commonly makes long flights over open areas. Forages often in company with *C. chrysops*, and both species recorded in mixed-species flock at swarm of ants (Formicidae) in a dry forest in Paraguay. Associates also with large icterids (Icteridae).
Breeding. Eggs recorded from early Oct to early Dec in Paraguay and Nov in Argentina. One nest described, built with twigs and creeper stems, lined with leaves, placed 3 m above ground in low tree covered with creepers. Clutch 2–6 eggs, chiefly 3 or 4; no information on incubation and nestling periods.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Generally fairly common. Locally common in Paraguay and Argentina; rare in Peru. It is possible that deforestation has allowed an expansion of its geographical distribution in W São Paulo (Brazil).
Bibliography. Azpiroz (2006), Barnett & Pearman (2001), Blake & Vaurie (1962), Brooks *et al.* (2005), Brumfield *et al.* (2004), Cavalcanti & Marini (1993), Clements (2000), Clements & Shany (2001), Dickinson (2003), Dubs (1992), Flores *et al.* (2001), Goodwin (1976), Hardy (1961, 1969a, 1984), Hayes (1995), Hayes & Scharf (1995a, 1995b), Hennessey *et al.* (2003), von Ihering & von Ihering (1907), MacLeod *et al.* (2005), Madge & Burn (1994), Madroño *et al.* (1997), Mercado (1985), Meyer de Schauensee (1966, 1970), Narosky & Yzurieta (2003), Nores (1992), Oniki & Willis (1999), Pinho & Nogueira (2003), Pinto (1944), Remsen *et al.* (2009), Ridgely & Tudor (1989), Robbins *et al.* (1999), Ruschi (1979), Scherer-Neto (1983), Scherer-Neto & Straube (1995), Sibley & Monroe (1990), Sick (1985, 1986, 1997), Sigrist (2006), Souza (2004), Stotz *et al.* (1996), Straube & Bornschein (1995), Straube *et al.* (1996), Tubelis & Tomás (1999, 2003), Wetmore (1926), Willis & Oniki (1990, 1993, 2003), Zyskowski *et al.* (2003).

26. **Azure Jay**

Cyanocorax caeruleus

French: Geai azuré **German**: Azurblaurabe **Spanish**: Chara Cerúlea

Taxonomy. *Pica caerulea* Vieillot, 1818, Paraguay.
Possibly forms a superspecies with *C. cyanomelas*; it has been suggested that *C. violaceus* and *C. cristatellus* could be members of same superspecies. Monotypic.
Distribution. S & SE Brazil (Rio Grande do Sul, Santa Catarina, Paraná, SE São Paulo), extreme E Paraguay, NE Argentina (Misiones, Corrientes, Chaco, Formosa) and NE Uruguay (Cerro Largo).

Descriptive notes. 38 cm; 272 g. Small bristly frontal crest formed by long stiffened feathers of forehead; two morphs, differing in blue tone of body plumage. Has forecrown blackish, crown, nape, side of head, side of neck, throat and breast sepia; remainder of plumage, including outer margins of primaries, tending to bright cerulean blue on some individuals and to bright ultramarine-blue on others; inner margins of primaries brownish, as are underwing and undertail; iris dark brown; bill and legs black. Sexes similar. Juvenile has back, wings and tail purplish-blue, underparts and rump indigo, and a yellow spot close to base of lower mandible (still visible on juvenile at 6 months). Voice. Total of 14 basic calls identified in detailed study. Basic calls may grade into intermediate ones during change in motivation level of individual. Typical vocalization an inflected and melodic note, repeated several times, "caa-caa-caa" (social call), audible at up to 200 m, given in territory defence, flock movements, and flock congregation; shorter, slightly inflected variant delivered more quickly by highly excited individuals, as when mobbing (social alarm call). Also has *Corvus*-like harsh sound, when individuals foraging in forest (contact call), audible to 50 m. Flight call a variation of contact call. Imitations of birds of prey given. Other vocalizations, rarely heard, are quiet and associated with agonistic contexts. Subsong (*sotto voce*) commonly heard and frequent during courtship (courtship call); can be emitted also by solitary individuals. Vocalizations resemble those of *C. cristatellus* and *C. cyanomelas* because of harsh notes, quite different from those of *C. chrysops*.
Habitat. Interior and edges of tropical and subtropical forests; commonly associated with temperate forest, where the conifer *Araucaria angustifolia* the dominant tree, but found also in other types of forest, such as tropical lowland forest on coast. In S Brazil inhabits natural patches of southern temperate forest (*capões*) in grassland regions (to reach these isolated patches flock makes uninterrupted flight of 1000 m over grassland); recorded in mangrove and also on islands (covered by forest) 2 km from coast in Paraná (S Brazil). Frequent also in secondary forest not far from primary forest. Breeding territories often close to small hill with stream nearby.
Food and Feeding. Seeds, fruits; also animal items, including beetles (Coleoptera), Formicidae (the ants *Labidus praedator* and *Crematogaster* recorded in stomach), Gonyleptidae (Opiliones), spiders (Araneae), mantis (Mantodea), the crab *Pachygrapsus transverses*, passerine eggs and nestlings, and adult small birds; takes eggs of domestic hens and fresh meat around human settlements. Feeds almost exclusively on seeds of *Araucaria angustifolia* (taken directly from tree) during autumn–winter (Apr–Jul) in temperate forest; in tropical lowland forest (where *Araucaria angustifolia* absent) and at other seasons in temperate forest, feeds on fruits of Myrtaceae (*Campomanesia* and *Eugenia uniflora*), Rosaceae (*Prunus sellowii*), Moraceae (*Ficus* and *Coussapoa microcarpa*), Myrsinaceae (*Rapanea ferruginea*), Solanaceae (*Solanum pseudoquina*), and Lauraceae; fruits of the palm *Euterpe edulis* seem to be an important item in tropical lowland evergreen forest; seeds of a Magnoliopsida and fibres of Magnoliophyta also recorded. Seen to visit maize (*Zea mays*) plantations; other cultivated items recorded are *Ipomoea batata* (Convolvulaceae), *Eriobotrya japonica* (Rosaceae), *Musa paradisiacal* (Musaceae). One seed of pine (*Pinus*), an exotic tree species in Brazil, was found in one stomach. Seen to conceal seed of *Araucaria angustifolia* at base of branches in taller trees, but no records of recovering food; in captivity, individuals regularly hid food, usually not on ground, and recovered it later. In studies in southern temperate forest, flocks of 3–9 individuals foraged in canopy, sometimes in subcanopy; rarely recorded below 2 m or on ground. Where sympatric with *C. chrysops* (most of range) tends to stay mostly in canopy, while that species forages in subcanopy and understorey. During foraging, maximum individual distance within group often 50 m; when foraging for mature seeds of *Araucaria* can form subgroups (2–4 individuals each), which feed up 200 m from one another. One observation of a group attending ants (Formicidae) in mixed flock with Rufous-bellied Thrush (*Turdus rufiventris*), Yellow-legged Thrush (*Turdus flavipes*), Squirrel Cuckoo (*Piaya cayna*), Planalto Woodcreeper (*Dendrocolaptes platyrostris*), and Black-goggled Tanager (*Trichothraupis melanops*); individuals seen very close to the ground.
Breeding. Nests found Oct–Jan. Social breeder; helpers at nest seen to mob a Roadside Hawk (*Buteo magnirostris*). Nest of sticks and large twigs, inner cup lined with roots and fibrous materials (probably from some epiphyte), external diameter 40–50 cm (one with more oval shape, 55 × 35 cm) and height 18–19 cm, internal diameter 16–19 cm and depth 6–9 cm; in temperate forest placed 10–20 m up in *Araucaria angustifolia* (mostly young trees) or in Lauraceae tree; territory estimated at 9–12 ha in temperate forest, seemingly smaller in tropical lowland forest. Clutch 2–4 eggs; estimated incubation period 17–21 days and nestling period 18 days.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Locally common to uncommon or rare; declining. Estimated home range of flock large, 30–40 ha. In Paraguay a single confirmed record of a pair in extreme E (close to Ciudad del Este), but no recent records; old records questionable, and several instances of published records and museum specimens from Argentina and Paraguay relate to misidentified *C. cyanomelas*. Rare in Argentina; in Misiones, where there are more records (but still considered rare), occurs patchily, apparently where groups of *Araucaria angustifolia* are present. In southern temperate forest of Brazil rarer than in lowlands of Atlantic forest near coast. Owing to habitat degradation, this species has become extinct in some areas where previously recorded, e.g. near Porto Alegre, in S Brazil. In contrast, appears to be increasing, unexpectedly, on island of Santa Catarina (S Brazil), where now common in urban areas and secondary forest. Recently recorded at R Yaguarón (Cerro Largo) in NE Uruguay. This species contributes to the dispersal of *Araucaria angustifolia*, as it often does not retrieve dropped seeds. Seeds of this tree exploited for human consumption in S Brazil, and thousands are taken from the trees each year; this could have adverse impact on present species, as it is highly dependent on *Araucaria* seeds during winter. Although it lives at forest edge, forest fragmentation seems another factor in the population decline; presence of primary forest within its range appears to be important.

27. Curl-crested Jay

Cyanocorax cristatellus

French: Geai à plumet **German**: Krauskopf-Blaurabe **Spanish**: Chara Crestada

Taxonomy. *Corvus cristatellus* Temminck, 1823, Ipanema, São Paulo, Brazil.
Formerly placed in a monotypic genus, *Uroleuca*. Has been thought to form a superspecies with *C. violaceus*, *C. cyanomelas* and *C. caeruleus*. Monotypic.
Distribution. Brazil (S Pará, S Maranhão, S Piauí and W Bahia S to Mato Grosso do Sul and NE Paraná), extreme CE & NE Paraguay (Concepción and Canindeyú) and extreme E Bolivia (NE Santa Cruz).

Descriptive notes. 35 cm; 178 g. Distinctive, with long, recurved black frontal crest; short nasal tuft. Forehead, crown and side of head are black, nape, side of neck, throat and breast sepia; upper mantle sepia, becoming washed cyan-blue towards rump, rump almost pure cyan-blue; upperwing bright cyan-blue, primaries with outer margins cerulean blue and inner margins blackish; underparts below breast whitish, on some individuals washed cream and on others washed grey; underwing brownish, whitish underwing-coverts; basal half of tail bright cyan-blue above and blackish below, rest white (or whitish) on both surfaces; iris dark brown; bill and legs black. Sexes similar. Juvenile is duller than adult, with shorter and less curled crest, terminal third of tail washed mauve, wing-coverts tipped brownish. Voice. Repertoire resembles that of *C. caeruleus*. Farthest-carrying (at least 200 m) vocalization a melodic and inflected note, "kyaar", repeated several times by individuals during territorial defence, flock movements, and congregation (social call); similar, but shorter call, "kyap", constantly emitted, usually by all individuals in flock, in situation of extreme excitement, as when mobbing bird of prey (social alarm call). Quite variable harsh note, like that of *Corvus*, audible to less than 50 m, given during foraging by flock-members (contact call). Begging call resembles contact call, but longer. Other vocalizations, rarely heard, are related to agonistic behaviour. Subsong (*sotto voce*) recorded.
Habitat. Dry forest of *cerrado*; also in riparian forest, forest edge and grassland areas with sparse covering of shrubs and trees. At 150–1100 m. Can be found in many modified landscapes, such as edge of eucalypt (*Eucalyptus*) plantations and gardens very close to cities; has benefited from logging. Overlaps widely with *C. cyanopogon*; in study in NE Minas Gerais, in a transect from *cerrado* to *caatinga*, present species was progressively replaced by *C. cyanopogon*; in another study site, in SE Tocantins, was significantly more numerous than that species in *cerrado*.
Food and Feeding. Insects (47%), fruits (40%), nectar (12%) and small vertebrates (1%) recorded as food for four groups studied in C Brazil. Among fruits consumed are *Shefflera macrocarpa*, *Psitacanthus robustus*, *Caryocar brasiliense*, *Syagrus flexuosa*, *Eugenia calycina*, *Copaifera langsdorffii*. Among 13 bird species that visited three flowering trees of *Caryocar brasiliense*, present species remained for longest mean time (more than 3 minutes); groups of 3–6 probed flowers. Also, in Brazil, reported as preying on nest of a social wasp (*Apoica pallens*) near Brasília, and recorded as preying on eggs of Ruddy Ground-dove (*Columbina talpacoti*) and nestling of Sayaca Tanager (*Thraupis sayca*) in São Paulo. Observations of four flocks (9–11 individuals) in C Brazil indicated that chief vegetation layer used during foraging was above 4 m (64% of events), then shrubby vegetation (29%), and lowest layer (7%), and most frequent foraging technique was gleaning (59%), followed by sallying (25%), then hanging, hammering, and taking insects in steady flight; foraged mainly in morning (06:00–10:00 hours) and later afternoon (14:00–18:00 hours). Sentinel behaviour quite evident during foraging, accounting for 50% of total activity time during day; sentinels generally use high perches (5–10 m up), most frequently selecting *Dalbergia miscolobium* as lookout post. In Bolivia, this jay species was observed in groups of 6–9 individuals. May associate with flocks of *Ramphastos* toucans.
Breeding. Breeds Sept–Mar in Brazil; observations suggest more than one nest per season in each group. Social breeder, with helpers. Nest cup-shaped, built with twigs (diameter 0·7 cm), lined with thin vegetation such as lianas and roots, external diameter 47·4 cm, depth 15·4 cm, internal diameter 15·8 cm and depth 6·5 cm; placed 2·7–6·6 m up in tree (of 18 nests in Brazil, eleven were in *Caryocar brasiliense*); territory size 20–41 ha in C Brazil, although true defensive behaviour observed only around nest. Clutch 5–6 eggs; incubation by breeding female, period 18–20 days; chicks brooded by more than one individual, fed by at least four, nestling period c. 24 days.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Common. Home range of group estimated at 172 ha, territory per active nest c. 29 ha. Although *cerrado* is suffering drastic alterations, this species remains common. It has benefited from logging activities, and has expanded its range; in SE Brazil has extended E in São Paulo and S in Rio de Janeiro (Serra dos Órgãos), and in SE Paraguay reported by local native Indians in Department of Canindeyú.

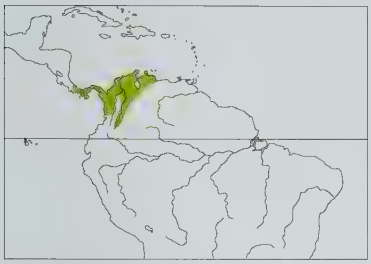
28. Tufted Jay

Cyanocorax dickeyi

French: Geai panaché **German**: Schopfblaurabe **Spanish**: Chara Pinta
Other common names: Dickey's Jay

Taxonomy. *Cyanocorax dickeyi* R. T. Moore, 1935, Rancho Batel, 5 miles [8 km] north-east of Santa Lucia, 5200 feet [1585 m], Sinaloa, Mexico.
Has been suggested as forming a superspecies with *C. chrysops* and *C. cyanopogon*; another suggestion is that its nearest relative may be *C. mystacalis*. Monotypic.
Distribution. Pacific slope of Sierra Madre Occidental (SE Sinaloa, NE Nayarit and SW Durango), in W Mexico.



Descriptive notes. 37 cm; 160–185 g. Distinctive, with prominent stiff, bristly, fan-shaped crest over crown starting at base of bill. Forehead and crest are black, crest feathers becoming dark blue towards bases; large white rounded patch above eye and very extensive white patch on cheek and malar region (both facial patches bluish at edges), black loral region, throat and upper breast, and black stripe extending from rear crown down side of neck and meeting black of upper breast; nape, hindneck, upper mantle, lower side of neck and underparts from lower breast white, rest of upperparts indigo-blue; upperwing-coverts indigo-blue, outer margins of primaries bright cyan-blue, inner margins blackish; tail bright cyan-blue at base and white on terminal part (terminal half of central feathers white, widening to terminal two-thirds on outermost); iris bright yellow; bill and legs black. Sexes similar. Juvenile has short crest, blue patch on side of head (lacks patch above eye), dark iris and flesh-coloured base of bill; bill becomes black after few months of life, and iris becomes yellow early in following year, second-year birds like adult. Voice. Very large repertoire well studied. Most typical vocalization a staccato double "chuk-chuk" or "ca-ca-ca-ca", highly variable and used in several situations, as by incubating female or during feeding movements (social call); rapid high-pitched version, but with more notes, used by all members of flock in defence of nest or young (social alarm call). During flock movements "ped-el" (contact call) and, more rarely, "wheeuh" (uncertain meaning). Low-intensity, nasal "aaagh", emitted with the bill closed, by individuals near each other, as during resting periods, when one perches among others, or birds bringing food for female or young. Begging call similar to harsh sound of *Corvus* crows, given by young and by incubating females when accepting food from another flock-member. Vocalizations by males "guarding" nest site while female incubating include, among others, highly metallic ricochet sound, low-intensity "tuk" (repeated in quick sequence of 5 notes), double "tst". Mimicry of Blue Mockingbird (*Melanotis caerulescens*) and grackles (Icteridae) recorded. Subsong (*sotto voce*) during courtship display.
Habitat. Hilly areas with mixed deciduous and evergreen forest, close to watercourses in lower valley bottoms (riparian forest), and on ridges with oak (*Quercus*) and mixed oak–pine (*Quercus–Pinus*) areas; 1350–2150 m. Commonly seen in oak and pine–oak areas during autumn, apparently attracted by acorn crop.
Food and Feeding. Plant material (70%), including acorns, plant fibres, seeds and fruits; animal items (30%), including insects, mainly beetles (Coleoptera) and Orthoptera, arachnids, and also eggs and nestlings of other bird species. Obtains food in trees, particularly in canopy, and hardly ever seen on ground; may pluck berries from thin twigs while hovering momentarily. Large items not eaten in place where captured. Foraging individuals investigate bromeliads (particularly *Tillandsia*) and other epiphytes, tearing them apart to retrieve berries, seeds and acorns from inside cupped leaves (uncertain whether fallen in or previously hidden food); will hang briefly upside-down and hover while feeding. Agave inflorescences and grassy rocks also hold special interest; visits flowers to catch insects drawn to nectar. In flocks of 4–16 individuals; larger flocks found in extensive areas of wide ravines supporting continuous stretches of large shade trees with dense understorey vegetation; flocks (especially large ones) tend to break up into small units when breeding season approaches. Morning feeding movements (2·5–7·8 km) last for 4·5 hours, followed by several hours of preening or resting in large trees; another feeding bout in early afternoon until dusk, usually terminating at roosting area; during breeding, these two feeding bouts replaced by short feeding trips from nest. When acorns not available, foraging time 50% in mixed broadleaf barranca trees, 25% in pure oak stands or oak with associated broadleaf, 15% on cliffs with grass and agave, and 10% in pine and pine–oak.
Breeding. Laying Apr and early May. Social breeder, with up to at least ten helpers, including first-year individuals; only one breeding pair in flock. Helpers participate in nest-building; large, bulky nest fairly well constructed from larger sticks, with smaller twigs towards interior, lined with fine twisted rootlets of epiphytic plants, outside diameter 33–53 cm, height 15–28 cm, internal diameter 13–16·5 cm, depth 5–7·6 cm, placed 5–15 m above ground in densely foliaged tree, in broadleaf vegetation, close to flooded area in watercourse; old nests usually found in same area, but apparently not reused. Clutch 2–5 eggs; incubation by female breeder, fed at nest by male and several helpers, period 18–19 days; chicks fed by male and helpers, nestling period 24 days; fledglings fed by all (or most) of group.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Sierra Madre Occidental and Trans-Mexican Range EBA. Uncommon to fairly common within its small global range. Limited geographical distribution (estimated at 8250 km²) and forest-dependent habits could put this species at risk in the near future. In Mexico listed as endangered, because there are no designated protected areas within its range. It has recently been suggested that this species should perhaps be considered globally threatened.

(2008p), Blake (1953), Blake & Vaurie (1962), Butchart & Stattersfield (2004), Clements (2000), Crossin (1967), Dickinson (2003), Escalante & Néquiz (2004), Goodwin (1976), Hardy (1961, 1969a, 1984), Howell & Webb (1995), Madge & Burn (1994), Moore (1935, 1938), Peterson & Navarro Sigüenza (2000), Remsen *et al.* (2009), Sibley & Monroe (1990), Skutch (1987), Stattersfield & Capper (2000), Stotz *et al.* (1996), Van Perlo (2006), Verbeek (1973).

29. Black-chested Jay

Cyanocorax affinis

French: Geai à poitrine noire **German**: Schwarzbrust-Blaurabe **Spanish**: Chara Pechinegra

Taxonomy. *Cyanocorax affinis* Pelzeln, 1856, "Bogota" [Colombia].
Two subspecies recognized.
Subspecies and Distribution.
C. a. zeledoni Ridgway, 1899 – extreme SE Costa Rica (Caribbean slope) and tropical and subtropical zones of Panama.
C. a. affinis Pelzeln, 1856 – N & NE Colombia (S to R San Juan and Huila) and NW Venezuela (Zulia, Táchira, Mérida, Trujillo, W Lara and Falcón).

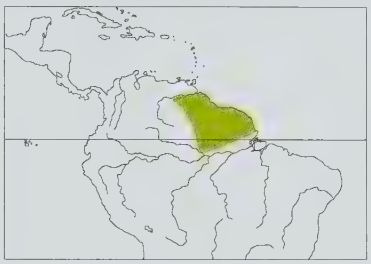
Descriptive notes. 33–36 cm; 194–232 g. Feathers on forehead, together with nasal plumes, stiffened and forming short, more or less laterally compressed frontal crest. Male nominate race has head mostly black, with large elongated blue spot above eye, smaller (half the size) blue spot below eye, blue malar stripe; nape bright cyan-blue, often partly concealed by crown feathers; upperparts dull violet suffused with brown, especially on mantle and back, uppertail-coverts cyan-blue; upperwing bright cyan-blue, inner margins of primaries dark brown, tail also bright cyan, tips of all rectrices whitish-cream; throat and upper breast sepia, rest of underparts whitish, underwing whitish, underside of tail dusky; iris yellow or yellowish-white; bill and legs blackish. Female is similar to male, but tends to be more brownish on mantle and back. Juvenile is duller and browner than adult, wings predominantly dark purplish-brown (rather than violet-blue), malar stripe duller and less conspicuous, blue spots above and below eye absent or vestigial. Race *zeledoni* has underparts and tail tips more creamy than nominate, throat and upper breast tend towards black, the bright blue of nape more visible, wings and tail brighter blue, back sometimes tinged cyan-blue. Voice. Repertoire quite varied, of harsh, squeaky and metallic short notes. Social call transcribed as "peeeoh", which may grade into "cheoo!"; chatter call (social alarm call) a sequence of notes as "pyou-pyou-pyou" or "kyoop-kyoop-kyoop". Full-grown juveniles emit "jeeer". Loud and ringing "cho! cho!" and "chowng-chowng" also mentioned.
Habitat. Wide variety of seasonal forests (wet and dry), from sea-level to 2600 m, usually in foothills; avoids interior of dense continuous forest. Recorded in clearings along rivers and at borders of dense secondary growth at fringes of cultivation (cocoa and banana plantations).
Food and Feeding. Diet includes various fruits, berries, also invertebrates, also occasional small lizard or frog. Forages in flocks of 3–8 individuals, at all levels of forest, also on ground; move through trees or on ground by long and agile hops. Normally keeps well hidden in foliage; not giving to flying over open spaces. Often attends trail of army ants (Formicidae) to feed on disturbed insects.
Breeding. Recorded between Jan and May. Possibly a social breeder. Nest bulky, of sticks and twigs, lined with finer twigs and plant fibres, built towards end of branch or in upright fork in small tree; one nest in isolated small tree was covered by creeping spiny palms. Clutch 3–5 eggs. No other information.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Relatively uncommon to locally common in Venezuela and Colombia; rather local in Panama and Costa Rica.
Bibliography. Blake & Vaurie (1962), Clements (2000), Dickinson (2003), Goodwin (1976), Haffer (1975), Hardy (1969a, 1984), Hilty (1977), Hilty & Brown (1986), Madge & Burn (1994), Meyer de Schauensee (1966, 1970), Meyer de Schauensee & Phelps (1978), Remsen *et al.* (2009), Restall *et al.* (2006), Ridgely & Tudor (1989), Sibley & Monroe (1990), Souza (2004), Stiles & Skutch (1989), Stotz *et al.* (1996), Van Perlo (2006).

30. White-tailed Jay

Cyanocorax mystacalis

French: Geai à moustaches **German**: Nacktwangen-Blaurabe **Spanish**: Chara Coliblanca

Taxonomy. *Pica mystacalis* de Sparre, 1835, Guayaquil, Ecuador.
Possibly closely related to *C. cayanus* or to *C. dickeyi*. Monotypic.
Distribution. SW Ecuador (Guayas, El Oro and W Loja) and NW Peru (S to W La Libertad).



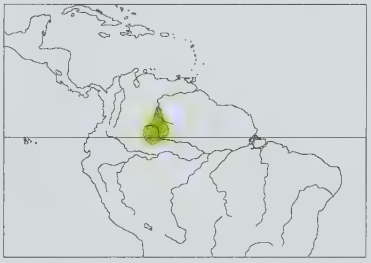
Descriptive notes. 33 cm; one male 160 g, one female 149 g. Feathers of forehead short-tufted and stiffly erect. Forehead, crown, side of head, side of neck, throat and upper breast are black (throat and upper breast of some individuals tend towards sepia), small white (sometimes blue-tinged) patch above eye, elongated white malar patch; nape, hindneck, upper mantle and lower side of neck white, rest of upperparts cyan-blue, sometimes tinged greyish; upperwing bright cyan-blue, inner margins of primaries blackish; tail white except for central feather pair, which bright cyan-blue with white tip; iris bright lemon-yellow; bill and legs black. Sexes similar. Juvenile has feathers of malar patch tipped and more or less suffused with purplish-blue, white spot above eye lacking until first moult, iris pale brown. Voice. Few vocalizations known. Typical is chatter call, which variable in pitch, and transcribed as "cha-cha-cha-cha" (possibly social call); another call is a double high-pitched "clewp-clewp".
Habitat. Inhabits several types of semi-humid forest to dry woodland, particularly thick growth near streams and rivers, from sea coast to 2600 m; in Loja (Ecuador) occurs in patches of semi-evergreen lower montane cloudforest. Associated particularly with mesquite woodland and shrubby cactus steppe. Recorded in cultivated areas with trees.
Food and Feeding. Beetles (Coleoptera), ants (Formicidae), other insects and seeds recorded in stomach contents of specimens. Pair reported as raiding nest of Pale-legged Hornero (*Furnarius leucopus*), having apparently excavated a hole in side of baked-mud structure in order to reach eggs. Forages in flocks up to ten individuals, also in pairs and singly, at all levels of forest, woodland or scrub areas; frequently on ground, more so than congeners, this perhaps due to its open or semi-open habitats. Seems to approach human settlements more frequently than do other jays; forages in gardens and eats eggs of domestic fowl and ducks.
Breeding. Adult carrying nest material in Feb–Mar. Probably solitary breeder. Nest said to be built in large tree adjacent to village. No other information.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in Tumbesian Region EBA. Uncommon to locally fairly common. Appears to have declined; was considered fairly common in Loja Province of Ecuador, but now generally in low numbers there. Habitat destruction is reducing the amount of this species' typical habitats.
Bibliography. Best, Checker *et al.* (1996), Best, Clarke *et al.* (1993), Blake & Vaurie (1962), Clements (2000), Clements & Shany (2001), Dickinson (2003), Goodwin (1976), Haffer (1975), Hardy (1961, 1969a, 1984), Madge & Burn (1994), Meyer de Schauensee (1966, 1970), Parker & Remsen (1987), Remsen *et al.* (2009), Restall *et al.* (2006), Ridgely & Tudor (1989), Sibley & Monroe (1990), Stotz *et al.* (1996).

31. Cayenne Jay

Cyanocorax cayanus

French: Geai de Cayenne **German**: Cayenneblauhäher **Spanish**: Chara de Cayena

Taxonomy. *Corvus cayanus* Linnaeus, 1766, Cayenne, French Guiana.
Possibly closely related to *C. mystacalis*. Monotypic.
Distribution. SE Venezuela (N & E Bolívar and S Delta Amacuro), the Guianas, and N Brazil (Roraima S to Manaus area, and E to N Amapá).



Descriptive notes. 33 cm; 147–230 g. An inconspicuous frontal crest with nasal tuft and forehead feathering stiffly erect but short. Has forehead, forecrown, side of head and side of neck black, posterior crown, nape and upper mantle white, slightly tinged blue; very small elongated white spot above eye and other below eye (on some individuals these spots bluish), white malar patch broader just below eye; upperparts from lower mantle light drab brown, somewhat tinged indigo-blue; upperwing pale indigo-blue, colour more intense on outer margins of primaries, inner margins dark brown; tail indigo-blue, all feathers with broad white tips (white area tends to increase slightly from central to outermost rectrices); throat and upper breast sepia, tending to black on some individuals, rest of underparts white or whitish-yellow; underwing with whitish coverts and blackish flight-feathers; iris pale blue to pale yellowish-white; bill and legs black. Sexes similar. Juvenile is duller than adult, with eye spots bluish and smaller (sometimes absent) and malar patch bluish (malar becomes white before eye spots do), also white of tailband suffused with violet-fawn, especially in centre. Voice. Repertoire quite varied. Clear downslurred whistle transcribed as "keyow" (possibly social call) and more sustained "jaaay!"(possibly social alarm call), given in sequence. Other calls transcribed as loud "choh-choh-choh", "perk-perk-perk", staccato "penk-penk", and metallic "ree". Short nasal buzzing note suggesting a trogon (Trogonidae) or a toucan (Ramphastidae), and other harsh notes, also reported.
Habitat. Woodland of various types, such as wooded savanna, riparian forest, and scrub on sandy soil, to 1100 m. Avoids interior of forest, recorded mostly at forest edge; enters gardens of settlements and even towns to feed at fruit trees. In Brazil, recorded at low-canopy forest (7–20 m) with understorey dominated by small-diameter trees, in vegetation called *campinarana* (adapted to poor soil types), and in shrubby vegetation with sparse trees, most of which less than 5 m tall (*campina*); recorded also in *terra firme* forest and disturbed vegetation.
Food and Feeding. Diet includes beetles (Coleoptera) and Orthoptera, and berries and fruits. Forages in canopy in small flocks; individuals tend to fly only short distances between branch perches, usually gliding and not flapping wings.
Breeding. Season apparently Dec–Mar. Communal breeder; usually one to three helpers. All members of one group participated in defence of nest. Large cup-shaped nest made of twigs, unlined, externally 23 cm high and 27 cm in diameter, placed 2–5 m above ground in tree, often an isolated one (e.g. mango tree on outskirts of a small native settlement). Clutch 4 eggs; nestlings seen to be fed by more than two individuals. No other information.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Fairly common to common but somewhat local in Venezuela and the Guianas; scarce in Brazil.
Bibliography. Blake & Vaurie (1962), Borges (1994, 2004), Bosque & Molina (2002), Clements (2000), Dickinson (2003), Goodwin (1976), Haffer (1975, 1992), Hardy (1961, 1969a, 1984), von Ihering & von Ihering (1907), Madge & Burn (1994), Meyer de Schauensee (1966, 1970), Meyer de Schauensee & Phelps (1978), Naka *et al.* (2006), Pelzeln (1868-71), Pinto (1944), Remsen *et al.* (2009), Restall *et al.* (2006), Ridgely & Tudor (1989), Robbins, Braun & Finch (2004), Robbins, Braun, Milansky *et al.* (2007), Ruschi (1979), Santos & da Silva (2007), Sibley & Monroe (1990), Sick (1985, 1997), Sigrist (2006), Souza (2004), Stotz *et al.* (1996).

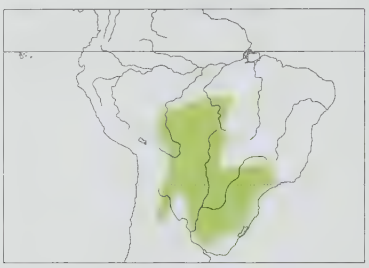
32. Azure-naped Jay

Cyanocorax heilprini

French: Geai à calotte azur **German**: Fliederblaurabe **Spanish**: Chara Nuquiazul
Other common names: Heilprin's Jay

Taxonomy. *Cyanocorax heilprini* Gentry, 1885, Rio Negro, Brazil.
Monotypic.
Distribution. Extreme E Colombia (S Guainía and extreme E Vaupés, possibly also SE Vichada), extreme S Venezuela (W Amazonas) and extreme NW Brazil (upper R Negro).

Descriptive notes. 33–36 cm. Nasal tuft and forehead feathering stiffy erect but short, forming frontal crest. Forehead, forecrown and side of head black, side of neck, throat and upper breast sepia, narrow cyan-blue malar stripe; hindcrown, nape and hindneck sky-blue, washed white, upperparts bluish-mauve more or less suffused with brown-grey; upperwing greyish-horn, somewhat tinged blue on outer margins of primaries; tail greyish-horn, tinged blue, all feathers with narrow whitish tips (more conspicuous on underside); underparts below upper breast greyish-horn, heavily tinged blue, particularly on breast, paler on lower belly, becoming pale cream on undertail-coverts, underwing brownish; iris yellowish-white to golden-yellow; bill and legs black. Sexes similar. Juvenile not yet described. Voice. Loud, harsh "jeer", similar to that of *C. violaceus* but thinner, higher and more descending. Also nasal honking "duk-duk", a smooth and abrupt "keop", liquid "puk", rapid "je-je-je".
Habitat. Forest borders, secondary growth and savanna woodland, on sandy soils; recorded at 100–250 m. In Brazil found in *campinas* (shrubby vegetation with sparse trees, most of which less than 5 m tall) and *campinaranas* (low-canopy forest, 7–20 m, with understorey dominated by small-diameter trees).
Food and Feeding. No information available. Was found, supposedly while foraging, in small trees and bushes between forest edge and more lightly wooded savanna grassland.



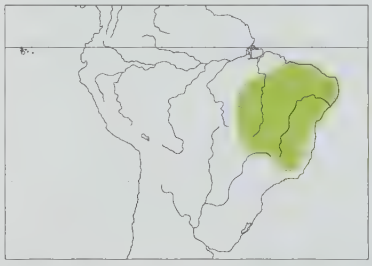
Breeding. Two juveniles noted in Mar and Apr in Venezuela. Nest described as basin-shaped structure of twigs, appearing carelessly made, placed 2–3 m above ground. No further information available.
Movements. Probably sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in Orinoco-Negro White-sand Forest EBA. Very poorly known species. Appears to be very local and perhaps not uncommon.
Bibliography. Blake & Vaurie (1962), Borges (2004), Clements (2000), Dickinson (2003), Goodwin (1976), Haffer (1975), Hardy (1969a), Hilty & Brown (1986), von Ihering & von Ihering (1907), Madge & Burn (1994), Meyer de Schauensee (1966, 1970), Meyer de Schauensee & Phelps (1978), Olivares (1955), Pinto (1944), Remsen *et al.* (2009), Restall *et al.* (2006), Ridgely & Tudor (1989), Ruschi (1979), Sibley & Monroe (1990), Sick (1985, 1997), Sigrist (2006), Souza (2004), Stotz *et al.* (1996).

33. Plush-crested Jay

Cyanocorax chrysops

French: Geai acahé **German**: Kappenblaurabe **Spanish**: Chara Moñuda
Other common names: Plush-capped/Band-tailed/Urraca Jay

Taxonomy. *Pica chrysops* Vieillot, 1818, Paraguay.
Forms a species pair, and previously regarded as conspecific, with *C. cyanopogon*; it has also been suggested that the two form a superspecies with *C. dickeyi*. Proposed race *interpositus* (described from Alagoas, in NE Brazil) seems to be based on a female of *C. cyanopogon* in worn subadult plumage, but possibly a valid taxon. Four subspecies currently recognized.
Subspecies and Distribution.
C. c. diesingii Pelzeln, 1856 – N Brazil in extreme E Amazonas (right bank of lower R Madeira) and on S side of Amazon in W Pará (lower R Tapajós).
C. c. insperatus Pinto & Camargo, 1961 – W Pará (restricted to E lower R Tapajós, Serra do Cachimbo), in NC Brazil.
C. c. chrysops (Vieillot, 1818) – N, E & SE Bolivia (Beni, Cochabamba, Santa Cruz, Chuquisaca and Tarija), SE Brazil (Mato Grosso do Sul and São Paulo S to Rio Grande do Sul), Paraguay, NE Argentina (S to Chaco and Entre Ríos) and NW Uruguay.
C. c. tucumanus Cabanis, 1883 – NW Argentina (Salta, Tucumán, Catamarca and La Rioja).



Descriptive notes. 32–35 cm; 127–170 g. Stiffened feathers on forehead become less stiff on forecrown and crown, with very velvety texture at tips, creating peculiar plush-like cap. Nominate race has forehead, crown and side of head black, rather elongated ultramarine spot over eye (washed white at upper edge), smaller spot of pure ultramarine-blue below rear eye, large cyan-blue malar stripe becoming quite broad in region just below eye; nape white, tinged ultramarine, hindneck pure ultramarine, upperparts indigo-blue; upperwing bright indigo-blue, inner margins of primaries brownish; tail bright indigo-blue with pale yellowish or white tips (tips 2·5 cm long on central feathers, 5 cm on outers); side of neck, throat and upper breast sepia; rest of underparts variable, from creamy to whitish, underwing brownish, except for creamy coverts, undertail brownish; iris bright lemon-yellow to pale yellow; bill and legs blackish. Sexes similar. Juvenile has nape pale bluish-mauve, but facial markings appear only at end of first month and similar to adult at second moult, browner iris becomes yellow before third month. Race *tucumanus* is similar to nominate, but larger; *diesingii* has more domed crown shape (longer feathers), smaller eye spots (larger spot not tinged white), smaller malar, paler nape and hindneck tending to lavender-blue, shorter whitish band at tail tip; *insperatus* is similar to last, but underparts and tail tips tend to be pure white. Voice. Large repertoire, 23 vocalizations identified, almost all consisting of melodic notes, with the exception of the harsh begging call of the juvenile. Louder vocalization (audible to 80 m), for territorial defence, and movements and gathering of flock, a single metallic and downward-inflected melodic note (social call). Social alarm call quite different, a single inflected note, this call part of a complex system of alarm calls which vary according to distance of predator; when predator far off alarm consists of single notes, when closer a sequence of 3–6 shorter notes. Five vocalizations related to contact, emitted mainly by foraging individuals; all comprise sequence of 2–6 very short notes, "chyup-chyup". Others vocalizations related to agonistic behaviour, carry very short distances. Repertoire includes imitations of other bird species, e.g. Collared Forest-falcon (*Micrastur semitorquatus*). Subsong (*sotto voce*) seems shorter and less frequently given than are those of congeners.
Habitat. Various types of forest, such as tropical lowland evergreen forest, tropical deciduous forest and temperate rainforest; usually from lowlands to 1500 m, but recorded at 2800 m in Bolivia. Common in patches of forest in open country, riparian forest, secondary forest and rural areas close to forest, especially where maize (*Zea mays*) plantations nearby; also in disturbed areas, such as eucalypt (*Eucalyptus*) plantations and suburban areas. Favours forest edge. In S Brazil found in *capões* (patches of southern temperate forest where the conifer *Araucaria angustifolia* dominates) in grassland areas. In Uruguay quite frequent in riparian forest. In Amazonia, race *diesingii* occurs in areas where forest broken by more or less isolated patches of dry forest (*cerrado*). It region of Pantanal, in SW Brazil, recorded in patches of forest and in riparian forest, although appears much less numerous than is *C. cyanomelas* in that ecosystem. Seems to live in drier areas in Paraguay and Bolivia: in Paraguay, recorded in *cerrado* and woodland *chaco*; in Bolivia, found in an area with the palm *Parajubaea torallyi* (Arecaceae) mixed with evergreen *Podocarpus* at 2300–2800 m, in another dry area with thorny forest at 1600–2500 m, and in another with *chiquitano* (xeric forest similar to *chaco*, but with stratification more like that of Amazonian forest).
Food and Feeding. In three study sites in S Brazil (Paraná), annual diet mainly small invertebrates (80% of records), mostly insects; also some fruits from 24 plant species (mostly *Casearia*, *Syagros*, *Psidium*, *Rapanea*, *Urera*, *Ficus* and *Phylodendrum*). Occasionally takes nestlings of small birds and frogs, and eats eggs of other bird species when it finds them; records of individuals eating dead snake. Also, regularly visits settlements for food scraps; maize an important food resource when available. During winter in S of range, when forest fruits not available, may exploit fruits from exotic plants such as *Diosporus kaki*. During autumn and winter in temperate forest of S Brazil, frequently eats seeds of *Araucaria angustifolia*; unlike *C. caeruleus*, takes these not only on tree but also on ground, where present as a result of foraging activity of other species, especially tufted capuchin monkey (*Cebus apella*); seems less dependent on *Araucaria* seeds than *C. caeruleus*. Seeds of *Araucaria angustifolia* and some other items, mainly animals, are not eaten where captured, but taken to another spot at least 5 m away, in the case of *Araucaria* seeds sometimes more than 60 m away. After examination, holds the food item with the feet and pecks and eats it piecemeal; in the case of large insects, such as Lepidoptera and Ortoptera, removes wings before swallowing item. Storing of food (e.g. seeds of *Araucaria*, maize, *Siagrus* nuts, dead animals) frequently observed, but recovering of items by same individual incompletely documented, although individuals seen to eat cached food. Caching sites on ground, when food covered with leaves, or in trees, between branches or epiphytes. Forages in flocks of 3–10 individuals in all forest strata, including ground, but canopy used less; in forest with dense understorey tends to forage less frequently on ground. Where co-exists with *C. caeruleus* it tends to forage in lower strata than latter, and at sites where it co-exists with *C. cyanomelas* or *C. cristatellus* forages more in areas with higher tree density. Exploits forest edge more than interior; commonly forages along edge or in riparian forest. Flock-members move singly across forest clearings and rivers; individuals usually fly short distances (less than 100 m) over open spaces. Hops along branches and flies for short distances, while pecking items or pursuing fleeing ones; sallying and flycathing sometimes used. Captures items on branches, leaves and epiphytes; on ground, removes and turns over dry leaves and twigs by sweeping bill sideways. Several records of this species in ant-following mixed flocks; in Paraguay, recorded in mixed flock with *C. cyanomelas* in dry forest.
Breeding. Breeds in Oct–Dec in Paraguay and S Brazil. Communal breeder; with two or three helpers; helpers assist with nest-building and mobbing of predators. Nest built with twigs, which form rounded external cup 28–34 cm across, inner cup lined with finer twigs and plant fibres, usually placed 4–7 m up in densely foliaged tree at middle level of forest; territory size 9–15 ha in S Brazil. Clutch 2–4 eggs; at five nests studied in S Brazil (Paraná), incubation period 18–20 days and nestling period 22–24 days; adults feed juveniles for 90 days after departure from nest.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Common to abundant in most parts of range. In Paraná state, in S Brazil, flocks had estimated home range of 20–30 ha. Has successfully expanded into urban areas of S & SE Brazil. Deforestation can lead to decrease in this species' numbers, but it may live in isolated forest fragments of 10–20 ha if not too far from larger forest fragments; among the bird species analysed in N Paraná, this species was considered to have one of lowest sensitivities to forest fragmentation.

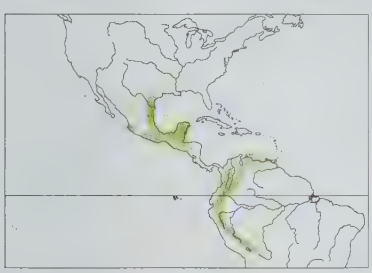
34. White-naped Jay

Cyanocorax cyanopogon

French: Geai à nuque blanche **German**: Weißnacken-Blaurabe **Spanish**: Chara Nuquiblanca
Other common names: Blue-bearded Jay, White-collared Jay(!)

Taxonomy. *Corvus cyanopogon* Wied, 1821, Rio Cachoeira (a headwater of the River Ilhéos), eastern Bahia, Brazil.
Forms a species pair, and previously regarded as conspecific, with *C. chrysops*; it has also been suggested that the two form a superspecies with *C. dickeyi*. Proposed race *C. chrysops interpositus* (described from Alagoas, in NE Brazil) seems to be based on a female of present species in worn subadult plumage, but possibly a valid taxon. Monotypic.
Distribution. NE & E Brazil from Maranhão E to Ceará and Paraíba, S to SE Pará (upper R Xingú, Gorotire), extreme E Mato Grosso (R das Mortes), Goiás, Minas Gerais and Bahia, and isolated population in Espírito Santo.

Descriptive notes. 35 cm; 132–160 g. Feathers of forehead stiff, becoming softer and velvety in texture over crown and forming a soft, velvet-like, but not bulging cap. Forecrown and crown are black, side of head, side of neck, throat and breast sepia, small ultramarine-blue (heavily washed white) spot above eye, small pure ultramarine spot below rear eye, dark cyan-blue malar patch (hardly distinguishable from side of head); nape and hindneck white, hindneck slightly tinged blue on some individuals (those on upper R Xingu more heavily tinged blue), upperparts greyish-horn, upperwing dull dark brown, tail sepia with wide white at tips of all feathers (narrowest, but still broad, on central pair, widest on outermost); underparts below breast whitish, slightly tinged cream on some individuals; iris bright yellow; bill and legs blackish. Sexes similar. Juvenile has very small, dull eye spots and narrower and duller malar stripe than adult. Voice. Large repertoire seems very similar to that of *C. chrysops*, but not studied in detail. Most frequently heard call in the field a melodic and metallic "chyup-chyup". Includes imitations of other bird species, such as Yellow-headed Caracara (*Milvago chimachima*). Subsong (*sotto voce*) recorded in field, apparently more frequently given outside reproduction context than is the case with *C. chrysops*.
Habitat. Inhabits mostly dry scrub areas (*caatinga*) and dry forest (*cerrado*), at 400–1100 m. In a transect from *caatinga* to *cerrado* in NE Minas Gerais, however, this species was replaced by *C. cristatellus*; in another study, exhibited very high rates of relative abundance in two *caatinga* sites. Also, in SE Tocantins, present species had significantly lower abundance than *C. cristatellus* in *cerrado* sites. Commonly seen in riparian forest, secondary woodland, and at borders of tropical deciduous forest.
Food and Feeding. Poorly documented. Flying termites (Isoptera) and fruits of *Cereus jamacaru* recorded in NE Brazil. Seems regularly to visit plantations near human settlements.
Breeding. No documented details. One unconfirmed report from local people suggests that nest is poorly built, placed 3 m above ground, and that clutch contains up to 2 eggs.



Movements. Sedentary.
Status and Conservation. Not globally threatened. Common over parts of its range. Evidence of some decline in Bahia state, perhaps a result of trapping for cagebird trade. Recent expansion into state of Espírito Santo evidently due to deforestation

35. Green Jay

Cyanocorax yncas

French: Geai vert **German**: Inkablaurabe **Spanish**: Chara Verde
Other common names: Inca Jay ("nominate group")

Taxonomy. *Corvus yncas* Boddaert, 1783, Chilpes, Junín, Peru.
Formerly placed in a monotypic genus, *Xanthoura*. Races fall into two groups, one in Central America (first eight listed below), known as the "*luxuosus* group", and the other in Andes of South America (remaining five races), known as "nominate group"; the groups are sometimes treated as two separate species. Race *luxuosus* intergrades with *vividus* in SE Sierra de Tuxtla and Catemaco region of S Veracruz. Proposed race *andicolus* (Andes of Mérida, Venezuela) subsumed into *cyanodorsalis*. Thirteen subspecies recognized.
Subspecies and Distribution.
C. y. glaucescens (Ridgway, 1900) – extreme S USA (S Texas) and NE Mexico (W Tamaulipas and Nuevo León).
C. y. luxuosus (Lesson, 1839) – extreme S USA (lower Rio Grande valley and SE corner of Texas) S through E & SC Mexico (S to Puebla and S Veracruz).
C. y. speciosus (Nelson, 1900) – Pacific slope of Mexico in Nayarit and Jalisco.
C. y. vividus (Ridgway, 1900) – Pacific slope of S Mexico (from Colima and Guerrero E to W Guatemala (Solola, in Patulul).
C. y. maya (van Rossem, 1934) – Tabasco and Yucatán Peninsula (except extreme S Quintana Roo), in E Mexico.
C. y. cozumelae (van Rossem, 1934) – Cozumel I (off NE Yucatán Peninsula).
C. y. centralis (van Rossem, 1934) – SE Mexico (extreme E Tabasco and adjacent parts of Chiapas E through extreme S Quintana Roo), N & E Guatemala, Belize and N Honduras.
C. y. confusus A. R. Phillips, 1966 – Pacific slope of S Chiapas (Mexico) and Guatemala.
C. y. galeatus (Ridgway, 1900) – subtropical zone of Colombia W of E Andes.
C. y. cyanodorsalis (A. J. C. Dubois, 1874) – C & E Colombia (subtropical zone of E Andes) and NW Venezuela (Zulia, and S Lara S to Táchira and Barinas).
C. y. guatimalensis (Bonaparte, 1850) – mountains of N Venezuela (Falcón E to Sucre and Anzoátegui.
C. y. yncas (Boddaert, 1783) – SW Colombia (subtropical zone, in valleys of upper Cauca, Patía, and San Miguel) S through E Ecuador and Peru to C Bolivia (La Paz and Cochabamba).
C. y. longirostris (Carriker, 1933) – arid upper valley of R Marañón, in N Peru.

Descriptive notes. 25–27 cm; 66–92 g. Short bushy frontal crest formed by tufted and stiffly erect nasal and frontal plumes. Nominate race has forehead and small rounded spot above eye ultramarine, large ultramarine malar patch ending at posterior region below eye; crown and nape pale yellow (whitish on some individuals), base of nape bluish (some birds have crown and nape heavily tinged blue); remainder of face black, reaching down onto black region of throat and upper breast; upperparts, including upperwing, shamrock-green, rump tinged sulphur-yellow on some individuals; tail dark green, outermost feather pair sulphur-yellow; underparts below breast sulphur-yellow, underwing brownish with sulphur-yellow base, undertail mostly blackish; iris brown to yellow; bill black; legs dull brownish-flesh. Sexes similar. Juvenile has shorter frontal tuft, and lacks spot above eye, acquires eye spot at first moult, after which much as adult; one individual had iris dull violet. Races differ mainly in plumage coloration and size, "*luxuosus* group" (Middle America) smaller than "nominate group" (Andes) and with short and inconspicuous frontal tuft and ultramarine crown and nape: *longirostris* is similar to nominate but larger, with iris yellow; *galeatus* has larger frontal crest and iris yellow; *cyanodorsalis* has larger frontal crest, short white band on front of crown, rest of crown and nape heavily tinged ultramarine, upperparts (back) tinged blue, iris yellow, legs brownish; *guatimalensis* is like previous, but crest shorter, less blue wash above, narrower white band on forecrown, legs grey; *luxuosus* has underparts yellowish, heavily washed lime-green, legs brown, iris yellow; *glaucescens* is overall paler than last, has tail tinged blue, legs blackish, iris dark brown; *centralis* has underparts sulphur-yellow, lighter than nominate, tinged lime-green (one individual was heavily washed lime-green, like *luxuosus*); *speciosus* has forecrown yellowish, and quite intense sulphur-yellow on underparts; *vividus* is similar to *luxuosus*, but larger, and yellow of underparts brighter, tail tinged blue; *confusus* is similar to previous, but smaller, and slightly darker above and, especially, on side of head; *maya* has underparts lighter sulphur-yellow; *cozumelae* is smallest race, with pale blue crown and bright yellow underparts. Voice. Very large vocal repertoire, not well described. Typical calls include metallic "cleeop" note and nasal "nyaa", which may be repeated faster several times, and a querulous 2-note call. Mewing, chattering, clicking, rattling, buzzing, squeaking and rasping notes also recorded. Mimicry common.
Habitat. Occupies variety of habitats, including tropical deciduous forest, humid forest edge, grassland with scattered tress, dense thickets along watercourses, open areas in interior of cloudforest, dry scrub areas and matorral; recorded also in marshland. Central America races typically inhabit drier areas at lower altitudes (sea-level to 2000 m in Mexico), such as subtropical forest of Rio Grande (Texas; mean annual rainfall 450 mm), in broadleaf forest and scrub at 100 m in Belize (1650 mm), and in evergreen forest dominated by ebony (*Pithecellobium flexicaule*) at 250 m in R Corona floodplain (900 mm mean annual rainfall). In South America primarily in montane forest (800–3000 m), but sometimes as low as 900 m (Pacific slope of Colombia) or down to sea-level in more humid areas. Can live in areas influenced by human impact, such as dense second-growth forest in lowlands, pine–oak (*Pinus–Quercus*) associations, pine and cypress plantations; also in canopy of trees 20–40 years old in shade coffee plantations and cacao plantations. Territories of four flocks studied in Colombia contained 5–70% grassland with scattered trees, 7–47% plantations of exotic trees (*Eucalyptus*, *Cupressus*, *Pinus*), and 10–15% secondary growth and meadow.
Food and Feeding. Diet of four groups studied in Colombia contained similar proportions of animal and plant matter (57% and 43%, respectively); in N races animal matter could account for larger proportion. In Colombia, feeds on beetles (Coleoptera), bugs (Hemiptera), grasshoppers and crickets (Orthoptera), eggs of lizards, and fruits of variety of plant species e.g. *Solanum*, *Rubus*, *Miconia*, *Palicourea*, *Clusia*, Myrtaceae, and Peruvian plum (*Spondias*), berries and probably fruits of other species; exploited several sources of food that became temporarily abundant, e.g. caterpillar of *Glena bisulca* (geometrid moth), earthworms, grubs, nymphs of beetles, and crickets in borders of recently ploughed fields (unavailable before being uncovered by plough). N races feed on beetles, bugs, grasshoppers and crickets, acorns (probably important when available) and fruits; said to show preference for acorns, and fruits of the palmetto palm. Small birds (nestlings and probably fledglings) also taken. Readily takes household scraps and other provided foods at feeders when not far from forest; reported as entering tents and houses; eggs of domestic fowl consumed when available. Food items rarely eaten immediately; instead, are carried in bill to a perch, where held with the feet, pecked apart and swallowed in small bits. Forages in small groups usually in subcanopy and in shrubby understorey, searching for food in all available strata, including ground, tree trunks and branches; rotten stubs of branches, lichens and bromeliads regularly exploited. Groups avoid clearings or other open spaces; flights across open spaces start from tallest available tree, rarely more than one individual at a time crossing open space. In Colombia all individuals in group forage within radius of less than 30 m, but, when moving onwards, some become isolated (35–40 m) from rest of group for a few minutes; observations showed that foraging jays distributed themselves along a wide front, instead of following each other along a narrow path. When searching for food on ground, removes and turns over dry leaves and twigs by sweeping bill sideways. On trees and shrubs usually proceeds from lower branches to top, and from trunk to tips of branches; hops along branches and pecks at any prospective food item, not infrequently stretching up to take an item from foliage directly overhead, or hanging down to reach branch immediately below. Often hangs upside-down in manner of a tit (Paridae) to explore foliage at tips of slender branches, or drops to ground to retrieve fallen items. Also seen to pursue insects in flight and to hover to take fruits and insects from small shrubs and ferns of understorey.
Breeding. Eggs recorded Apr–Jun in USA and Mar–Aug in Colombia. Two breeding systems recorded: co-operative breeding with more than two individuals (helpers) tending single nest (S races), and simple pair without helpers (N races). In both groups young stay in family flock for one year, but in N yearlings (which provide significant amount of territorial defence) are then driven from parental group; in S races, young do not disperse from parental group and all members of flock (both immatures and unmated adults) participate in nest-building and feeding of young, and at some nests helpers contribute more than half of food for nestlings (and often remain to guard nest when female absent); hypothesized that difference in breeding strategy due to more severe habitat saturation in Andean group (food less abundant, more patchily distributed, and with less seasonal variation than in Middle America), so that helpers should increase ultimate numbers of fledglings produced by being able to locate more food over a given time interval. Flocks (4–9 individuals) defend stable territories throughout year, average size 16·2 ha for Central American races (USA) and 43–87 ha for Andean ones (Colombia). Nest a shallow, loosely woven basket of slender twigs, inner cup containing fine roots, fine wiry twigs, vine stems, dried grass, pine needles, lichens and leaves, external diameter 23 cm and depth of inner cup 9 cm; placed usually in fork of twig close to trunk of tree or in bush, with various degrees of exposure, but usually not far from ground (1·5–10 m) in dense shrubbery. Clutch 3–5 eggs, commonly 4; incubation period thought to be 17–18 days; nestling period 19–22 days; fledglings fed for 3 weeks or longer after leaving nest, by both parents and, in S, by helpers. In S races, apparently does not breed until at least 2 years old.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Generally common to fairly common; often local. Very limited range in USA. Uncommon to locally common in Venezuela; common but very local in Colombia; fairly common in Ecuador and Peru.

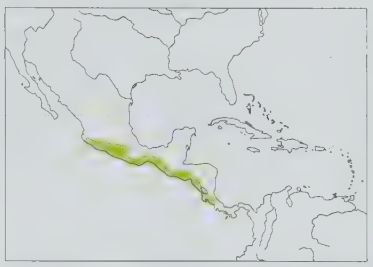
Genus *CALOCITTA* G. R. Gray, 1841

36. **Black-throated Magpie-jay**

Calocitta colliei

French: Geai à face noire **German**: Blauwangenhäher **Spanish**: Urraca Hermosa Carinegra
Other common names: Collie's Magpie-jay

Taxonomy. *Pica colliei* Vigors, 1829, San Blas, Nayarit, Mexico.
Genus sometimes subsumed in *Cyanocorax*. Forms a superspecies with *C. formosa*; often considered conspecific, and the two interbreed in Jalisco and Colima (birds with intermediate characters locally common). Monotypic.
Distribution. NW Mexico from S Sonora and SW Chihuahua S through Sinaloa to Jalisco and Colima.



Descriptive notes. 58–77 cm; 225–251 g. Exceptionally long-tailed jay, long black feathers on forehead (almost 80 mm in length), sometimes tipped white or blue, form erect and slightly recurved crest. Crown, lores, side of head and side of neck are black, throat and breast sepia (throat may be partly or mostly white in N of range, S at least to Sinaloa); elongated white patch (washed cobalt-blue) above eye, sometimes connecting with sides of nape, and another below eye, large cobalt-blue malar patch, quite broad in region just below eye, bordered at base by narrow white band; nape and hindneck cobalt-blue, heavily washed white, on some individuals a narrow cobalt-blue band borders black area of side of neck and sepia area of breast; upperparts cobalt-blue, sometimes tinged grey; upperwing bright cobalt, outer margins of primaries cerulean-blue and inner margins brownish; very long tail graduated, two central feathers entirely bright cobalt-blue, outer feathers also cobalt but with wide whitish terminal band; underparts below breast white, somewhat tinged grey; underwing brownish, underwing-coverts white, underside of tail feathers brownish where blue above; iris dark brown; bill and legs black. Sexes similar, female with shorter tail than male. Juvenile has whitish throat and breast (but chin black), with sepia colour only on side of neck and in U-shaped collar enclosing breast, malar stripe and eye spots not so clearly defined as on adult, upperparts lighter and duller, tail shorter, and bill and legs paler; second-year has some white tips (as well as blue tips) on crown feathers. Voice. Quite rich repertoire, not studied in detail. Scolding call a short and repeated "keu-keu-keu". Among incredible variety of sounds that may be heard are harsh ("rrrrik" or "krrrrup" and "rroik"), whistled ("wheeoo") and "squeaking-gate" ("kyooh") notes, besides liquid, trilled and rattled ones, which sometimes combined. Each individual seems to emit large variety of sounds over short period. Raucous cries may resemble those of parrots (Psittacidae).
Habitat. Arid bushy country, thorn-forest, deciduous open woodland and riparian forest, from sea-level to 1800 m.
Food and Feeding. Feeds on invertebrates, berries and fruits. Forages at top of trees or in bushes, in more open areas; few other details. Forages in company of large passerines, such as Yellow-winged Cacique (*Cacicus melanicterus*).
Breeding. Eggs recorded in Apr. Social nester. Nest a very bulky structure of twigs, lined with mosses, lichens and roots, placed in thorny tree. Clutch 3–7 eggs. No other information.
Movements. Resident. Occasional records in C Sonora; one individual, presumed vagrant, reach extreme S of USA (Douglas, in Arizona).
Status and Conservation. Not globally threatened. Few data. Seems common to fairly common in its relatively small range. Forest fragmentation has had adverse effects locally on this species.
Bibliography. Blake & Vaurie (1962), Clements (2000), Dickinson (2003), García-Trejo & Navarro Sigüenza (2004), Goodwin (1976), Gordon & Ornelas (2000), Hardy (1961, 1969a, 1984), Howell & Webb (1995), MacGregor-Fors (2005), Madge & Burn (1994), Peterson & Navarro Sigüenza (2000), Remsen *et al.* (2009), Sibley & Monroe (1990), Stotz *et al.* (1996), Van Perlo (2006), Winterstein (1985).

37. **White-throated Magpie-jay**

Calocitta formosa

French: Geai à face blanche **German**: Langschwanzhäher **Spanish**: Urraca Hermosa Cariblanca

Taxonomy. *Pica formosa* Swainson, 1827, Temiscaltipec, Mexico.
Genus sometimes subsumed in *Cyanocorax*. Forms a superspecies with *C. colliei*; often considered conspecific, and the two interbreed in SW Mexico (Jalisco and Colima, where birds with intermediate characters locally common). A hybrid between present species and *Psilorhinus morio* recorded in S Mexico (Chiapas). Nominate race intergrades with *azurea* in Oaxaca (S Mexico). Three subspecies recognized.
Subspecies and Distribution.
C. f. formosa (Swainson, 1827) – S Mexico from Colima, Michoacán and Puebla S to Oaxaca.
C. f. azurea Nelson, 1897 – Pacific slope in SE Mexico (Oaxaca and Chiapas) and W Guatemala.
C. f. pompata Bangs, 1914 – SE Mexico (interior of E Oaxaca, interior of Chiapas) and Atlantic side of Guatemala (Motagua Valley) S through El Salvador and W Honduras to NW Costa Rica.
Descriptive notes. 43–56 cm; 205–213 g. Long-tailed jay with slightly recurved erectile forecrown crest of long black feathers (reaching 70 mm on some individuals) with whitish or bluish margins at base or, sometimes, reaching middle and almost all of feather. Male nominate race has crown and nape variable, black, or black with some feathers barred white and blue, or black just behind crest and sky-blue elsewhere; side of head, side of neck and throat to breast white (on some slightly washed bluish), sometimes white above eye forming supercilium (which begins at base of upper mandible); some dark feathers, sometimes bluish, around eye, and a blue-black malar stripe (often mottled) not reaching bill; sepia or blackish area bordering rear ear-coverts and extending as narrow U-shaped band across lower breast and frequently over base of hindneck; upperparts sky-blue, heavily tinged grey, rump slightly tinged green; upperwing bright sky-blue, inner margins of primaries brownish; long tail graduated, two central pairs of feathers entirely bright blue, other feathers blue only on basal

half and whitish elsewhere; underparts below breastband white, somewhat tinged grey; underwing-coverts white, contrasting somewhat with grey underside of flight-feathers; iris dark brown; bill and legs black. Female is like male, but has shorter tail, more extensive blackish on ear-coverts, narrower breastband, and upperparts slightly duller. Juvenile is similar to female, but central tail even less elongated, crown whiter, crest shorter and with feathers tipped blue and/or white, bill and legs greyer, upperparts duller greyish-blue, breastband narrower; much as adult after first moult, except that tail shorter. Race *azurae* is slightly larger than nominate, with crown and nape also variable but blue deeper, normally less black on face, female and juvenile more greyish on upperparts and wings, male brighter, tending to cobalt-blue, on upperparts and wings, no sepia on hindneck; *pompata* is smallest race, similar to previous, but upperparts and wings sky-blue with heavy grey tinge (as in nominate), side of head, throat and breast slightly washed blue. Voice. Quite rich repertoire, some vocalizations suggesting a large parrot (Psittacidae). Twelve vocalizations identified in one study, but variations of these quite common. Harsh downward-inflected "jeer!", and guttural "raah" or "reeah" when scolding. Other harsh notes include frog-like snore sound, squawking "schrrrr", and rolling or trilling downslurred "prrrreeeeeo". Melodic notes, sometimes described as liquid sounds, include clear inflected whistle, short snoring "clooo", "poop!", "weep-weep-weep", and piping note; also described are "kreeup", upslurred "reek", and loud "pee-ah", this last given by nesting female. Two vocalizations (termed "pump-handle" and "squeaky-gate" calls) sometimes combined in single vocalization, which is similar to those given by *Cyanocitta stelleri*. Subsong (*sotto voce*) recorded.
Habitat. Arid to semi-humid woodland, from lowlands to 800 m, reaching 1250 m in some localities. Inhabits areas of thorn-forest, deciduous forest and gallery forest, frequently visiting forest edges and bushy open country; regularly seen at borders of cultivation (coffee plantations). In C Mexico recorded, rarely, in columnar cacti forest. In most of range associated with more arid areas, but on Pacific side of S Chiapas and N Guatemala found in areas of heavier rainfall. In Central America, found in more arid habitats than those occupied by *Psilorhinus morio*. Also frequents larger clumps of trees and broken forest, especially along watercourses. In Costa Rica seems to prefer disturbed areas, being common in woodland and brushy cattle pasture; in Santa Rosa National Park, occurs in both woodland and pastures. In El Salvador considered an open-habitat generalist.
Food and Feeding. Reported items in diet are large invertebrates, small lizards, frogs, eggs and nestlings of small birds, also seeds, fruits, berries and grain (maize); nectar from large *Balsa* blossoms also consumed. In study in Costa Rica, this species spent more time foraging in woodland during wet season, when caterpillars (Lepidoptera) eaten in larger proportion than in dry season; during dry season consumed mostly fruits, particularly from acacia (*Acacia*) but also from *Curatella americana*, *Ficus*, *Spondias mombin*, *Byrsonima crassifolia* and *Muntingia calabura*; insects, including Orthoptera, and arachnids recorded in diet through the year. Fledglings in Costa Rica differed from adults in diet, taking relatively fewer arthropods and more fruits; young approach adult levels of foraging proficiency within one year. Forages in groups at all forest levels, including ground, where it moves in bouncing hops; investigates foliage, hanging tangles, leaf bases of bananas, and ground litter.
Breeding. Eggs recorded in Guatemala late Dec and early Jan in W and Jun and Jul on Caribbean slope, and mid-Apr in El Salvador; eggs in Feb–Jul and nest activity peaking in Mar–May in Costa Rica. Breeding system flexible, varying from single breeding pair within a given group range to multiple breeding pairs within a given group range, with partial range-sharing among related females; additionally, and unlike other American jays with helpers, has a male-biased natal dispersal, the groups consisting primarily of related matrilocal females which remain on natal territory as helpers, males dispersing from natal territory by 4–23 months of age to exist as floaters or join another group. Group-members assist with nest defence and the feeding of breeding female and her offspring; quantitative data from Costa Rica suggest higher proportion of food given by helpers when compared with other co-operatively breeding New World jays. In Costa Rica, territory size (10–31 ha) of 14 monitored groups (of 2–10 individuals) did not vary for three years, larger groups possessing larger territories containing more bull-horn (*Acacia*), a critical food resource during dry season; quantitative data suggests that group size and *Acacia* density are directly related to group breeding success. Detailed study in Santa Rosa National Park (Costa Rica) concluded that helpers increased breeding success by hastening onset of first laying, reducing predation on eggs and chicks, and decreasing hatching failure (presence of helpers did not affect incidence of clutch desertion or chick starvation). Bulky nest 12·7 cm in diameter, constructed by both sexes, made of large twigs, lined with rootlets, placed 6–30 m up in tree; in Guatemala (Colomba) one was placed in top of clump of tall bamboos growing beside stream and three others in shade tree of coffee plantation; in Costa Rica nests located in isolated trees in middle of pasture or near human dwellings, and suggested that sites chosen in order to avoid nest predation by monkeys. Clutch 2–6 eggs; incubation period unrecorded; nestling period 23 days.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Common resident in most of its geographical range. Common to fairly common in Mexico; common in Costa Rica.
Bibliography. Genus *PSILORHINUS* Rüppell, 1837

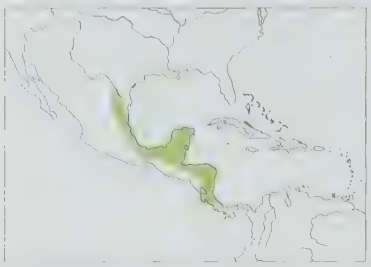
38. **Brown Jay**



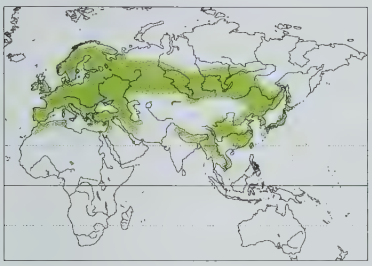
Psilorhinus morio

French: Geai enfumé **German**: Braunhäher **Spanish**: Chara Papán

On following pages: 39. Eurasian Jay (*Garrulus glandarius*); 40. Black-headed Jay (*Garrulus lanceolatus*); 41. Lidth's Jay (*Garrulus lidthi*); 42. Sichuan Jay (*Perisoreus internigrans*); 43. Siberian Jay (*Perisoreus infaustus*); 44. Grey Jay (*Perisoreus canadensis*).

Other common names: Plain-tipped/Plain-tailed Brown Jay (brown-tailed morph); White-tipped Brown Jay (white-tipped morph)

Taxonomy. *Pica morio* Wagler, 1829, Alvarado, Veracruz, Mexico.
Genus often subsumed in *Cyanocorax*. Occurs as two morphs, largely random in occurrence, white-tipped morph occurring at relatively high frequencies in arid and mesic regions, brown-tailed morph predominating in more humid areas; in Mexico, white-tipped morph, formerly treated as a separate species, "*C. mexicanus*", recorded N to C Veracruz (Plan del Río, 19°12' N), and brown-tailed morph found S to Montecristo, in Tabasco. Proposed race *cyanogenys* (described from Pearl Cay Lagoon, in Nicaragua) is synonymized with nominate. Three subspecies recognized.
Subspecies and Distribution.
P. m. palliatus van Rossem, 1934 – extreme S USA (lower Río Grande Valley, in extreme SE Texas), E Mexico (Nuevo León and Tamaulipas S to Veracruz, extreme E Tabasco and SW Campeche), S in Central America to W Panama (Almirante Bay region).
P. m. morio (Wagler, 1829) – SE Mexico from coastal plain of C Veracruz S to E Tabasco (Montecristo) and N Chiapas (Palenque).
P. m. vociferus (S. Cabot, 1843) – N Yucatán Peninsula.



Descriptive notes. 38–44 cm; 173–224 g. Large jay with short bristly frontal crest somewhat inconspicuous, rather plush-like feathering on lores and around eye, highly graduated tail; small bare inflatable area on chest (the furcular sac), not visible unless calling. Nominate race has head sepia-coloured, small patch of black bare skin behind eye, and malar patch formed by different feather structure; upperparts, including upperwing and tail, dark brown, wing and tail with indistinct grey sheen in fresh plumage; tail plain (brown-tailed morph) or with white tips on all except central pair of rectrices (white-tipped morph); throat and breast dark brown, rest of underparts pale dull brownish-buff, becoming paler towards belly; iris dark brown, black orbital ring; bill and legs black. Sexes similar in plumage, female significantly smaller than male in all dimensions. Juvenile is a little paler than adult, with iris grey, narrow orbital ring and tiny bare eye patch yellowish (often becoming greenish soon after fledging), legs and bill yellow; ageing process individually variable, in general first-year has patchy yellow-and-black bill and legs, and bill may retain yellowish patches for several years. Race *palliatus* is larger than nominate, has underparts light drab, becoming pale towards belly; *vociferus* is paler overall than nominate, underparts paler buff, outermost tail feathers with whitish tips. Voice. Small repertoire. Most frequently heard is a loud "pay-ah" or "peer", with several variations in intonation, pitch and speed, delivered repeatedly by members of flock while moving; during mobbing (or when human present) becomes modified to a loud scream, higher-pitched and more strongly accented; "pay-ah" or variations of it given by nestlings and fledglings, also by female from nest during pre-laying period and throughout incubation (function unclear, but female more likely to call when flock-members present than when absent, suggesting that she vocalizes in order to attract attention). Sudden expansions of furcular pouch produce snapping and clicking sounds, these sometimes combined with "pay-ah". In aggressive situations, as during inter-group encounters at territory borders, harsh churring notes. Juvenile gives "hew" note, also calls as do older birds but more softly and at higher pitch.
Habitat. Mosaic of habitats, from coastal areas to 2500 m, with notable preference for disturbed areas (edges of plantations) over undisturbed ones; avoids interior of forest. In long-term study in Monteverde (Costa Rica), flocks occupied woodlots and ravines with remnants of lower montane moist/wet forest and with open pastures, cultivated bananas and coffee. In Tamaulipas and San Luis Potosí (Mexico) recorded along river in climax evergreen forest and in border of tropical deciduous forest. In E Honduras and N Nicaragua (region known as Moskitia), recorded in varied habitats ranging from forest (mature and young) to open areas (e.g. coastal regions and mangroves). Recorded in a reserve with thorn-forest, a vegetation type endemic in Mexico, dominated by tinto tree (*Haematoxylon campechianum*).
Food and Feeding. Takes insects, spiders (Araneae), lizards, nectar of banana and balsa flowers, and fruits, especially those of *Castilloa elastica*, *Passiflora* and catkin-like fruits of *Cecropia*; also takes nestlings of smaller birds. Forages in flocks of 5–24 individuals (average 10), usually with adults, young and immatures, which maintain overlapping home ranges of 10–20 ha; new flocks probably formed by splitting of very large flocks and, in some cases, by fusion of individuals from separate neighbouring flocks. Flocks known to occupy same home range for long periods (5 years). Foraging activity begins after "rallying" behaviour (a seemingly spontaneous burst of calling and rapid flight through canopy, starting half an hour before sunrise); as day progresses, flock tends to forage in lower vegetation strata. Gleans foliage for insects, probes rotten wood or under loose bark; occasionally flies out to catch insects on the wing. Less than 10% of daily activity spent on the ground, and then only for capturing food item. During foraging, adults normally quiet, but juvenile may call loudly while moving through canopy. Three records of following ant swarms (Formicidae) out of total of 17 separate army-ant swarms observed in subtropical forests of Cordillera de Tilarán at Monteverde, in Costa Rica.
Breeding. Eggs recorded in Mar–Jun, with peak in Apr. Social nester, but breeding behaviour varies more than in other co-operatively breeding New World jays, from one or more nests with helpers (young, non-breeding birds) in same territory to true communal breeding; such variation possibly due to both availability of suitable habitats and density of individuals. Groups contain 3–17 individuals during breeding season. In Monteverde (Costa Rica), group-members collaborate in nest-building, feeding of incubating female, and feeding and defending of nestlings and fledglings, 29% of groups contain two or three breeding females with separate nests but successful reproduction normally limited a single female per group. Aggressive behaviour (aerial chasing and harsh calls) common in territorial encounters between flocks, can last from 10 minutes to 3 hours, accompanied by fighting (pecking and foot-grappling) in 31% of observed encounters, but non-aggressive behaviour also seen in 27% of encounters (some between individuals of different flocks). Nest a very bulky mass of large twigs and vines, lined with fibrous roots, usually placed 8–12 m above ground in isolated tree (e.g. *Ficus tuerckheimii*, *Croton gossypifolius*, *Inga tonduzzii*) well away from woods, but protected from wind, less often 3–6 m up in crown of banana plant; nests in isolated trees in pastures produced more fledglings than did nests located along windbreaks or in forest, because latter more exposed to predation. Clutch 2–8 eggs, larger clutches the product of more than one female; incubation period 18–20 days; nestling period c. 22–18 days; fledgling period 22–31 days, young birds protected by older flock-members for up to a year after fledging; in contrast to most other corvids, dispersal male-biased within the population and occurs mostly at 2–3 years of age, almost always to an adjacent territory, and in new groups males and females must often wait several years before breeding; individuals of both sexes older than 4 years more likely to become breeders. Success variable; small groups in Monteverde more likely than large groups to have total reproductive failure in a season; one study revealed, however, that success seems related to number of old birds instead of simply flock size. Survivorship of adults high, annual survival 86%.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Common in most of its range. Recently reported from El Salvador. Has benefited from forest fragmentation, which has created more open areas; this species has expanded in Costa Rica, spreading into Pacific lowlands, and in Panama.
Bibliography. (2000, 2004), Williams, D.A. & Hale (2006), Williams, D.A. *et al.* (1994).

Genus *GARRULUS* Brisson, 1760

39. Eurasian Jay
Garrulus glandarius

French: Geai des chênes **German**: Eichelhäher **Spanish**: Arrendajo Euroasiático
Other common names: Common/European/Acorn/White-eared Jay; Black-crowned Jay ("*cervicalis* group"); Black-capped Jay ("*atricapillus* group"); Iranian Jay (*hyrcanus*); Brandt's Jay ("*brandtii* group"); Japanese Jay ("*japonicus* group"); Himalayan/Red-crowned Jay ("*bispecularis* group"); White-faced Jay ("*leucotis* group")

Taxonomy. *Corvus Glandarius* Linnaeus, 1758, Sweden.
Geographical variation complex, races divided into eight groups: European "nominate group" (first eleven races listed below), N African "*cervicalis* group" (*whitakeri*, *minor*, *cervicalis*), Middle Eastern "*atricapillus* group" (*samios*, *anatoliae*, *iphigenia*, *krynicki*, *atricapillus*), "Caspian group" (*hyrcanus*), Siberian "*brandtii* group" (*brandtii*, *kansuensis*, *pekingensis*), "*japonicus* group" (*japonicus*, *tokugawae*, *hiugaensis*, *orii*), Chinese "*bispecularis* group" (*sinensis*, *taivanus*, *bispecularis*, *interstinctus*, *oatesi*), and Indochinese "*leucotis* group" (*haringtoni*, *leucotis*). DNA research into relationships among these groups has so far been limited, but revealed only minor differences of little significance. Numerous additional forms have been described, all of doubtful validity, the majority referable to intermediate populations, and these are best treated as synonyms of recognized races: thus, *armoricanus* and *caledoniensis* are synonyms of *rufitergum*, *septentrionalis* of nominate, *lusitanicus* of *fasciatus*, and *yugoslavicus* and *jordansi* of *albipectus*; *oenops* and *theresae* are synonyms of *minor*; *rhodius*, *zervasi*, *chiou*, *susianae* and *hansguentheri* are synonyms of *anatoliae*, and *nigifrons* of *krynicki*; *caspius* is a synonym of *hyrcanus*; *sewerzowii*, *bambergi*, *pallidifrons*, *kurilensis* and *ussuriensis* are synonyms of *brandtii*, and *diaphorus* is a synonym of *pekingensis*; *namiyei* is a synonym of *japonicus*, and *schimoizumii* of *hiugaensis*; and *insularis* is a synonym of *taivana*, *persaturatus* and *azureitinctus* are synonyms of *interstinctus*, and *rufescens*, *rubrosus* and *minhoensis* are synonyms of *sinensis*. Thirty-four subspecies currently recognized.
Subspecies and Distribution.
G. g. hibernicus Witherby & E. J. O. Hartert, 1911 – Ireland.
G. g. rufitergum E. J. O. Hartert, 1903 – C & S Scotland, England, Wales and NW France.
G. g. glandarius (Linnaeus, 1758) – N & C Europe E to Urals.
G. g. fasciatus (A. E. Brehm, 1857) – Spain and Portugal.
G. g. corsicanus Laubmann, 1912 – Corsica.
G. g. ichnusae O. Kleinschmidt, 1903 – Sardinia.
G. g. albipectus O. Kleinschmidt, 1920 – Italy, Sicily and Dalmatian coast.
G. g. graecus Keve-Kleiner, 1939 – W Balkans, including mainland Greece.
G. g. ferdinandi Keve-Kleiner, 1943 – E Bulgaria and adjacent N Thrace.
G. g. cretorum R. Meinertzhagen, 1920 – Crete.
G. g. glaszneri Madarász, 1902 – Cyprus.
G. g. whitakeri E. J. O. Hartert, 1903 – N Morocco and NW Algeria.
G. g. minor J. Verreaux, 1857 – C Morocco and Saharan Atlas range of Algeria.
G. g. cervicalis Bonaparte, 1853 – N & NE Algeria and Tunisia.
G. g. samios Keve-Kleiner, 1939 – Samos and possibly Kos (Greece), in SE Aegean Sea.
G. g. anatoliae Seebohm, 1883 – W, C & E Turkey E to N Iraq and W Iran.
G. g. iphigenia Sushkin & Ptuschenko, 1914 – Crimea.
G. g. krynicki Kaleniczenko, 1839 – Caucasus & NE Turkey.
G. g. atricapillus I. Geoffroy Saint-Hilaire, 1832 – W Syria, W Jordan and adjacent part of Israel.
G. g. hyrcanus Blanford, 1873 – S Caspian forests of SE Azerbaijan and N Iran.
G. g. brandtii Eversmann, 1842 – S Siberia from Urals E to Sakhalin I, S to N Mongolia, NW & NE China, Korea and N Japan (Hokkaido).
G. g. kansuensis Stresemann, 1928 – C China (Qinghai, Gansu and NW Sichuan).
G. g. pekingensis Reichenow, 1905 – E China (S Liaoning, Beijing Shanxi, Hebei).
G. g. japonicus Temminck & Schlegel, 1847 – C Japan (Honshu and Oshima).
G. g. tokugawae Takatsukasa, 1931 – Sado I (off Honshu).
G. g. hiugaensis Momiyama, 1927 – Kyushu (SC Japan).
G. g. orii Nagamichi Kuroda, 1923 – Yakushima (S Japan).
G. g. sinensis Swinhoe, 1871 – SC, S & E China and N Myanmar.
G. g. taivanus Gould, 1863 – Taiwan.
G. g. bispecularis Vigors, 1831 – W Himalayas E to W Nepal.
G. g. interstinctus E. J. O. Hartert, 1918 – E Himalayas, S Assam and SE Xizang.
G. g. oatesi Sharpe, 1896 – NW Myanmar.
G. g. haringtoni Rippon, 1905 – W Myanmar.
G. g. leucotis Hume, 1874 – C & E Myanmar, S China (S Yunnan), Thailand and C & S Indochina.
Descriptive notes. 32–36 cm; 150–190 g. Distinctive, rather broad-winged woodland bird with hesitant, shallow-flapping wing action; small to medium-sized bill, nostrils just concealed by soft nasal tuft, slightly elongated crown feathers which can be elevated into short, ruffled crest, medium-length tail with squared tip; plumage pinkish-grey or reddish-brown with wholly black tail and contrasting white rump. Nominate race has forehead and crown, lores and area around eye whitish, crown streaked black, nasal tuft whitish or buff; chin and throat whitish, bold black malar stripe; rear crown, side of head and most of body plumage light to medium pinkish-brown to

reddish-brown, vent and both uppertail-coverts and undertail-coverts white; tail black, becoming greyer towards base; upperwing pattern complex, but essentially lesser and median coverts rufous, primary coverts and outer greater coverts bright blue with fine black barring, inner greater coverts black, primaries greyish-black with narrow whitish edges on outer webs, secondaries blackish with white bases on outermost five feathers, innermost tertial chestnut with black tip; iris bluish-white; bill brownish-horn; legs flesh-brown. Sexes similar. Juvenile is similar to adult, but body darker reddish-brown, legs brighter fleshy-yellow, iris more bluish and bill greyer; much as adult by first autumn, but with more irregular black barring on blue wing patch. Races differ mainly in tone of body plumage, and in crown and wing patterns, also in size: *rufitergum* is more reddish, less grey, than nominate; *hibernicus* is even redder brown, especially below; *fasciatus* is much greyer and has bolder crown streaks; *ichnusae* is smaller and redder above than previous, and has finer crown streaks; *corsicanus* is close to nominate, but richer vinous above and below; *albipectus* is paler above and below than nominate, and has more extensive white on belly; *graecus* is similar to last, but has less white on belly; *ferdinandi* is pinker, less grey, overall; *cretorum* has even less, or no, white on belly; *glaszneri* is rather dark dull brownish, with rufous forehead and weak bill; in N Africa, *cervicalis* has whitish sides of head and neck, two-toned upperpart coloration, and solidly black cap, *whitakeri* has cap broadly streaked and less extensive white on head, and *minor* is smaller and darker, with pinkish side of head and boldly streaked crown; in Middle East, *atricapillus* has solidly black rear crown (like *cervicalis* of N Africa), extensive white forecrown, uniform upperpart coloration, and dark iris, *anatoliae* is darker than last and with white of face and forecrown washed vinous, *samios* also is dark and has vinous and reddish-brown feathering mixed on underparts, *krynicki* is darker, with pale areas of face and forecrown washed vinous-pink, and *iphigenia* is paler and greyer than last, with whiter forecrown and face; *hyrcanus* is rather small, dark vinous-pink in overall tone, with shorter crown feathers than others, and black cap extends onto forehead but rear crown mottled; in Siberian group, *brandtii* has dark iris, dusky nasal tuft and blackish lores, bright rufous head and neck contrasting with grey upperparts, *kansuensis* has less black on face, is less grey than previous and has less white in secondaries, *pekingensis* is a variable form, close to *leucotis* but with white secondary patch; in Japanese group, *japonicus* is quite large, has pale eyes, dusky face, blackish but streaked crown and a large white secondary patch, *tokugawae* is larger and paler, *hiugaensis* is darker and has brownish rear crown, and *orii* has less white in wings and is darkest of group; in Chinese group, *bispecularis* is dark-eyed, lacks white wing patch, has only weak-streaked or unmarked crown and (apart from black malar stripe) uniformly pinky-rufous head and body colour, *interstinctus* is darker, more reddish-brown, above, *sinensis* is vinous-toned on body and with grey wash above, *taivanus* is smaller and weaker-billed than last and has paler underparts and black nasal tufts, and *oatesi* has very pale face, weakly marked crown and pinkish-brown crown and body; in Indochinese group, *leucotis* lacks white secondary patch, has dark eyes and whitish side of head and is darker overall, with most of crown black, and *haringtoni* is similar but paler, and has crown weakly streaked. Voice. By far the most familiar call is a loud, dry, rasping screech, "shaaaaak", often repeated when individual alarmed. Apart from this, has wide vocabulary of subdued notes, which based on mimicry. These notes generally worked into subdued warbling song, the most obvious mimicry being of the mewing of Common Buzzard (*Buteo buteo*); this song easily overlooked in the wild, but well documented for captives.

Habitat. Inhabits woodlands and forests of all kinds, especially beech (*Fagus*) and hornbeam (*Carpinus*), although oak (*Quercus*) preferred. N populations occur also in conifers and birch (*Betula*) forest. Found also in parks, orchards and large gardens. Only rarely seen in open country, even then chiefly during sporadic irruptive movements. From lowlands to 4000 m.

Food and Feeding. Omnivorous. Chiefly invertebrates during breeding season, notably caterpillars and beetles (Coleoptera) gleaned from foliage of trees; diet also includes eggs and nestlings of a range of birds up to size of a sparrowhawk (*Accipiter*); wide variety of seeds and berries eaten, especially in autumn and winter, including grain, beech mast, chestnuts and acorns; in Siberian taiga feeds mainly on pine (*Pinus*) seeds. Although not a carrion-eater it seems to be an opportunist, having taken to visiting garden birdtables in recent decades in areas where unmolested, even attempting to cling to suspended bags of peanuts. One reported as pausing to dip down to pick a small live fish from surface of a river as it flew across; perhaps even more remarkably, one was seen to take bats from a tree hole. Throughout autumn and into winter builds up caches of acorns, burying them individually in leaf litter on forest floor or beneath clumps of brambles or ferns, and has been estimated that a single jay could store c. 3000 acorns in one month, making this species one of the most prolific planters of oaks; by following summer many acorns will have germinated, and the jay has learnt that a germinating seedling is attached to an acorn and will select these while foraging in summer. Normally extremely shy and wary, keeping very much to cover of dense foliage, although in city parks can become remarkably confiding. Typically solitary, and rarely found in numbers greater than a family group, but small gatherings of unmated birds form in spring, with much posturing to attract a mate, and quite large communal roosts sometimes develop in late summer and autumn (seem to be of a temporary nature, and possibly associated with eruptive activity). Normally utilizes lowest airspace, flying between trees with hesitant action; during sporadic eruptive movements, however, flocks form and unite, sometimes several hundreds together, climb high and move out with steadier wing action. Observed with foraging flocks of White-crested Laughthrushes (*Garrulax leucolophus*) in Thailand.

Breeding. Laying mainly from mid-Apr in most of Europe, towards end of Apr in N and a week or so earlier in S; in Israel from as early as late Feb, and primarily in Mar in N India. Long-term, probably lifelong, pair-bond. Solitary nester. Nest built by both sexes, well constructed, a platform of twigs around a relatively deep cup, lined with soft plant materials; placed 4–6 m above ground and often at junction of substantial branch and main trunk, rarely in tree cavity, well concealed by foliage, typically near tree centre or lower crown; sometimes in large nestbox or on old building. Clutch 3–10 eggs, chiefly 5–7; incubation by female only, period 16–19 days (mainly 16–17 days); chicks fed by both parents, nestling period c. 19–23 days, mostly 21–22 days; young independent of parents at c. 7–8 weeks, when parents can become aggressive towards them. First breeding at 2 years of age, sometimes even at 1 year.

Movements. Mainly resident, with irregular movements, including irruptions and seasonal altitudinal movements. Almost all (98%) recoveries of British-ringed individuals are within 50 km of ringing site. S races often altitudinal migrants in montane regions, making post-breeding descent to lower elevations. In some autumns, when the acorn crop fails, those in Scandinavia form huge flocks and travel towards SW, recent notable years in this respect being 1955, 1977 and 1983; examples of the numbers involved include 34,000 which moved through at a count point near St Petersburg (Russia) in 1975, and some 35,000 flew over Gdansk (Poland) during a four-week period (mid-Sept to mid-Oct) in 1964; one of the most striking was in 1983, when 10,000 moved through S Sweden in late Sept prior to the biggest invasion ever in Britain, culminating in 6000 in one day over Cornwall. Such movements occur also farther E, but are less well documented; movements are regular in SE Russia (Ussuriland) and in the N Altai ranges of C Asia.

Status and Conservation. Not globally threatened. Common to locally abundant. The following estimates (territories/pairs) have been made for most countries within W Palearctic: Britain 160,000, Ireland 10,000, France 100,000–1,000,000, Belgium 22,000, Luxembourg 15,000–20,000, Netherlands 30,000–60,000, Germany 440,000–560,000, Denmark 15,000–160,000, Norway 10,000–100,000, Sweden 200,000–500,000, Finland 100,000–150,000, Estonia 30,000–50,000, Latvia 20,000–40,000, Czech Republic 150,000–300,000, Slovakia 15,000–30,000, Hungary 60,000–100,000, Austria 25,000–40,000, Switzerland 35,000–50,000, Italy 50,000–200,000, Spain 540,000–1,100,000, Portugal 10,000–100,000, Greece 20,000–50,000, Albania 5000–10,000, Croatia 150,000–200,000, Slovenia 20,000–30,000, Bulgaria 1,000,000–5,000,000, Romania 350,000–500,000, Russia 1,000,000–10,000,000, Belarus 220,000–250,000, Ukraine 55,000–60,000, Moldova 35,000–50,000, Azerbaijan 1500+, Turkey 100,000–1,000,000. In addition, it is said to be common in Lithuania, fairly numerous in Poland, common in Cyprus, locally common in suitable habitats in Jordan and Israel; in Morocco and Algeria widespread but localized in N, and in Tunisia uncommon. Densities vary considerably, 0·3–5·5 pairs/10 ha in SE Poland, 5 pairs/10 ha in Hungary, and in prime forest in Switzerland as many as 12 pairs/10 ha. In early 20th century, this species' colourful blue wing feathers became very fashionable, both as a hat decoration and in the making of "flies" for salmon-fishing. Long persecuted by gamekeepers and farmers owing to its egg-stealing and nest-robbing habits, but reduction in keepering intensity since 1920s has allowed a steady increase, which accelerated in 1950s as the creation of larger suburban gardens and city and town parks provided habitats safer from human persecution. Over much of its European range is now increasing; surprisingly, the Irish population contracted considerably between 1970s and 1990s, reasons for which uncertain. Farther E, it is thinly distributed across Siberia, but becomes more numerous in China and Japan; farthest S in range, in Himalayan regions and elsewhere in SE Asia, locally numerous but by no means common.

40. Black-headed Jay

Garrulus lanceolatus

French: Geai lancéolé **German**: Strichelhäher **Spanish**: Arrendajo Cabecinegro
Other common names: Black-throated(!)/Lanceolated Jay

Taxonomy. *Garrulus lanceolatus* Vigors, 1831, Simla–Almora district, north India.
This species and *G. lidthi* sometimes placed together in a separate genus, *Lalocitta*. Monotypic.

Distribution. E Afghanistan (mountains near Kabul and Paktia) and W Himalayas across N Pakistan (S to Safed Koh range) and Kashmir (absent from the Vale) E to Nepal (E to vicinity of Kathmandu).

Descriptive notes. 33 cm; 84–104 g. Unmistakable, with black hood, elongated crown feathers erectable into ruffled crest, greyish-pink body and relatively long, barred blue tail; bill small, rather stout. Almost entire head is black, chin and throat streaked white on black background, side of neck, hindneck and most of body plumage pinkish-grey, with grey tones highlighted when viewed in dull light; underparts, especially belly and undertail-coverts, pinker than greyer upperparts; tail blue, closely barred with black, wider but still narrow black subterminal bar highlighting white tips of all feathers; upperwing pattern complex, in essence lesser and median coverts black, primary coverts white, outer secondaries blue and narrowly barred black, with wider black subterminal bar and white tip, tertials light grey with black subterminal bar and white tip, primaries dark grey, outer webs marbled bluish and narrowly edged whitish; iris reddish-brown to dark brown; bill pale olive-grey to pale horn; legs bluish-grey. Sexes similar. Juvenile is duller and browner overall than adult, lacks white tips on wing feathers, has greyish tips on duller tail feathers, crest shorter than that of adult; after autumn moult, head and body like adult, but most of juvenile wing and tail feathers retained. Voice. Similar to that of *G. glandarius*. Typical call a dry rasping "skaaaak", somewhat thinner than that of *G. glandarius* and usually uttered only singly; rather flat "krah" given more frequently than by *G. glandarius*, and mewing call similar to latter's but higher in pitch. Subdued song of mixed bubbling, whistling and mewing notes interspersed with mimicry recorded in captivity; quiet nature of song renders it almost inaudible in the wild.

Habitat. Forests, preferring mixed pine–oak (*Pinus–Quercus*) and cedar–oak (*Cedrus–Quercus*) woodlands. Shows distinct preference for more open forest than that used by *G. glandarius*, the latter preferring to be concealed amid dense foliage. Freely found on shrubby hill slopes and degraded forest; including edges of clearings and villages. Breeds between 1500 m and 4000 m, descending a little lower in winter.

Food and Feeding. Omnivorous. Chiefly invertebrates during breeding season, also small lizards and the eggs and nestlings of small birds; diet includes variety of seeds and berries, especially in autumn and winter, including pine seeds. Scavenges discarded household food scraps around villages. Like *G. glandarius* is very fond of acorns, and stores them for later use. Usually encountered in pairs or small parties; sometimes as many as 30 or 40 congregate in winter and may loosely associate with both *G. glandarius* and *Urocissa flavirostris*. Forages in more open situations than either of those, and often found alongside mixed-species groups, such as babblers and laughingthrushes (Timaliidae), as they roam through shrubby gulleys. Readily perches in open situations, such as rock outcrops in forests, prominent treetops, or large bushes on scrubby hillsides.

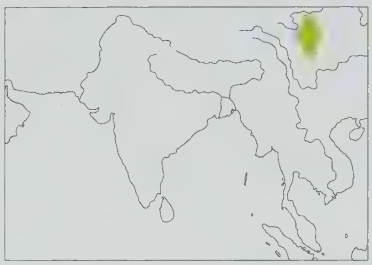
Breeding. Eggs recorded in Apr and May. Probably has long-term pair-bond. Solitary breeder. Nest built by both sexes, a deep loose foundation of twigs, with deep cup lined with rootlets, grass stems and black fungal rhizoids (resembling horsehair), usually positioned c. 5–7 m from ground in fork towards top of small tree, usually an oak, or in large shrub on degraded hillside or near edge of forest. Clutch 3–5 eggs, mostly 3–4; incubation by female only, fed on nest by male, period 16 days; nestling period suspected to be c. 20 days, but confirmation required.

Movements. Resident, with some altitudinal migration linked with colder weather at higher elevations. In winter can be quite numerous about many Indian hill-stations, including Naini Tal, Mussooree, Simla and Kulu; also in Murree Hills, in Pakistan, and around city of Jalalabad, in Afghanistan.
Status and Conservation. Not globally threatened. Locally common in W Himalayas, especially so in Indian sector; reasonably common also across N Pakistan into extreme E Afghanistan; E limit of range in vicinity of Kathmandu, in Nepal, but throughout W regions of Nepal it is nowhere common. The future for this species appears to be secure, not least because of its tolerance of, and even preference for, secondary forest and scrubby slopes.
Bibliography. Ali (1949), Ali & Ripley (1972, 1987b), Bates & Lowther (1952), Goodwin (1951, 1953, 1954, 1956, 1986), Grimmett *et al.* (1998), Inskipp & Inskipp (1985), Kroker (1973), Madge & Burn (1994), Paludan (1959), Rasmussen & Anderton (2005a, 2005b), Roberts (1992), Vaurie (1959), Vietinghoff-Scheel (1992b), Zahler *et al.* (1997).

41. Lidth's Jay
Garrulus lidthi

French: Geai de Lidth **German**: Prachthäher **Spanish**: Arrendajo de Lidth
Other common names: Purple/Amami/Ryukyu Jay

Taxonomy. *Garrulus lidthi* Bonaparte, 1850, "Asia orientali" = Amami-O-shima, Japan.
This species and *G. lanceolatus* sometimes placed together in a separate genus, *Lalocitta*. Monotypic.
Distribution. Amami-O-shima, in N Ryukyu Is (S Japan).



Descriptive notes. 38 cm; c. 125 g. A rather large, dark purplish-blue and chestnut jay with forehead and loral feathering somewhat stiffened, crown feathers very slightly elongated (can be inconspicuously erected), tail relatively longer than that of *G. glandarius* and somewhat graduated at tip, bill rather stout; in shade of forest overall appearance of a very dark bird, with contrasting pale bill and with narrow white trailing edge on innermost secondaries and tail. Has nasal tuft, forehead, loral region, chin and throat black, throat with short white streaks; remainder of head, neck, mantle and breast dark purplish-blue, lower breast gradually merging into rufous-chestnut, washed with mauve, of remainder of body plumage (with wear, chestnut colour prevalent as purplish feather fringes abraded); tail dark purplish-blue, black subterminal band and white tip; upperwing dark purplish-blue, wing-coverts and secondaries finely barred black, tertials unbarred but with prominent white tips; iris dark violet-blue; bill clear pale yellowish, greener base; legs dark grey. Sexes similar. Juvenile is much drabber than adult, with purplish areas of plumage dull brownish or dark greyish, and chestnut areas dull brown, lacks white tips on tertials and tail. VOICE. Most frequent call a harsh, grating "kraah", readily given in alarm by flushed birds, or when mobbing predators; can be uttered at variety of pitches. High-pitched mewing call presumed to be a contact call, as frequently heard from foraging birds. Screech call seems to be given only during display. May call repeatedly from tops of tall trees for up to 3 minutes, speeding up in frequency towards end and ceasing abruptly.
Habitat. Mature forest of various types, both subtropical evergreen broadleaf forest and conifers; also plantations or small stands of trees at edges of villages. Widespread both in lowlands and in mountains.
Food and Feeding. Omnivorous. Chiefly invertebrates, but also small snakes and lizards, during breeding season; at other times has fondness for chestnuts and acorns, and stores them for later use. Diet includes variety of seeds and berries, especially in autumn and winter, including small sweet-potatoes. Usually encountered in pairs or small parties; sometimes as many as 100 congregate in winter to roam through forest undergrowth and clearings. Rather ponderous, moving between foliage and branches and inspecting every nook and cranny; reported as using the relatively large bill as a climbing aid, giving impression like that of a parrot (Psittacidae). Readily perches in open situations, such as rock outcrops in forests, prominent treetops, or large bushes on scrubby hillsides.
Breeding. Eggs recorded in Feb and Mar. Probably has long-term pair-bond. Solitary breeder. Nest a foundation of twigs, with deep cup lined with rootlets and other soft plant materials, built up to 5 m from ground inside tree hole, on cliff ledge under overhang, or inside old building; maintains small breeding territory of 150–300 m². Clutch 3–5 eggs; no information on incubation and fledging periods.
Movements. Mainly sedentary; some altitudinal migration at higher elevations.
Status and Conservation. VULNERABLE. Restricted-range species: present in Nansei Shoto EBA. Found only on Amami-O-shima and nearby tiny island of Kakeroma-jima. In 1983 a single individual was reported from Iriomote-jima, in Yaeyama Is, but this most likely an escaped bird or a released illegal captive. Population estimated at 5800 birds in 1970s, but considered to have decreased considerably since then as a result of introduced predators, notably small Indian mongoose (*Herpestes auropunctatus*), and increasing numbers of *Corvus macrorhynchos*. Jay numbers once again rising, due to natural forest regeneration and efforts to control the mongooses. Was for many years persecuted through uncontrolled shooting and trapping for the fashion industry, its unusual plumage making it popular in the hat trade in early 20th century. Now fully protected by Japanese law, having been declared a National Monument; a National Wildlife Protection Area has been created at Yuwandake for present species and Common Scaly Thrush (*Zoothera dauma*) of highly endangered race *major*, often treated as a full species ("Amami Thrush"). In 1920s was said to have been common in C mountains of nearby island of Tokun-O-shima, but doubt has been expressed over this as no subsequent reports and no conclusive proof of its presence there.

(2008p), Austin & Kuroda (1953), Brazil (1991), Bruce (1975, 1979), Butchart & Stattersfield (2004), Ezra (1936), Goodwin (1986), Ishida *et al.* (1998), Madge & Burn (1994), Oliver (1964), Reichenow (1906), Stattersfield & Capper (2000), Takatsukasa (1937), Ueta & Yamaguchi (1997), Vietinghoff-Scheel (1992a).

Genus *PERISOREUS* Bonaparte, 1831

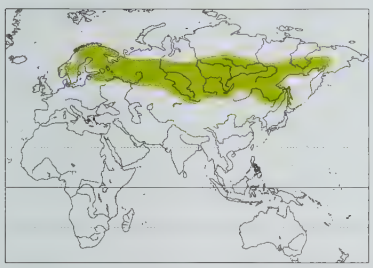
42. Sichuan Jay
Perisoreus internigrans

French: Mésangeai du Sichuan **German**: Sichuanhäher **Spanish**: Arrendajo de Sichuán
Other common names: Sichuan/Szechuan Grey Jay, Black-headed(!)/Chinese/Sooty Jay

Taxonomy. *Boanerges internigrans* Thayer and Bangs, 1912, Shuowlow, west Sichuan, China.
In certain aspects of structure (particularly bill shape) appears close to *Garrulus lanceolatus*, and some plumage features (e.g. faint suggestion of barring on secondaries) echo that genus, but drabness of plumage (resembling juveniles of darker populations of *P. canadensis*) and vocalizations much nearer present genus; could perhaps be considered a link between the two genera. On the other hand, recent DNA-sequencing indicates that this genus and *Cyanopica* form unique clades, separate from other corvids; significance of this requires further research, but it may suggest that *Perisoreus* is not very closely related to *Garrulus*. Probably forms a superspecies with *P. infaustus* and *P. canadensis*. Monotypic.
Distribution. C China from extreme SW Gansu S along borders of N Sichuan (Min Shan range), also extreme SE Qinghai and extreme NE & E Xizang.

Descriptive notes. 30 cm; 92–123 g. A relatively small and quite long-tailed sooty-grey jay, with a small but often surprisingly conspicuous, pale bill. Similar in proportions to *P. canadensis* of North America, but somewhat larger, and with a stouter bill. Entire plumage medium-dark grey, becoming almost blackish on head and throat; throat feathers blackish at tip with greyer bases, which could show as a grey throat when blackish feather tips have worn away; thighs (feathered portion of tibia) also blackish; wings and tail somewhat darker, with brown tinge to wing feathers; bill yellowish-olive to horn (can appear strikingly pale against darkness of remainder of plumage), with a distinct angle along lower mandible; nasal tuft short and dense; iris brown; legs blackish. All plumages seem to be similar. VOICE. Two types of call recorded, both given by foraging birds, but neither seems to be far-carying and could well be forms of contact call. One call is a high-pitched, rather plaintive "kyip", with a rising inflection, which can be accelerated into a more prolonged "kyip, kyip, kyip, kyip, kyip,ip,ip,ip,ip,ip" which has something of a woodpecker (*Dendrocopos*)-like quality about it. The other call is a buzzard (*Buteo*)-like plaintive mewing "meeeoo-meeeoo", also delivered with a rising inflection.
Habitat. Dense coniferous forests on slopes of mountain valleys and on high plateaux, between 2800 m and 4270 m. Generally found in mixed spruce (*Picea*) and mature fir (*Abies*) or in fir with a rhododendron (*Rhododendron*) understorey; can be found also in rather dry high-altitude coniferous forest with poorly developed understorey.
Food and Feeding. Omnivorous; diet includes seeds, berries, insects and other invertebrates; said also to take carrion. Forages in pairs or family groups amid dense foliage of conifers, where difficult to see. Searches along branches and on main trunk from mid-height upwards, inspecting and pecking at scaly bark; then moves on to an adjacent tree, or drops down slope to work another patch of forest. Sometimes perches briefly at top of tall conifer, and frequently feeds on ground. The slight chisel-like shape of lower mandible may be useful aid in prising open pieces of bark or even forcing open pine (*Pinus*) cones to get at nuts. Stores food in autumn; hides items behind bark and moss and among pine needles in a variety of caches, returning to dig out stores during cold winter months.
Breeding. Breeds Mar–May; nest construction begins Mar, incubation (probably wholly by female) from late Mar until mid-Apr, when eggs hatch, and young leave nest in early May. Probably monogamous. Solitary nester, but additional non-breeding helpers (probably relatives and young of previous breeding season) share territory and help to feed young. Two nests found, each contained clutch of 3 eggs; young forage with parents for some time, perhaps into following breeding season. No further information.
Movements. Presumed sedentary. In some regions not regularly seen during spring and summer, but this possibly due to even more secretive nature during breeding season.
Status and Conservation. VULNERABLE. Restricted-range species: present in West Sichuan Mountains EBA. Probably overlooked owing to its shy and unobtrusive habits, but clearly rare, with small, declining and fragmented population. Recorded at only 14 sites in total, in four states (mostly in N Sichuan and SW Gansu, with one or two sites in NE Xizang and E Qinghai); most records have involved small number of individuals. During survey in 1987 (walking at speed of 2 km/hour), average of fewer than two birds seen per hour; given relatively small number of documented localities and the species' apparently low population density, it could have a small global population. Its range has become fragmented following long-term timber-felling throughout, and recent climatic changes over Qinghai–Xizang plateau, which has become progressively drier during recent decades. E part of its range overlaps with N range of giant panda (*Ailuropoda melanoleuca*), which has several quite extensive forest reserves allocated for its survival; most of these forests, however, have received little ornithological fieldwork, and present species has so far been found at only one protected area, Jiuzhaigou Nature Reserve (Sichuan), which has area of 200 km²; forest and other habitats are mainly in excellent condition, but this scenically beautiful reserve likely to be under pressure from tourism. Probably because of accessibility, majority of sightings in recent years have come from Jiuzhaigou and forests flanking nearby Sungpan Pass. Recently added to category 2 of China's list of protected species.
Bibliography. Anon. (2008p), Butchart & Stattersfield (2004), Chen Fuguan *et al.* (1998), Cheng Tsohsin (1976, 1987), Goodwin (1986), Jing Yu *et al.* (2003), Lei Jinyu & Liu Yang (2006), MacKinnon & Phillipps (2000), Madge & Burn (1994), Martens & Sun Yuehua (2003), Meyer de Schauensee (1984), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), Sun Yuehua *et al.* (2001), Zhao Zhengjie (1995).

43. Siberian Jay
Perisoreus infaustus



French: Mésangeai imitateur **German**: Unglückshäher **Spanish**: Arrendajo Siberiano
Other common names: Grey Jay(!)

Taxonomy. *Corvus infaustus* Linnaeus, 1758, Europae alpinis sylvis = Sweden.
Recent DNA-sequencing indicates that this genus and *Cyanopica* form unique clades, separate from other corvids; significance of this requires further research, but it may suggest that *Perisoreus* is not very closely related to *Garrulus*. Probably forms a superspecies with *P. internigrans* and *P. canadensis*. Geographical variation complex, with clines in colour tones, greyest in C Siberia and becoming more rufous towards W and again towards E, but tones and extent of rufous in wing vary also from S to N; further, clinal intergradation has created much taxonomic confusion in terms of number of races that should be recognized, various reviews allowing as many as 17 and as few as four. Conservative assessment suggests that *manteufeli* (from upper R Severnya Dvina, in NW Russia) be included within nominate, that *monjerensis* (lower R Yenisei to Olenek basin, in C

Siberia) is synonym of *ostjakoram*, that *bungei* (NC Siberia between lower R Lena and lower R Kolyma) and *sokolnikowi* (NE Siberia) be treated as synonyms of *jakutensis*, that *rogosowi* (Yenisei valley S to Sayan Mts) and *suschkini* (Transbaikalia, Russia) be synonymized with *sibericus*, that *varnak* (NE China and middle R Amur, in SE Russia) be considered synonym of *tkachenkoi*, and that *sakhalinensis* (Sakhalin) be considered synonymous with *maritimus*. Nine subspecies currently recognized.

Subspecies and Distribution.

P. i. infaustus (Linnaeus, 1758) – Norway, Sweden, Finland, Estonia and NW Russia.
P. i. ostjakoram Sushkin & Stegmann, 1929 – N Russia E (S to 64° N) to W R Lena basin.
P. i. yakutensis Buturlin, 1916 – C & E Russia (Siberia from R Yenisei E to Anadyrland).
P. i. ruthenus Buturlin, 1916 – W Russia (from St Petersburg E to Tomsk, S of Ostjakoram).
P. i. sibericus (Boddaert, 1783) – C Russia (C Siberia) and N Mongolia.
P. i. tkachenkoi Sushkin & Stegmann, 1929 – E part of SC Russia (Yakutsk S to Zhigansk, on R Lena, E to middle Amur and Stanovoy Mts).
P. i. opicus Bangs, 1913 – E Kazakhstan, NW China (N Xinjiang), SC Russia (Tuva, W & C Altai and W Sayans).
P. i. caudatus Buturlin, 1913 – NC Mongolia and CS Russia (S Buryatia).
P. i. maritimus Buturlin, 1915 – E Russia (Amurland, Ussuriland), NE China (NE Heilongjiang) and Sakhalin I.

Descriptive notes. 25–31 cm; 72–101 g. A drab brownish or greyish, relatively long-tailed forest jay with some rufous in tail and wing; bill short and small, with straight culmen but lower mandible somewhat upturned towards tip. Nominate race has head and nape dusky brown, blackest on lores and about eye, contrasting with very pale buff nasal tuft, and lighter buffy-grey throat and underparts, latter washed rufous-cinnamon on breast and flanks, becoming purer cinnamon on lower belly and undertail-coverts; mantle, back and scapulars buffy brown, washed grey in fresh plumage, with lower scapulars washed cinnamon; rump cinnamon-brown, grading into bright rufous on uppertail-coverts; central pair of tail feathers grey, remainder bright cinnamon-rufous, narrowly tipped and edged grey; lesser and median upperwing-coverts grey-brown to buff-brown, greater coverts (except dusky innermost) cinnamon-rufous, alula and flight-feathers blackish-grey, cinnamon-rufous wingpanel formed by bases of flight-feathers (obvious in flight), paler and more extensively pinkish-cinnamon on underside; iris dark brown; bill and legs blackish. Sexes similar in plumage, male on average larger than female. Juvenile has distinctly shorter and looser body plumage than adult, has less obvious dark hood, and is greyer overall. Races differ mainly in plumage tone and amount of rufous in wing: *ostjakorum* has light grey body, virtually no rufous in wing; *yakutensis* has very grey body and extensive rufous in wing; *ruthenus* is mainly rufous-buff on body, but with little rufous in wing; *sibericus* has buffish-grey body, extensive rufous wingpanels; *tkachenkoi* has pure grey body plumage, intermediate extent of rufous in wing; *opicus* is dark-hooded and rufous, with intermediate extent of rufous in wing; *caudatus* has dusky grey-brown body and minimal amount of rufous in wing; *maritimus* has buffish body, moderate deep rufous wingpanels. Voice. Vocabulary quite varied, but all vocalizations rather subdued. Song an insignificant twittering and chattering, mixed with whistling and mewing cries, includes mimicry of other birds, i.e. tits (Paridae), *Turdus* thrushes, redpolls (*Carduelis*) and bullfinches (*Pyrrhula*). Most audible is a harsh "kreee", rather softer than similar call of *Garrulus glandarius*, and a mewing reminiscent of that of buzzard (*Buteo*). When agitated may give nervous, repeated "ful-ful" or "fu-fee" at variety of speeds and pitches, as well as high-pitched repeated "jik" (similar to that of some *Dendrocopos* woodpeckers). In recent experimental studies, this species used 14 different calls when mobbing predators; these provided information to other group-members about both the category of predator and, simultaneously, the risk posed by it at the particular time.

Habitat. Boreal forest (taiga zone); favours dense closed-canopy, mature forest of spruce (*Picea*), pines (*Pinus*) and larches (*Larix*), with stands of birches (*Betula*). Lowlands and foothills, to 2200 m in Altai Mts.

Food and Feeding. Omnivorous. Diet includes berries, seeds, various insects and their larvae, notably beetles (Coleoptera) and moths (Lepidoptera), and wide variety of other invertebrates; feeds on carrion, and scavenges scraps provided by humans; takes eggs and nestlings of small birds, and small rodents; exceptional reports of chasing and killing adult birds, e.g. Willow Tit (*Poecile montanus*). Although generally unobtrusive, can be conspicuous and often very tame in remote areas, even coming to take food from the hand; scavenges at camp-sites, seeking out temporary ones by locating fires. Feeds in pairs or family groups, spending much time on the ground; in spring feeds actively in crowns of conifers, at other seasons much lower in tree foliage. Searches along branches and main trunk, pecking at scaly bark; then moves on to adjacent tree, or drops down slope to work another patch of forest. Sometimes perches briefly at top of tall conifers. On occasion will take flying insects flycatcher-fashion from treetops, or even by leaping from ground. Stores food items for winter but, unlike most other hoarding jays, conceals these in crevices of tree bark, using its very sticky saliva to stick them into position; saliva can also be used for sticking pieces of bark or needles over foodball for concealment. May store up to 200 items in one day.

Breeding. Breeds late Mar to May. Monogamous, with lifelong pair-bond. Solitary nester, but additional bird sometimes present with pair and may help with incubation or brood-feeding (such helpers probably relatives and young birds from previous breeding season); nests 500–1000 m apart. Male initiates building, soon joined by female, construction work taking 11–26 days; nest a rather loose structure of twigs, with well-lined cup of lichens, feathers and reindeer (*Rangifer*) hairs, placed at base of branch close to trunk of tree; breeding territory 45–57 ha. Clutch 3–4 eggs, but 6 reported from nest with two females sharing incubation; incubation wholly by female, period 19 days; chicks brooded by female, fed only by male for first few days, thereafter fed by both sexes, nestling period 21–24 days; after leaving nest young fed by adults for at least a month, but often beg throughout first year. May breed in parents' territory in second year, but most do not commence breeding until they have established own territory, typically in third year. Oldest ringed individual reached 11 years 5 months.

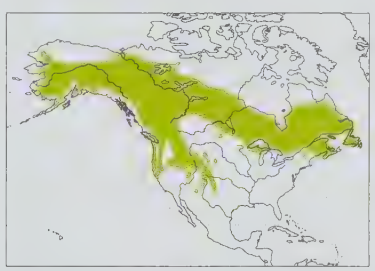
Movements. Sedentary over most of range. In W, rarely moves S in winter as far as St Petersburg and Moscow region, from where only two reports (both in Oct) in 60 years up to 1968. Farther E, likely that populations in extreme N move S in some winters, as indicated by Jan and Feb influxes in Yakutsk region. Vagrancy extremely rare, but reported from Estonia (where formerly bred), Latvia, Poland, Belarus, Slovakia and Ukraine.

Status and Conservation. Not globally threatened. Common to abundant; unobtrusive habits no doubt give false impression of scarcity, but this species, with a range extending across entire length of boreal zone of Palearctic Region, must have a very large global population. In parts of European range it is declining, owing to felling and fragmentation of forests, the latter opening up dense forest and allowing such predators such as *Corvus corax* easier access to nests of this and other bird species. Most noticeable range contraction has been in NE Baltic; probably ceased breeding in Estonia in mid-19th century, since when has become hardly more than a vagrant there; marked decrease in Finland, population falling by two-thirds between 1940s and 1970s, decline continuing into 1990s, and in 1992 Finnish population estimated at between 40,000 and 70,000 pairs. Despite quite extensive forest clearance in N Sweden, a decrease has hardly been noticed in either Sweden or Norway; Swedish population estimated at 50,000–200,000 pairs, with between 10,000–50,000 pairs in Norway and between 10,000 and 100,000 pairs in European Russia. Little published on populations of C & E Siberia, although population density seems to be greater in C Siberia than in Europe; as many as 12–16 birds/km² reported from mixed fir, birch and larch forests of S taiga of C Siberia, whereas densities in prime habitats in N Sweden have not exceeded 2 birds/km².

Bibliography. Blomgren (1964, 1971), Buturlin (1915), Chen Fuguan *et al.* (1998), Cheng Tsohsin (1976, 1987), Coombs (1978), Cramp & Perrins (1994), Dementiev *et al.* (1954, 1970), Ekholm (1989), Ericson *et al.* (2005), Goodwin (1986), Hagemeijer & Blair (1997), Helle & Järvinen (1986), Hudec (1993), Järvinen *et al.* (1977), Lindgren (1975), Madge & Burn (1994), Nechaev (1991), Rogacheva (1988, 1992), Stepanyan (2003), Tucker & Heath (1994), Vaurie (1959, 1964).

44. Grey Jay

Perisoreus canadensis



French: Mésangeai du Canada **German**: Meisenhäher **Spanish**: Arrendajo Canadiense
Other common names: Canada Jay

Taxonomy. *Corvus canadensis* Linnaeus, 1766, Quebec, Canada.

Recent DNA-sequencing indicates that this genus and *Cyanopica* form unique clades, separate from other corvids; significance of this requires further research, but it suggests that *Perisoreus* is not very closely related to *Garrulus*. Probably forms a superspecies with *P. internigrans* and *P. infaustus*. Size tends to increase clinally from S to north (and perhaps from coast towards interior). Additional proposed races are *arcus* (described from Coast District, in British Columbia) and *nigricapillus* (from Labrador), both subsumed in nominate, and *griseus* (L Keechelus, in Washington), considered a synonym of *obscurus*. Six subspecies recognized.

Subspecies and Distribution.

P. c. pacificus (J. F. Gmelin, 1788) – Alaska and NW Canada (Yukon and NW British Columbia).
P. c. canadensis (Linnaeus, 1766) – N Canada from MacKenzie River Delta E to Labrador, Newfoundland and Nova Scotia, S to N Alberta, C Saskatchewan and S Manitoba, S in N USA to NE Minnesota E to N New England.
P. c. albescens J. L. Peters, 1920 – E Rocky Mts (from SE Yukon, S Northwest Territories, NE British Columbia and NW & C Alberta) E to C Saskatchewan and WC Manitoba, S in USA to E Montana, NE Wyoming, Black Hills of South Dakota and NW Minnesota.
P. c. obscurus Ridgway, 1874 – SW British Columbia (including Vancouver I) and W USA in W Washington (Olympic Peninsula and Cascade Mts), Oregon (Cascade and Coast Ranges) and extreme N California.
P. c. bicolor A. H. Miller, 1933 – NC Rocky Mts from SE British Columbia S in USA to E Washington, E Oregon and Idaho.
P. c. capitalis S. F. Baird, 1874 – S Rocky Mts in E Idaho, W Wyoming, C Utah, W Colorado, EC Arizona and NC New Mexico.

Descriptive notes. 27–31 cm; 50–85 g. A small, crestless, long-tailed jay with grey, white and black plumage. Nominate race has forehead, forecrown, face, neck and upper breast bright white to light greyish-white, distinct black to dark brown central crown back to nape (extending down to level of eye); upperparts, including upperwing and tail slate-grey; underparts below breast light grey, slightly darker on side of breast and flanks, whitish on undertail-coverts; in worn plumage generally browner; iris dark brown; bill and legs black. Sexes similar, male c. 10% larger than female. Juvenile is darker than adult, uniformly blu-ish-slate above and slightly lighter below, head dull blackish-slate, lower abdomen whiter than rest of underparts, wings and tail dark slate-grey with whitish tips; after body moult in late summer–early autumn similar to adult, except for narrow and poorly defined whitish areas at tips of secondary coverts and finely tapered (rather than truncate) rectrices. Races vary mainly in depth and tone of coloration and in head pattern, also in size: *pacificus* is relatively large-bodied, has less white in crown than nominate, and dorsal plumage brownish-grey; *albescens* is relatively pale; *obscurus* is small-bodied and distinctively white-bellied; *bicolor* has reduced dark crown patch, and dorsal plumage grey and black (intermediate between nominate and *capitalis*); *capitalis* is small, with pale grey back, and distinctive white head owing to reduced and less dark crown patch. Voice. A very quiet-voiced corvid, often seen before it is heard. Accomplished mimic (often of various raptors), with described repertoire of ten vocalizations; in need of further study. Members of social group stay in contact with frequently repeated single "whuit" notes; two-part clear whistle, "whee ooo", may be used by male to invite mate to follow; social conflict indicated by rapid series of low-pitched semi-musical "chook, chook, chook"; territory defence and aggression signalled with "chick-wurr" (emphasis on second syllable). Pair-members may "twitter" softly while together and compose soft, melodious "whisper-song". Predators mobbed with loud, harsh, grating, rapid series of "cha-cha-cha-cha"; discovery of a stationary predator may elicit a series of soft musical whistles, "hoo, hoo, hoo". Young and adults (both sexes) beg from providers in typical corvid fashion. Constrained or captured adults may give hoarse, grating "screams".

Habitat. Coniferous and mixed conifer–deciduous (especially *Populus* and *Acer*) forests of N latitudes and high mountain elevations (2440–3050 m in S Rocky Mts). Spruce (*Picea mariana*, *P. glauca*, *P. engelmannii*, *P. sitchensis*) a common denominator of most forests where this jay occurs. Most common in large, ancient, contiguous forests of *Pseudotsuga menziesii* and *Picea sitchensis* on Olympic Peninsula (which contrasts with greater occurrence of *Cyanocitta stelleri* in fragmented, variable-aged forests and brush clearcuts). Absent from coniferous forests lacking spruce in Sierra Nevada and SW Oregon.

Food and Feeding. Omnivorous. Diet includes beetles (Coleoptera), Lepidoptera, Hymenoptera, flies (Diptera), bugs (Hemiptera), Orthoptera; also spiders (Araneae), centipedes (Chilopoda); also berries, regularly of *Vaccinium*; fungi (including poisonous *Amanita*). Occasionally preys on small vertebrates, e.g. small passerine birds, frogs, snakes, mice, shrews, voles, and bird-nest contents; rarely, pursues and catches small adult songbirds in flight. Known to glean blood-engorged ticks

(Ixodoidea) from large ungulates. Regularly takes and carrion (from great variety of aquatic and terrestrial animals). Boldly takes food from humans; regular visitor to birdtables and unattended pet food, and common denizen of picnic areas and campgrounds in appropriate habitat. Forages in small groups (typically of 2–4 individuals) from tree canopy to ground; systematically searches foliage. Moves between trees with short flights and glides to vantage points. Sophisticated forager that appears to process considerable information to select food items. In field experiments, decisions on food selection apparently based on context, including relative reward rate (less selective when rewards frequent), relative size of and difficulty of obtaining reward, and presence of novel, unattractive rewards. Prodigious cacher of excess food; in Alaska, may make more than 1000 caches in a single summer day and total of order of 100,000 during summer and autumn; hoards opportunistically at all times of year. Enlarged salivary glands utilized for coating and impregnating food items, which then cached in trees behind bark, in branches, in foliage, or under moss and lichens; caches often covered with bark, lichen, moss or foliage. Uses short-term memory of cache locations to recover stores; caches may be optimally spaced, trading off need to minimize travel distance against need to minimize excessive risk of theft by competitors.

Breeding. Nesting begins in late winter, when snow is substantial, laying late Feb to mid-Apr. Permanent monogamous pair-bond. In Algonquin Provincial Park (C Ontario, in Canada), 20% of pairs accompanied by third individuals (75% of which were offspring, usually male, of pair); third bird aggressively excluded from nest by breeding male, but sometimes allowed to feed fledglings, and mobs potential predators, defends territory against intruders, and gives alarm calls. Defends all-purpose territory of average size 40–146 ha. Male selects nest-site; nest a bulky outer platform (14–16 × 10–15 cm) of twigs well insulated with cocoons placed in exterior interstices, with thick inner cup (7·8 × 5·6 cm) of shredded bark, lichens, hair and feathers, placed 1·7–15 m above ground close to trunk of coniferous tree (especially spruce or fir). Clutch 1–5 eggs, usually 3–4; incubation by female alone (may occur at temperatures as low as –30°C), period 18·5 days; chicks brooded by female, fed by both sexes; male feeds female, usually off the nest, often with previously stored food; nestling period 22–24 days; young fed by parents, and sometimes by helper (when present), for c. 1 month after fledging; family breaks up when young 55–65 days old, as dominant juveniles force subordinates to disperse, and by late summer/early autumn fewer than 50% of pairs have juveniles (usually one, sometimes two); retained juveniles frequently (30% of pairs in Algonquin Provincial Park) unrelated subordinates forced to disperse from natal territory that are accepted by pairs without juveniles. Nest predators include pine squirrels (*Tamiasciurus*). Maximum recorded lifespan 16 years.

Movements. Resident; most pairs spend entire breeding life on a single territory. Some annual movements in S part of range (including Olympic Peninsula) from high to low elevations, and to reliable food sources (human-provided) during winter. Occasional irruptive movements in areas S of normal range. Widowed breeders may disperse c. 10 km to fill breeding vacancies; subordinates expelled from natal territory known to disperse up to 11 km.

Status and Conservation. Not globally threatened. Locally common. Populations generally stable; range contracting in some S areas (Alberta, Michigan, Quebec) and potentially at substantial risk from warming climate. Population in Algonquin Provincial Park, at S edge of range (Ontario), has undergone rapid decline since 1980. Timing and success of breeding attempts appears to be compromised by warm autumns, suggesting that climate warming may have caused rotting of food hoards; possible poleward shift of species' range via contraction along S edge. Exotic disease (e.g. West Nile Virus) could become additional concern. Most core areas of range are at latitudes or elevations where human exploitation of resources currently minimal; this species' use of unfragmented, structurally complex forests does, however, make it vulnerable to logging and road-building should human activities intensify within the jay's range. Potential role of this species as nest predator of other sensitive birds, e.g. Marbled Murrelet (*Brachyramphus marmoratus*) in NW USA and SW British Columbia, especially where jays locally congregate to exploit human subsidies, is a recent concern.

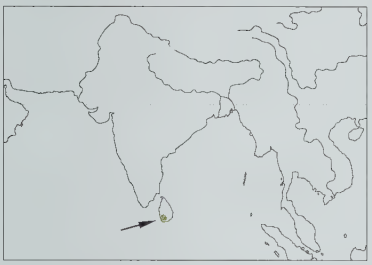
PLATE 33 ➤

PLATE 33

inches 5

cm 13



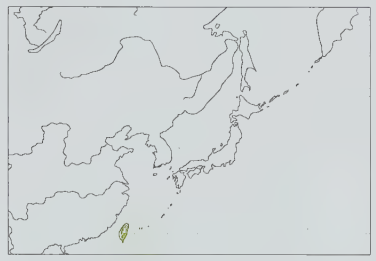
Genus *UROCISSA* Cabanis, 1851

45. Sri Lanka Blue Magpie

Urocissa ornata

French: Pirolle de Ceylan **German**: Schmuckkitta **Spanish**: Urraca Cingalesa
Other common names: Ceylon Blue Magpie, Ceylon/Sri Lanka Magpie

Taxonomy. *Pica ornata* Wagler, 1829, "India orientali" = Sri Lanka.
Genus has sometimes been subsumed in *Cissa*, but three members of latter seem to form a distinctive group; present species perhaps links the two genera. Monotypic.
Distribution. SW Sri Lanka.



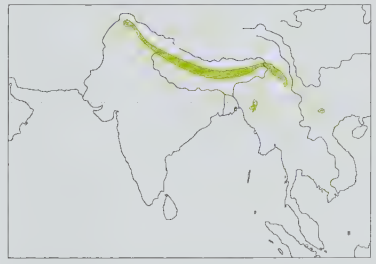
Descriptive notes. 40–47 cm; one bird 196 g. Unmistakable, gaudy forest magpie with rather prominent bill, nostrils concealed by soft plumes (not bristles), wide area of bare skin about eye, slightly crested rear crown, long and strongly graduated tail with projecting central feather pair. Whole head down to nape, throat and upper breast reddish-chestnut; remainder of body plumage purplish-blue, becoming sky-blue on rump and uppertail-coverts and on belly and undertail-coverts; upperwing-coverts dark purple-blue, except for lighter purple-blue lesser coverts; primaries and secondaries chestnut-red, a shade redder and less brown than colour of head, inner webs of secondaries dark blue, tips showing as stripe down tertials merging into blackish primary tips formed by blackish inner webs of primaries; tail greenish-blue, feathers with broad white tips and black subterminal bars, white tips becoming progressively more extensive towards shorter outermost feathers; iris brown, orbital ring red, bare skin around eye deeper red; bill and legs coral-red. Sexes similar. Juvenile is duller than adult, body plumage washed greyish, all bare parts drabber and browner. VOICE. Noisy. Presence often first indicated by contact call, a loud, repeated, metallic "chink-chink-chink...", variable in emphasis and in number of repetitions; also utters loud, raucous "crakarakarakarak...". Variety of quieter calls given, including high-pitched squeaky "creeik" and rising "whee-whee"; parakeet-like "whittee" and a rapid "chit-chee-chit" could be variations of the above. Variety of short metallic chirps and squeaks may be heard from foraging party. In captivity subdued "song" noted, this consisting of a series of chattering, squeaking and chirping sounds incorporating some mimicry, including crowing of Ceylon Junglefowl (*Gallus lafayetii*). Most vocal early and late in day, especially so in wet weather; can be quiet for long periods.
Habitat. Tropical broadleaf evergreen forest, including edges of tea plantations. Occurs from as low as 50 m up to 2100 m, in lowlands and hills of wet zone.
Food and Feeding. Chiefly carnivorous; prey items include wide variety of invertebrates, especially crickets (Orthoptera), beetles (Coleoptera), caterpillars, especially large hawkmoth (Sphingidae) caterpillars; also tree-frogs and small lizards. Takes some fruits and berries, e.g. fruits of *Freycinetia*. Rubs hairy caterpillars against branches to remove hairs. Usually met with singly or in small parties of six or seven individuals, presumably family-based groups. Generally rather shy and difficult to observe; parties feed inside forest canopy and seem reluctant to cross open stretches of countryside. Forages at all levels, including forest floor, working up through the foliage, sometimes swinging upside-down at end of a branch like some giant gaudy tit (Paridae) or clinging to a tree trunk upside-down as it prises into bark crevices for invertebrates. Outside breeding season readily associates with mixed-species flocks of small birds, which generally include Sri Lanka Crested Drongos (*Dicrurus lophorinus*) and Ashy-headed Laughingthrushes (*Garrulax cinereifrons*).
Breeding. Season mid-Jan to late Mar. Solitary breeder. Nest of sticks and twigs, lined with fine roots and beard-like lichens (resembles that of *Corvus*, but smaller), generally placed 5–13 m from ground near top but inside canopy of tall sapling, or towards outermost part of branch of small tree. Clutch 3–5 eggs, usually 3; no information on incubation and fledging periods. Nest parasitized by Common Koel (*Eudynamys scolopacea*).
Movements. Sedentary.
Status and Conservation. VULNERABLE. Restricted-range species: present in Sri Lanka EBA. Locally fairly common. Although quite common in some places, parties have very large foraging areas, and therefore liable to give false impression of abundance. Fragmentation of rainforest habitat through forest fires and felling is biggest threat to this and many other Sri Lankan endemics; also, the breaking-up of formerly extensive forest has permitted increase in forest edge, which in turn has allowed increase in numbers of Common Koel, a nest parasite of this and other corvids. Healthy population present in Sinharaja Forest Reserve, where it can often be observed well near the reserve headquarters.
Bibliography. Ali & Ripley (1972, 1987b), Anon. (2008p), Butchart & Stattersfield (2004), Collar & Andrew (1988), Dickinson *et al.* (2004), Goodwin (1986), Grimmett *et al.* (1998), Harrison (1999), Henry (1971), Madge & Burn (1994), Phillips (1975), Rasmussen & Anderton (2005a, 2005b), Stattersfield & Capper (2000), Vaurie (1958a).

46. Taiwan Blue Magpie

Urocissa caerulea

French: Pirolle de Taiwan **German**: Dickschnabelkitta **Spanish**: Urraca de Formosa
Other common names: Formosan (Blue) Magpie, Taiwan Magpie

Taxonomy. *Urocissa caerulea* Gould, 1863, Taiwan.
Genus has sometimes been subsumed in *Cissa*, but three members of latter seem to form a distinctive group. Present species forms a superspecies with *U. flavirostris* and *U. erythroryncha*. Monotypic.
Distribution. Taiwan.
Descriptive notes. 63–68 cm; 254–260 g. Distinctive black-hooded, pale-eyed blue magpie with very long, strongly graduated tail, central pair of rectrices projecting beyond next by up to c. 40%;



rather stout bill with curved culmen, nostrils concealed by soft plumes (rather than bristles), crown feathers slightly ruffled. Entire head down to upper breast and nape black with dark blue feather tips; remainder of body plumage deep azure-blue, narrow whitish fringes on undertail-coverts; uppertail-coverts black with narrow whitish scale-like fringes; upperwing dark azure-blue, narrow white fringes on tertials, minute white marks at primary tips; tail azure-blue, feathers with broad white tips and wide black subterminal bands (ladder-like impression when viewed from below); iris lemon-yellow to yellowish-white, narrow dull scarlet to blackish orbital ring; bill and legs scarlet. Sexes similar. Juvenile is duller than adult, body plumage more greyish-blue, with greyish-black hood, brown iris and drab pinkish bill and legs, but wings and tail similar to those of adult. VOICE. Usual call a loud chattering "kyak-kyak-kyak-...", not unlike call of *Pica pica* but slower and higher in pitch. Also a harsh, ringing "go-kang, go-kang" and several softer calls, notably a "kwee-eep" or "garsee-eep".
Habitat. Broadleaf forest at 400–1000 m, but reported down to 300 m and as high as 1200 m.
Food and Feeding. Omnivorous; as well as wide variety of invertebrates, takes various berries and figs (*Ficus*). Usually encountered in small parties of six or seven individuals, presumably family groups, but larger gatherings after young have fledged. Rather shy and wary, keeping very much inside forest canopy (making prolonged observation difficult). Although reluctant to cross open stretches of countryside, will do so in "follow-my-leader" manner typical of genus (several short flaps and a glide). Forages at all levels, including forest floor; on ground makes bounding hops with tail raised, the very end curving as if tip drooped.
Breeding. Season May and Jun; eggs recorded mid-May to late May. Social and co-operative breeder; helpers assumed to be young of previous year, which assist in feeding fledglings. Nest a quite large platform-like construction of sticks and twigs, built on horizontal bough at junction of several smaller branches. Clutch 5 or 6 eggs. No other information.
Movements. Mainly sedentary; some movement to lower elevations in winter.
Status and Conservation. Not globally threatened. Restricted-range species: present in Taiwan EBA. Status not well known; generally considered uncommon and elusive. Prefers to keep to shadowy gloom of dense forest (where it can appear to be wholly dark, but white-spotted tail conspicuous when it flies). Absent from lowland areas and C belt of mountains, but does occur in several protected areas, notably the Yangmingshan National Park and the Huisun National Forest Recreation Area. Fragmentation of forest habitat through felling is biggest threat to this and several other Taiwan endemics.
Bibliography. Brazil (1991, 1992), Chawner (1937), Chen Fuguan *et al.* (1998), Fang Woeihorng & Sykes (2004), Goodwin (1986), Lee Peifen *et al.* (1998), MacKinnon & Phillipps (2000), Madge & Burn (1994), Severinghaus (1986, 1987).

47. Yellow-billed Blue Magpie

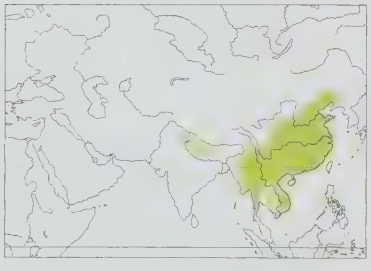
Urocissa flavirostris

French: Pirolle à bec jaune **German**: Gelbschnabelkitta **Spanish**: Urraca Piquigualda
Other common names: Gold(en)-billed/Black-headed Magpie, Golden-billed Blue Magpie

Taxonomy. *Psilorhinus flavirostris* Blyth, 1846, Darjeeling, India.
Genus has sometimes been subsumed in *Cissa*, but three members of latter seem to form a distinctive group. Present species forms a superspecies with *U. caerulea* and *U. erythroryncha*. Race *cucullata* intergrades with nominate in C Nepal. Four subspecies recognized.
Subspecies and Distribution.
U. f. cucullata Gould, 1861 – N Pakistan (from Hazara) E through NW India to Nepal.
U. f. flavirostris (Blyth, 1846) – Nepal E to NE India and N Myanmar, also in adjacent S China (extreme SE Xizang).
U. f. schaeferi Sick, 1939 – W Myanmar (Chin Hills).
U. f. robini Delacour & Jabouille, 1930 – extreme N Vietnam (NW Tonkin).

Descriptive notes. 55–61 cm; 123–180 g. Distinctive black-hooded, pale-billed blue-and-white magpie with very long, strongly graduated tail, central pair of rectrices projecting beyond next by up to c. 40%, drooping towards tip; rather stout bill with curved culmen, nostrils concealed by soft plumes (rather than bristles). Nominate race has head down to upper breast and upper mantle velvety black, clear whitish patch on upper nape; upperparts dull grey-blue, washed with olive when plumage fresh, uppertail-coverts with narrow whitish subterminal bars and black tips; upperwing dull blue, tips of primaries and secondaries narrowly whitish (this pattern clearest on tertials); tail grey-blue, feathers with broad white tips and black subterminal bars (latter weakest on longest central pair); underparts below upper breast whitish, washed lightly with grey and pale yellow (latter only in very fresh plumage); iris dark brown; bill and legs yellow, light orange or rich orange. Differs from superficially similar *U. erythroryncha* in having yellow bill and orange legs (both often confusingly bright orange), white on head confined to nape patch (not extending onto crown or reaching mantle). Sexes similar. Juvenile is duller than adult, with dusky bill and legs, nape patch whitish and more extensive. Races differ mainly in strength of olive and yellow tones in fresh plumage, as well as size: *cucullata* is smaller than nominate, blue above, purer white below, juvenile has white on nape more extensive, from mid-crown to lower nape and, on some, even over malar region; *schaeferi* also is on average smaller, but is close to nominate; *robini* has brighter yellow wash below and brighter olive above than others. VOICE. Quite a loud and varied vocabulary, but difficult to interpret differences from *U. erythroryncha*. Calls include wheezy "buzeep-peck-peck-peck", high-pitched "clear-clear"; other calls can be harsh, grating, piercing, whistled

On following pages: 48. Red-billed Blue Magpie (*Urocissa erythroryncha*); 49. White-winged Magpie (*Urocissa whiteheadi*); 50. Common Green Magpie (*Cissa chinensis*); 51. Indochinese Green Magpie (*Cissa hypoleuca*); 52. Short-tailed Green Magpie (*Cissa thalassina*); 53. Iberian Azure-winged Magpie (*Cyanopica cooki*); 54. Asian Azure-winged Magpie (*Cyanopica cyanus*).



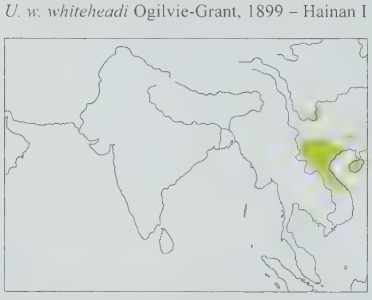
or squealing. Some recordings are of loud, strident raptor-like sounds, rising and falling in pitch. Other sounds clearly based on mimicry. Presumed alarm a gravelly, staccato "rak-rak-rak-rak"; also a series of faster notes, delivered at machine-gun speed.
Habitat. Moist deciduous and mixed temperate forests with oaks (*Quercus*), chestnuts (*Castanea*), conifers and rhododendrons (*Rhododendron*). Favours forest edge, such as clearings with settlements, with or without terraced agriculture; also borders of tea plantations and the like. Breeds above 2000 m, ascending to about 3600 m; occurs down to 1000 m farther E in range. More of a true forest bird than is *U. erythroryncha*; generally replaces latter above 1800 m in Himalayas.
Food and Feeding. Omnivorous, but mainly carnivorous. Takes all manner of invertebrates, small vertebrates and various fruits and berries; scavenges other bird's nests, taking both eggs and nestlings. Diet and general behaviour very much as *U. erythroryncha*. Usually in pairs or in parties of up to twelve individuals, presumably family-based groups. Generally rather shy, but can become relatively bold where food put down as offerings at temples by forest roadsides and passes. Forages at all levels, including forest floor, where it jumps about with tail raised, the very tip drooping. Group-members fly low across clearings, bounding along branches of trees and taking off one by one, finally swooping up under canopy of a tree. On occasion, one or two individuals have been found among parties of *U. erythroryncha*.
Breeding. Season late Apr to early Jul, with eggs reported mid-May and Jun. Most likely a solitary breeder with long-term pair-bond; could be a social breeder (as proven for closely related *U. caerulea*), as it is found in small parties throughout year. Nest built by both sexes, possibly with aid of a helper, made of sticks and twigs, cup lined with fine roots and plant fibres (resembles nest of *Corvus*, but smaller), positioned c. 5–6 m above ground in fork of long branch inside lower canopy, often in leafy sapling at edge of a clearing. Clutch 3–5 eggs, usually 4; incubation probably by female alone, fed at nest by male; chicks fed by both sexes, most of feeding by female; no information on incubation and fledging periods.
Movements. Mostly sedentary. Those inhabiting higher montane forests move to lower elevations in winter if weather conditions deteriorate; rarely descends as low as 1850 m in Nepal, while in Pakistan recorded down to 900 m.
Status and Conservation. Not globally threatened. Widespread and locally common over most of range, although at extreme W limits in Pakistan not well known. Races *robini* of NW Vietnam and *schaeferi* of W Myanmar (Chin Hills) poorly known, with restricted ranges; latter, at least, is known to be present at several forest sites. This species is clearly under no obvious threats, using secondary growth and thriving about mountain temples and villages.
Bibliography. Ali (1949, 1977), Ali & Ripley (1972, 1987b), Bates & Lowther (1952), Chen Fuguan *et al.* (1998), Dickinson *et al.* (2004), Fleming & Traylor (1964), Goodwin (1986), Grimmett *et al.* (1998), Inskipp & Inskipp (1991), Madge & Burn (1994), Rasmussen & Anderton (2005a, 2005b), Roberts (1992), Robson (2000), Robson *et al.* (1998), Stuart Baker (1928), Vaurie (1958a).

48. **Red-billed Blue Magpie**

Urocissa erythroryncha

French: Pirolle à bec rouge **German**: Rotschnabelkitta **Spanish**: Urraca Piquirroja
Other common names: Blue/Red-billed Magpie

Taxonomy. *Corvus erythrorynchus* Boddaert, 1783, Canton (Guangzhou) south China.
Genus has sometimes been subsumed in *Cissa*, but three members of latter seem to form a distinctive group. Present species forms a superspecies with *U. caerulea* and *U. flavirostris*. Race *alticola* initially described under name "*caerulea*", but this name is invalid, as preoccupied. Species name often misspelt "*erythrorhyncha*". Five subspecies recognized.
Subspecies and Distribution.
U. e. occipitalis (Blyth, 1846) – NW India (from Jammu and vicinity of Kangra, in Himachal Pradesh) E to extreme E Nepal.
U. e. magnirostris (Blyth, 1846) – NE India (S of R Brahmaputra) E across Myanmar and Thailand to NW Cambodia, Laos and Vietnam.
U. e. alticola Birckhead, 1938 – S China (NW & N Yunnan) and adjacent N Myanmar.
U. e. brevivexilla Swinhoe, 1874 – E China (from SE Inner Mongolia and W Liaoning S to S Gansu, S Ningxia, Shanxi and Hebei).
U. e. erythroryncha (Boddaert, 1783) – C, S & SE China (including Hainan).



Descriptive notes. 53–64 cm; male 145–192 g, female 106–155 g. Highly distinctive blue magpie with exceptionally long, strongly graduated, sweeping white-spotted tail, central feather pair projecting beyond next by up to c. 40–50% and drooping towards tip; bill rather prominent, nostrils concealed by soft plumes (not bristles). Nominate race has head down to upper breast and upper mantle velvety black, feathers of rear crown and nape with extensive white tips (showing either as spangling or as whitish area, depending on extent of feather wear), feathers of forecrown also with tiny whitish tips; upperparts dull medium-blue with weak mauve wash, uppertail-coverts with narrow whitish subterminal bars and black tips; upperwing brighter blue with stronger mauve tones, tips of primaries and secondaries narrowly whitish with narrow dark subterminal lines (this pattern clearest on tertials); tail mauve-blue, feathers with broad white tips and black subterminal bars (latter weakest on longest central pair), white tips progressively more extensive towards shorter outermost feathers; underparts below upper breast whitish, washed lightly with grey (and can be tinged salmon-pink in very fresh plumage), undertail-coverts whiter; iris dark brown; bill and legs reddish-pink to coral-red. Differs from similar *U. flavirostris* in having bluer and whiter general appearance, extensive white speckles and spangling over most of crown and nape (and reaching mantle), and red bill. Sexes similar. Juvenile is duller than adult, with throat, face and breast centre whitish, leaving black as mask across face and side of neck, bill and legs drab greyish, becoming dull yellowish-flesh. Races differ mainly in overall brightness of adult plumage, to certain extent also size: *occipitalis* has relatively bright bluish upperparts, bold white fringes on tertials, juvenile has blackish throat and chest; *brevivexilla* is palest and greyest, with very extensive pale lavender (rather than white) patch on rear crown and nape; *alticola* has bluer upperparts than nominate; *magnirostris* is brightest race, with strongest mauve tones in quite blue upperparts, bill relatively larger than in others. Voice. Noisy. Presence often first indicated by contact call, a loud, ringing, almost metallic "penk-penk-penk...". Other calls include piercing "quiv-pig-pig", softer "beeee-trk" and subdued "kluk". Also a harsh staccato "cha-chak, cha-chak", which can be repeated into a chatter; also a prolonged high-pitched scream, and various whistles and rattling sounds. Versatile mimic, with calls of black giant squirrel (*Ratufa bicolor*), Crested Serpent-eagle (*Spilornis cheela*), hawk-eagles (*Spizaetus*), Shikra (*Accipiter badius*) and Jacobin Cuckoo (*Clamator jacobinus*) reported as imitated.
Habitat. Tropical and subtropical broadleaf evergreen forest in Himalayan foothills; elsewhere in hill forests, including parks, botanical gardens and large gardens. Recorded in mangroves in Hong Kong. Sea-level to 2200 m in summer, chiefly below 1500 m. Replaced at higher elevations by *U. flavirostris* where ranges overlap, mainly in Himalayas.
Food and Feeding. Omnivorous, but mainly carnivorus. Recorded prey items include wide variety of larger invertebrates, especially beetles (Coleoptera), caterpillars, also land-leeches (Hirudinea), tree-frogs, small lizards, birds' eggs and nestlings, and even small mammals; also carrion and kitchen scraps. Variety of fruits and berries also taken. Usually encountered in small parties of six or seven, sometimes up to twelve, individuals, presumably family-based groups. Generally rather shy, but in some areas scavenges about villages and forest settlements, where may become less wary. Parties fly low across clearings in follow-my-leader style, swooping up under canopy of a desired tree. Forages at all levels, including forest floor, where it jumps about with tail raised, the very tip drooping. Occasional records of one or two *U. flavirostris* mixed with foraging parties of present species.
Breeding. Eggs reported Apr–Jun in India, Mar–Jun in Myanmar, Apr in S China and Jun in N China. Generally considered solitary breeder, but encountered throughout year in small parties and probably, therefore, social breeder (as proven for closely related *U. caerulea*). Nest built by both sexes, of sticks and twigs, cup lined with fine rootlets and plant fibres, generally 3–6 m above ground inside upper canopy of sapling or near end of long bough of larger tree. Clutch 3–6 eggs, usually 3; male feeds incubating female at nest and helps to feed nestlings; no information on incubation and fledging periods.
Movements. Mainly sedentary, but moves higher into montane forests in summer. One reported in Jun 1979 at exceptionally high elevation of 3050 m in W Nepal.
Status and Conservation. Not globally threatened. Widespread and locally common over most of extensive range. In extreme NE of range in China, said to be distinctly uncommon in Liaoning and Jilin; on the other hand, considered increasingly numerous in recent years in vicinity of Beidaihe (Hebei). Small feral population, originating as escaped cagebirds, became established for a while on Oahu, in Hawaiian Is, but seems now to have been exterminated.

49. **White-winged Magpie**

Urocissa whiteheadi

French: Pirolle de Whitehead **German**: Graubauchkitta **Spanish**: Urraca de Whitehead
Other common names: White-winged Blue/Whitehead's Magpie

Taxonomy. *Urocissa whiteheadi* Ogilvie-Grant, 1899, Five-finger Mountains, interior of Hainan, China.
Genus has sometimes been subsumed in *Cissa*, but three members of latter seem to form a distinctive group. This species sometimes allocated its own monotypic genus, *Cissopica*, but seems to possess sufficient features to allow its retention in present genus. Races well differentiated, possibly worthy of separate species status; further research required. Two subspecies recognized.
Subspecies and Distribution.
U. w. xanthomelana (Delacour, 1927) – S China (S Sichuan and SW Guangxi), N Vietnam (W & E Tonkin and N & C Annam) and N & C Laos.
U. w. whiteheadi Ogilvie-Grant, 1899 – Hainan I (SE China).

Descriptive notes. 43–46 cm; c. 200 g. A bulky-bodied forest magpie with relatively long and strongly graduated tail, central pair of feathers only a little longer than next; bill quite heavy and long, nasal tuft soft, small patch of bare skin behind eye. Nominate race has head, neck and breast sooty brown, crown feathers with narrow brownish fringes; upperparts blackish, rump yellowish, uppertail-coverts greyish with white feather bases and yellow tips; upperwing boldly patterned white to faintly yellowish-white on blackish background, lesser and median coverts white (forming band along leading edge of wing), greater coverts white with black bases (central wingband), inner secondaries with pale fringes, becoming wider towards outer wing, largest on tertials, which are whitish with black basal portion (these form whitish patch at base of hindwing and pale trailing edge on secondaries); tail largely black, central feathers grey with narrow black subterminal band, some yellowish-grey at base, all feathers with wide pale yellow-white or white tips, narrowest on central pair and most extensive on outermost (shortest) pair; underparts below breast greyish, shading into pale yellowish on belly and undertail-coverts; underwing and axillaries pale yellow; iris pale yellow, bare eye patch brownish-green; bill dull orange, greenish base; legs black. Sexes similar. Juvenile and first-year have head, neck and upperparts drab yellowish-grey, bill and iris drab brownish; older immature acquires reddish bill and pale iris before mantle blackens. Race *xanthomelana* is somewhat larger than nominate, has head, neck and breast black, throat and breast with yellowish bloom, more yellow in white wing and tail markings, central rectrices mostly black (not grey). Voice. Most frequently uttered call a repeated, hoarse, rising "shurreek". Similar, but lower in pitch, is a hoarse, almost purring "churrree", a repeated soft, liquid, rippled "brrriii...brrriii..." and a similar but harsher, rising "errreeep... errreeep...".
Habitat. Tropical broadleaf evergreen forests, including edges of cultivation and secondary growth; found particularly along watercourses in forest. Lowlands and foothills, from 50 m up to 1400 m.
Food and Feeding. Not well documented. Apparently omnivorous; said to feed on various invertebrates and berries, but no specific information available. Very sociable; large groups of 20–25 individuals (in various plumage stages) move through forest together. These foraging parties are quite active, flitting from tree to tree and into bamboo thickets in gulleys by streams.
Breeding. Little known. Perhaps a social breeder; seems to be encountered in quite large parties throughout year. Only described nest, on Hainan (nominate race), was a concave platform of closely interwoven stems of creepers and roots; nest under construction reported from Vietnam in Jul. Clutch 6 eggs. No other information.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Nominate race rare; race *xanthomelana* widespread on mainland, where locally not uncommon. Fragmentation of rainforest habitat through forest fires and felling is biggest threat. Particularly vulnerable is population of nominate race, confined to Hainan; huge-scale forest destruction on Hainan during Chinese Cultural Revolution,

but remnant patches of forest still remain, particularly on S side of the island, where species continues to be reported in very small numbers. Mainland form *xanthomelana* is much more widespread, but remains poorly known in China; known to occur in two protected areas in S Guangxi (Nonggang and Shiwandashan National Nature Reserves). In Vietnam not uncommon in forests S to C Annam, where described as common in Cat Bin area, and regarded as locally common in adjacent C Laos.

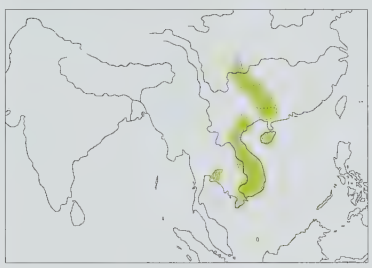
Genus *CISSA* Boie, 1826

50. Common Green Magpie

Cissa chinensis

French: Pirolle verte **German**: Jagdelster **Spanish**: Urraca Verde
Other common names: (Chinese) Green Magpie, Hunting Greenpie/Cissa, Green Hunting Crow

Taxonomy. *Coracias chinensis* Boddaert, 1783, Mergui, Tenasserim, Myanmar.
Although often expanded to encompass *Urocissa*, present genus is distinctive in appearance of its members (the green magpies). This species forms a superspecies with *C. hypoleuca* and *C. thalassina*. Race *robinsoni* poorly differentiated from *minor*, and perhaps better merged with it. Five subspecies tentatively recognized.
Subspecies and Distribution.
C. c. chinensis (Boddaert, 1783) – Himalayas from Uttarakhand (Garhwal) E to NE India (Arunachal Pradesh, S Assam hills), EC Bangladesh, N Myanmar, extreme S China (S Yunnan and SW Guangxi), N Laos and Vietnam (N Annam), and possibly also S Laos.
C. c. klossi Delacour & Jabouille, 1924 – C Annam (Vietnam) and C Laos.
C. c. margaritae Robinson & Kloss, 1919 – Mt Lang Bian (C/S Annam) in Vietnam.
C. c. robinsoni Ogilvie-Grant, 1906 – extreme SW Thailand and Peninsular Malaysia.
C. c. minor Cabanis, 1851 – Sumatra and Borneo.



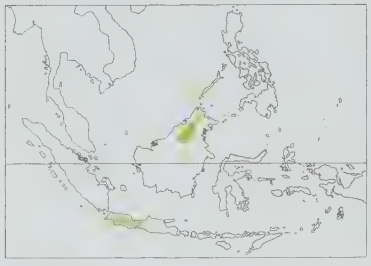
Descriptive notes. 37–39 cm; 120–133 g. Distinctive and striking green magpie with graduated long tail, slightly shaggy rear crown, rather prominent bill, nostrils concealed by soft plumes (not bristles); green, yellow and red colours of plumage bleach to, respectively, dull light blue, whitish and brown if exposed to prolonged bright sunlight. Nominate race has prominent black band from base of bill across side of head, enclosing eye and crossing under slight crest on nape; rest of head, entire body plumage, scapulars, lesser upperwing-coverts and upperside of tail grass-green to pea-green; remainder of wing reddish-chestnut, tertials prominently tipped black and white, forming "ladder" on closed wing; all tail feathers except pale-tipped central pair have black subterminal chevron and whitish tip, underside of tail appears pale with blackish band across base; with wear, plumage bleaches to light blue, with pale brown wings; iris dark brown, crimson orbital ring (in excitement can be inflated into small horn-like wattle); bill crimson to orange-red, often whitish at very tip; legs bright red to orange-red. Differs from similar *C. hypoleuca* in having relatively longer tail, bold black and white (not pale green) tertial tips, no yellow wash on underparts. Sexes similar. Juvenile is duller overall, becoming almost whitish on undertail-coverts, has bill and legs yellowish-horn, iris dull grey-brown, tail feathers relatively shorter and more pointed at tips than on adult, and tertial pattern duller with weaker dark marks. Race *minor* is similar to nominate but a little smaller; *robinsoni* is very like previous, but has larger white marks at tips of tertials; *klossi* has yellow forecrown, remainder of crown yellowish-green; *margaritae* has entire crown bright golden-yellow, prominent white spots on tertials, and longer tail (the longest within genus). Voice. Noisy; presence usually first indicated by its loud, penetrating calls, which vary in intensity of delivery. Typical is a penetrating series of high-pitched notes, often finishing with harsher note, "wi-chi-chi-chi-chao", repeated with variations. Also a scolding, hysterical, chattering "chakkakakakaaka", often followed by rising terminal note. Softer chattering phrases may be given, as well as variety of shrill whistles, often accompanied by some mimicry of calls of other birds.
Habitat. Tropical and subtropical broadleaf evergreen and mixed deciduous forests, chiefly in foothills. Favours forest borders, edges of tea and cardamom plantations and secondary forest, with shrubbery, ravines and bamboo thickets, especially along watercourses. At 600–1500 m in Malay Peninsula, up to 2100 m in Sumatra, 2075 m in Vietnam and 1200 m in Nepal.
Food and Feeding. Basically carnivorous. Diet includes beetles (Coleoptera), crickets (Orthoptera), mantises (Mantidae), small frogs, snakes, lizards and birds' eggs and nestlings; seen to enter derelict building to raid nests of Glossy Swiftlets (*Collocalia esculenta*), and to return repeatedly to nest of hornet (*Vespa*) until it was devoid of grubs. Noted also as feeding on carrion, and probably takes fruits and berries, but clarification required. Usually met with singly, in pairs or in small family parties, moving through dense undergrowth, often associating with laughingthrushes (*Garrulax*) and drongos (*Dicrurus*). These noisy mixed foraging parties move from one thicket to another, sometimes pausing to mob human observer, but rarely coming into the open to do so. Avoid crossing open country or large clearings. Despite short legs, it readily forages on ground, noisily turning over leaf litter, working its way up through shrub layer, clambering between hanging creepers, sometimes ascending to upper canopy.
Breeding. Egg-laying in Apr and May in India, Apr in Myanmar and Jan and Feb in Borneo. Solitary breeder. Nest a bowl of twigs, interwoven with leaves and rootlets, the relatively deep cup lined with soft plant materials, including mosses, usually well concealed in small tree, amid shrubbery or in bamboo; when in bamboo thicket, woven around three or more bamboo stems, typically right inside heart of thicket. Clutch 3–7 eggs, mostly 4–6; no information on incubation and fledging periods.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Generally not uncommon to locally common over main part of range; distinctly scarce in W Himalayas (Uttarakhand, in N India); not well known in its limited range in extreme S China, where it just extends into SW Guangxi and S Yunnan; few data from Sumatra, where known to occur in the Barisan range. Reliance on foothill forest could make it vulnerable to habitat destruction; bearing in mind its extensive range and its favouring of secondary forest, however, the future of this attractive magpie appears to be secure.
Bibliography. Ali (1962), Ali & Ripley (1972, 1987b), Blake & Vaurie (1962), Chen Fuguan *et al.* (1998), Delacour (1929), Dickinson *et al.* (2004), Glenister (1951), Goodwin (1986), Grimmett *et al.* (1998), Lee Kwok Shing *et al.* (2006), Lekagul & Round (1991), MacKinnon & Phillipps (1993, 2000), Madge & Burn (1994), Rasmussen & Anderton (2005a, 2005b), Robson (2000), Sheldon *et al.* (2001), Smythies & Cranbrook (1981), Vaurie (1958a), Wells (2007).

51. Indochinese Green Magpie

Cissa hypoleuca

French: Pirolle à ventre jaune **German**: Goldbauchelster **Spanish**: Urraca Ventrigualda
Other common names: Yellow-breasted/Eastern (Green) Magpie

Taxonomy. *Cissa hypoleuca* Salvadori and Giglioli, 1885, Thu Dan Mot, Cochinchina, Vietnam.
Although often expanded to encompass *Urocissa*, present genus is distinctive in appearance of its members (the green magpies). This species forms a superspecies with *C. chinensis* and *C. thalassina*, and sometimes treated as conspecific with latter. Alternatively, races *concolor* and *jini* have sometimes been considered to represent a separate species, and *katsumatae* has likewise been treated as another full species. Five subspecies currently recognized.
Subspecies and Distribution.
C. h. jini Delacour, 1930 – SC China (S Sichuan S to S Guangxi).
C. h. concolor Delacour & Jabouille, 1928 – N Vietnam (E Tonkin, N Annam).
C. h. chauleti Delacour, 1926 – C Annam (Vietnam).
C. h. hypoleuca Salvadori & Giglioli, 1885 – SE Thailand, C & S Laos and S Vietnam (S Annam and Cochinchina).
C. h. katsumatae Rothschild, 1903 – Hainan I (S China).



Descriptive notes. 34–35 cm; c. 125 g. Distinctive and striking green magpie with fairly long, graduated tail, slightly shaggy rear crown, rather prominent bill, nostrils concealed by soft plumes (not bristles); green, yellow and red colours of plumage bleach to, respectively, dull light blue, whitish and brown if exposed to prolonged bright sunlight. Nominate race has prominent black band running from base of bill backwards across side of head, enclosing eye and crossing under slight crest on nape; rest of head, upperparts, scapulars, lesser upperwing-coverts and upperside of tail green, remainder of wing reddish-chestnut, tertials prominently tipped pale green, outer tail feathers with black subterminal chevron and pale grey tip; throat to undertail-coverts strongly washed with lemon-yellow, darker green visible at sides of throat and breast and merging with darker green of upperparts (thus, marked contrast between upperparts and underparts); with wear, plumage bleaches to light blue, with pale brown wings; iris dark brown, crimson orbital ring (in excitement can be inflated into small horn-like wattle); bill crimson to orange-red, often whitish at very tip; legs bright red to orange-red. Differs from similar *C. chinensis* in shorter tail, tertial pattern (plain pale green spots at tips of tertials), strong yellow wash below. Sexes similar. Juvenile is duller than adult, becoming almost whitish on undertail-coverts, has bill and legs yellowish-horn, iris dull grey-brown, tail feathers relatively shorter and more pointed at tips. Races vary mainly in intensity of yellow wash on underparts and relative tail length: *chauleti* has brightest and most extensive yellow on underparts, also head lightly washed yellow, and tail (especially tips of outer feathers) washed brownish-buff; *concolor* is darker green above, paler below, with relatively weak yellow wash, and pale buff tips of tail feathers; *jini* has rather longer tail than others, is less yellowish overall, and tail feathers are tipped light buff; *katsumatae* is similar to last, but central tail feathers washed yellowish-green and tipped blue-grey (not buff), tertials tipped bluer green. Voice. Variety of calls similar to that of *C. chinensis*, although most are uttered at different pitch. High-pitched penetrating series of notes, "po-puueeee-chuk", more plaintive, less shrill, either dropping in pitch or ending on flatter note, "eeeoooeeep groak". Also gives prolonged, piercing "peeeeooo", falling in pitch, as well as a series of abrupt "weep" notes. If surprised, gives vent to high-pitched scolding chatter of alarm.
Habitat. Tropical and subtropical broadleaf evergreen and semi-evergreen forests, with bamboo thickets; to 900 m in China (to 1300 m on Hainan) and 1600 m in Vietnam. Appears to replace *C. chinensis* at lower elevations where ranges meet.
Food and Feeding. Mainly carnivorous; diet includes various insects, frogs, snakes, lizards, and contents of birds' nests. Usually singly, in pairs or in small family parties, moving through dense undergrowth, often in mixed flocks with laughingthrushes (*Garrulax*) and drongos (*Dicrurus*). Forages on ground, turning over leaf litter, and up through shrub layer, clambering between creepers; sometimes in upper canopy.
Breeding. Eggs laid in May in N Annam. Solitary breeder. Nest built by both sexes, a bowl of twigs, interwoven with rootlets, relatively deep cup lined with dry grass and feathers, typically well concealed c. 2–3 m above ground in small tree. In captivity, clutch 4 eggs, female incubated for c. 18–20 days, chicks left nest 25 days after hatching; two young successfully reared.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Not uncommon to locally common over parts of Vietnam; in Thailand rare and very localized in extreme SE, but unrecorded from adjacent Cambodia. Isolated Chinese populations near Maupin, in S Sichuan, and in Yao Shan hills of Guangxi (*jini*) and on Hainan I (*katsumatae*) must be considered under greatest threat by virtue of their isolation from other populations; however, *katsumatae* occurs in 300 km² of old-growth forest at Yinggeling, the largest continuous tract of old-growth tropical forest in China. Main range of nominate race suggests that it is locally numerous in some areas, but on the whole this is a poorly studied species that could become endangered, despite its tolerance of secondary forest. Occupation of lowland and foothill forest could make it vulnerable to habitat destruction.
Bibliography. Blake & Vaurie (1962), Chen Fuguan *et al.* (1998), Delacour (1929), Dickinson *et al.* (2004), Fuchs *et al.* (2007), Goodwin (1986), Lee Kwok Shing, Pui Lok & Li Shining (2005), Lee Kwok Shing Lau Waineng *et al.* (2006), Lei Jinyu & Liu Yang (2006), MacKinnon & Phillipps (1993, 2000), Madge & Burn (1994), Robson (2000), Vaurie (1958a).

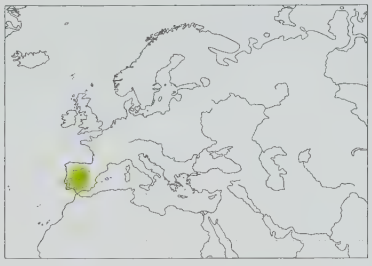
52. Short-tailed Green Magpie

Cissa thalassina

French: Pirolle à queue courte **German**: Buschelster **Spanish**: Urraca Colicorta
Other common names: Short-tailed Magpie/Cissa; Bornean Magie (*jefferyi*)

Taxonomy. *Kitta thalassina* Temminck, 1826, Java and Sumatra.
Although often expanded to encompass *Urocissa*, present genus is distinctive in appearance of its members (the green magpies). This species forms a superspecies with *C. chinensis* and *C. hypoleuca*, and sometimes treated as conspecific with latter. Race *jefferyi* well differentiated and has been considered a separate species; further study, including molecular analysis, required. Two subspecies currently recognized.
Subspecies and Distribution.
C. t. jefferyi Sharpe, 1888 – N Borneo from Mt Kinabalu S to Mt Murud, the Usan Apau plateau and Mt Dulit.
C. t. thalassina (Temminck, 1826) – W Java.

Descriptive notes. 31–33 cm; c. 125 g. Distinctive and striking green magpie with comparatively short, bluntly graduated tail, slightly elongated rear crown feathers, rather prominent bill, nostrils concealed by soft plumes (not bristles); green, yellow and reddish colours of plumage bleach to, respectively, dull light blue, whitish and brown if exposed to prolonged bright sunlight. Nominate race has prominent black band from base of bill across side of head, enclosing eye and crossing under slight crest on nape; rest of head, body plumage, scapulars, lesser upperwing-coverts and upperside of tail light green, yellower on crown and underparts; remainder of wing reddish-chestnut, tertials pale green with narrowly black-edged paler tips, outer tail feathers with whitish tips; iris dark brown, crimson orbital ring; bill red; legs bright red to orange-red. Sexes similar. Juvenile has duller, browner bill and legs, and tail feathers more pointed than those of adult. Race *jefferyi* is darker overall than nominate, almost uniform apple-green, lacking yellow wash, has outer webs of inner two tertials chestnut, narrow black subterminal marks on outer tail feathers, and iris whitish or bluish-white with light blue orbital ring. Voice. Markedly different from those of congeners, although vocabulary of nominate race poorly documented. Voice of *jefferyi* remarkably sweet and musical at times, a series of 4 or 5 clear, incisive notes rising and falling in pitch, repeated after short pause, "swe-swi-swee-swi-swe-sweet" or "swe-si-si-swee-sweep", with variations. Also has thin, penetrating "sweeeii" and a repeated 3-note "swe-swe-gurg" or 2-note "swe-gurg".
Habitat. In Borneo found exclusively in true montane forest, from 900 m up to tree-line at 2400 m. Javan population inhabits narrow belt of submontane rainforest in foothills, at altitudes of 1000–1200 m.
Food and Feeding. Poorly studied. Recorded food items in Borneo emphasize importance of snails (Gastropoda) in diet; feeds also on variety of insects and their larvae, and suspected to have taken small frogs. Usually singly, in pairs or in small family parties, moving through dense undergrowth; forages on ground among litter, and up through shrub layer, sometimes to upper canopy. General behaviour much as that of *C. chinensis*, but noted as feeding near limit of tree-line, foraging among moss-covered twisted trunks.
Breeding. Poorly documented. Family parties reported in Apr in Borneo, suggesting egg-laying in early Feb; two young reared to fledging appears to be average family size. Cup-shaped nest built from thin twigs on layer of bigger branches, mixed with dry leaves of bamboo and grass; inner cup lined with thin blackish roots. No further information.
Movements. Sedentary.
Status and Conservation. Not globally threatened. In Borneo (race *jefferyi*) not uncommon in higher-elevation forests of Mt Kinabalu National Park. In Java (nominate race) is not at all well known, being confined to areas of submontane rainforest between 1000 m and 1200 m in W Java, where its occurrence in Mt Halimun National Park ensures a degree of protection. As both taxa have such limited ranges and are likely to merit full species status, priority should be given to assessing their ecological requirements and populations.
Bibliography. Blake & Vaurie (1962), Davison (1992), Delacour (1929), Dickinson *et al.* (2004), Goodwin (1986), Jepson (1997), Lekagul & Round (1991), MacKinnon & Phillipps (1993), Madge & Burn (1994), Meyer (1884), Sheldon *et al.* (2001), Smythies & Cranbrook (1981), Wildash (1968).



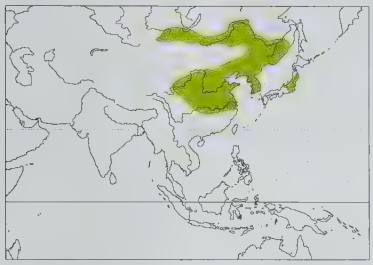
Genus *CYANOPICA* Bonaparte 1850

53. Iberian Azure-winged Magpie

Cyanopica cooki

French: Pie-bleue ibérique **German**: Blauelster **Spanish**: Rabilargo Ibérico
Other common names: Cook's/Spanish Azure-winged Magpie

Taxonomy. *Cyanopica cooki* Bonaparte, 1850, Madrid, Spain.
Recent DNA-sequencing indicates that this genus and *Perisoreus* form unique clades, separate from other corvids; significance of this requires further research. Usually treated as conspecific with *C. cyanus*. Because of peculiar global distribution of genus, with population in SW Europe (Iberia) separated by 9000 km from only other one (in E Asia), it was long speculated that Iberian population could have arisen from birds brought back E by Portuguese merchants and sailors in 16th/17th centuries; fossilized remains of this species found recently in caves on Gibraltar, however, indicate that distribution natural, which suggests that the populations had been separated during last glaciation. Further, two independent DNA studies of genus indicated that the two forms diverged at least one million years ago, and should therefore be treated as two species. Clarification of vocal differences from *C. cyanus* required. Birds of N part of interior Spain tend to be slightly larger and greyer than those of coastal areas, and could perhaps represent a geographical race (for which the name *gili* is available); overall variation is, however poorly defined. Treated as monotypic.
Distribution. Spain (except N & E) and E & S Portugal.
Descriptive notes. 34–36 cm; 65–76 g. Unmistakable within its range, where combination of black hood, greyish-brown mantle and blue wings and tail distinctive; head relatively large, slightly ruffled on nape, wings relatively short and broad, long tail quite broad and strongly graduated, bill rather small and pointed, nasal tufts short and dense, legs relatively short and not very sturdy. Has black hood down to below eye, ear-coverts and nape, glossed purplish on crown and nape, contrasting with white throat and malar region, highlighting very narrow pale collar on lower nape bordering hood; upperparts to uppertail-coverts grey-brown, tinged pinkish, uppertail-coverts also washed



blue; upperwing blue (cerulean or azure), remiges with inner web dull black, outer web azure-blue, white tip to outer web of primaries, increasing in extent outwards towards outermost primaries; tail uniform cerulean or azure-blue with horn-coloured feather shafts; underparts pinkish-grey, rather darker on side of breast and flanks, shading to almost white on central belly; iris dark brown to black; bill and legs black. Differs from very similar *C. cyanus* in smaller size, relatively shorter bill, somewhat brighter blue wings and tail, and lack of white tips on tail. Sexes similar. Juvenile is similar to adult, but hood brownish-black, crown feathers with pale fringes, wing-coverts with sandy fringes, greater coverts tipped white (forming narrow bar), tail tip blunter and with narrow buff fringe; like adult by end of first autumn. Voice. Typical call a hoarse, rising "zschreee", seemingly a little more rasping than that of *C. cyanus*, this and various rattling calls often repeated as birds move through bushy cover; some rattling calls more prolonged than those of *C. cyanus*, reminiscent of Mistle Thrush (*Turdus viscivorus*) call. Also variety of single-note calls with varying emphasis, and in alarm a loud "kree-kree-kree". Subdued chattering by male in display to female.
Habitat. Open woodland with grassy clearings, including orchards and olive (*Olea*) groves. Prefers oak woodland, especially holm oak (*Quercus rotundifolia*) and cork oak (*Quercus suber*) with scattered stone pines (*Pinus pinea*). Stands of introduced eucalypts (*Eucalyptus*) particularly favoured as communal roost-sites. Recorded locally to 700 m in foothill gorges; occurs down to sea-level, with largest concentrations in coastal wooded dunes of planted stone pines in SW Spain, one of the few habitats (albeit a somewhat artifical one) that allow it to compete successfully with normally dominant *Pica pica*.
Food and Feeding. Omnivorous. Takes wide variety of food items, especially beetles (Coleoptera) and other insects and their larvae, including hairy caterpillars, also millipedes (Diplopoda), snails (Gastropoda), leeches (Hirudinea); also quite a number of fruits and nuts, including grapes, olives, mulberries, myrtle, asparagus, cherries, daphne, acorns and pine seeds. Forages in small to quite large groups, moving from tree to tree in follow-my-leader manner. On reaching feeding site, some flock-members investigate tree canopy, examining foliage for insects and fruits, even hanging upside-down; others drop to the ground, hopping about as they turn over leaf litter and examine tree boles. Stores food items in caches in loose soil of banks. Generally shy and very wary, but can become confiding where unmolested. General behaviour very much as for *C. cyanus*.
Breeding. Laying from early Apr to late May, but at higher elevations in C Spain (1250 m) peak in mid-Jun. Believed to have monogamous pair-bond, pair-members keep together within flocks. Social breeder, forming loose colonies, but rarely more than one nest in a single tree. Helpers, presumed young from previous year, work with parents to feed nestlings. Nest construction mostly by female, although male brings material to site and helpers often participate, work taking 10–18 days; nest a foundation of twigs, with thick layer of mud or dung, topped by layer of soft plant material, wool and animal fur as main lining of cup, built 3–7 m above ground around fork in outer branch, usually in mid-canopy, as far as possible from main trunk. Clutch 4–9 eggs, usually 5–7; incubation by female alone, period 15–16 days; chicks fed by both parents, often by helpers as well, nestling period c. 14–16 days; family-members keep together within confines of flock. Nests parasitized by Common Cuckoo (*Cuculus canorus*) and Great Spotted Cuckoo (*Clamator glandarius*).
Movements. Basically sedentary; occasional reports from NE Spain and extreme SW France suggest that some individuals disperse farther than was previously thought.
Status and Conservation. Not assessed. Hitherto treated as race of *C. cyanus*. Recent population estimates suggest c. 40,000 pairs in Portugal and c. 250,000 pairs in Spain. A report of breeding in SW France remains unsubstantiated. Although most abundant in the S Spain–Portugal border regions, and said to be increasing in Portugal, it seems that total population could be declining. Destruction of extensive stands of holm oaks has been blamed for its disappearance over several areas; competition with increasing numbers of *Pica pica* has also been suggested as possible reason for local decreases, and it seems that, in places where one species is numerous, the other is excluded. Older records mention flocks of up to 300 individuals during late 1930s and early 1940s; such numbers not seen today.
Bibliography. Alarcos *et al.* (2007), Alonso *et al.* (1991), Cooper (1998), Cooper & Voous (1999), Cramp & Perrins (1994), de la Cruz (1988), Dos Santos (1968), Ferrer (1987), Goodwin (1975, 1986), Hagemeijer & Blair (1997), Madge & Burn (1994), Martí & del Moral (2003), Purroy (1997), Rooke (1999), Sacarrão (1974), Valencia (2002), Valencia, de la Cruz & Carranza (2000, 2004), Valencia, de la Cruz, Carranza & Solis (2005), Valencia, de la Cruz & González (2003), Vaurie (1959).

54. Asian Azure-winged Magpie

Cyanopica cyanus

French: Pie-bleue à calotte noire **German**: Azurelster **Spanish**: Rabilargo Asiático

Taxonomy. *Corvus cyanus* Pallas, 1776, Dauria = Transbaikalia (southern Siberia), Russia.
Recent DNA-sequencing indicates that this genus and *Perisoreus* form unique clades, separate from other corvids; significance of this requires further research. Usually treated as conspecific with *C. cooki*, but fossilized remains of latter (previously thought introduced) indicate that its distribution is natural; also, DNA studies of genus indicated that the two forms diverged at least one million years ago, and should be treated as separate species; clarification of vocal differences required. Geographical variation partly clinal, intergrading of mainland races making assessment tricky; validity of *koreensis*, *stegmanni*, *swinhoei* and *kansuensis* perhaps questionable. Other proposed races are *tristis* (described from near Chita, in Transbaikalia) and *pallescens* (from Radde, on R Amur, in extreme SE Russia), both synonymized with nominate, and *jeholica* (C Jehol, in NE China), treated as synonym of *interposita*. Seven subspecies tentatively recognized.
Subspecies and Distribution.
C. c. cyanus (Pallas, 1776) – NW & N Mongolia (E from Uliastay) E across Transbaikalia and S Yakutia to SE Russia (Amurland and Ussuriland), S to NE China (N Heilongjiang).
C. c. japonica Parrot, 1905 – C Japan (N & C Honshu).
C. c. stegmanni Meise, 1932 – S Heilongjiang (NE China).
C. c. koreensis Yamashina, 1939 – Korean Peninsula.
C. c. kansuensis Meise, 1937 – NC China (NE Qinghai, W Gansu and NW Sichuan).
C. c. interposita E. J. O. Hartert, 1917 – N China from Ningxia and E Gansu and Shaanxi E to Hebei and Shandong.
C. c. swinhoei E. J. O. Hartert, 1903 – EC & E China (N & C Sichuan E to Zhejiang and Jiangxi).

Descriptive notes. 36–38 cm; male 80–118 g, female 76–112 g. Unmistakable within its range, where combination of black hood, greyish mantle and blue wings and tail distinctive; head relatively large, slightly ruffled on nape, wings relatively short and broad, long tail quite broad and strongly graduated, bill rather small, slim and pointed, nasal tufts short and dense, legs relatively short and not very sturdy. Nominate race has black hood down to below eye, ear-coverts and nape, shiny black on crown and nape, contrasting white throat and malar region, highlighting very narrow pale collar on lower nape bordering hood; upperparts dull greyish (becoming paler but browner towards E), upperwing powder-blue, primaries with extensive black-edged white, chiefly on outer webs (distinct panel), and notches at tips, tail blue with brownish feather shafts, central rectrices with large white tips; underparts whitish with sandy-grey wash; iris dark brown to black; bill and legs black. Sexes similar. Juvenile is similar to adult, but hood browner, crown feathers with pale fringes, wing-coverts with sandy fringes, greater coverts tipped white (narrow bar), tail with ill-defined pale tips; like adult by end of first autumn. Races differ mainly in size and colour intensity: *stegmanni* is darker and greyer in body colour than nominate; *koreensis* is whiter below and browner above; *interposita* is a grey form, darker than *stegmanni*; *swinhoei* is similar to last but browner; *kansuensis* is greyish above, creamy whitish below, and has smaller bill than others; *japonica* is smaller and darker, with brighter blue wings and tail. Voice. Some apparent poorly understood geographical variation in certain calls. Typical call a shivery trilled, rising "screeep", often repeated as contact when birds moving through shrubbery. In general, vocalizations seem very much like those of *C. cooki* when compared with these regional variations. For race *swinhoei*, however, rattle has been described as slow and creaky, ending in high-pitched "keeow", latter reminiscent of call of *Corvus monedula*.

Habitat. Lowland thickets, especially mixed willow (*Salix*) and *Prunus* thickets with large mature deciduous trees on riverine islands; also parks (even in city centres) and overgrown gardens. Avoids dense forest and mountain slopes, but often in wooded farmland, orchards and broken deciduous and mixed woodland. From sea-level to 1600 m.

Food and Feeding. Omnivorous. Takes wide variety of food items, especially insects and their larvae, and quite a number of fruits and nuts. In Ussuriland, feeds chiefly on fruits, spiders (Araneae) and insects in spring, almost entirely spiders and insects in summer, fruits and berries in autumn, and, in winter, invertebrates found in leaf litter, galls, bark, fishermen's baits and carrion. Forages in small to, sometimes, quite large flocks (up to several 100 individuals), which move from tree to tree in follow-my-leader style; upon reaching a fresh feeding site, flock loosens up, some individuals investigating tree canopy, examining foliage for insects and fruits, even hanging upside-down in the process, while others descend to ground, where they hop around, tail raised, as they turn over leaf litter and examine tree boles. Stores food items, mostly acorns and pine (*Pinus*) seeds, in caches in loose soil. Apparently shy and wary over most of range; can become remarkably confiding in city parks and edges of villages, where it forages for scraps or raids rubbish dumps and litter bins.

Breeding. Egg-laying May–Jun, peak in second half of May in SE Russia (Ussuriland) and Japan. Believed to have monogamous pair-bond, as pair-members seem to keep together within flocks. Social breeder, forming loose colonies; nests on average 15–20 m apart, rarely more than one in any one tree. Helpers, presumed young from previous year, work with parents to feed nestlings. Nest built mostly by female, male brings material to site, helpers often participate, construction work takes 10–18 days; nest a mass of twigs and rootlets, often domed by naturally amassed twigs (such as would form after floodwater had receded), deep cup lined with soft plant material, particularly animal fur, placed inside outer foliage of long branch and rarely more than 2 m above ground, sometimes at ground level itself, or exceptionally as high as 15 m and frequently in tree hollow. Clutch 5–8 eggs, usually 6 or 7; incubation by female alone, period 15–16 days; chicks fed by both parents, often also by helpers, nestling period 16–19 days; in early Jul young gather in small flocks for a few weeks, many disperse as they meet up with other flocks from adjoining territories, later the adults join remaining, and additional, young and prepare for winter; in regions where winter dispersal unusual, family groups tend to keep together within local flock. Nests parasitized by Common Cuckoo (*Cuculus canorus*).

Movements. Most populations basically resident. In Ussuriland disperses in winter, turning up in open country and even on inshore islands, some reaching N Heilongjiang (NE China); no such movements recorded in Japan in winter, although may descend 1–2 km following heavy snowfall.

Status and Conservation. Not globally threatened. Widespread and locally common. Throughout its wide range can be relatively inconspicuous, its colonial habits also making it seem scarcer than it really is, particularly in W of range, where populations particularly fragmented. In E Siberia and China, considered common over much of its range in appropriate habitats. In Japan, widespread over C Honshu, but more localized in N Honshu; formerly occurred on Shikoku, but no recent reports from that island, and was widespread also on Kyushu, but last reported there in 1968; these localized extinctions have been blamed on competition with introduced *Pica pica*. Attempted introduction in Hong Kong was unsuccessful.

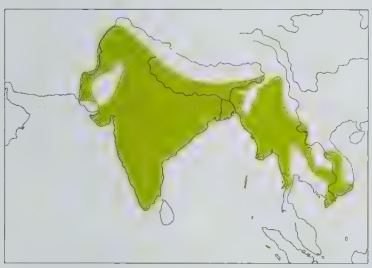
PLATE 34

inches 6
cm 15



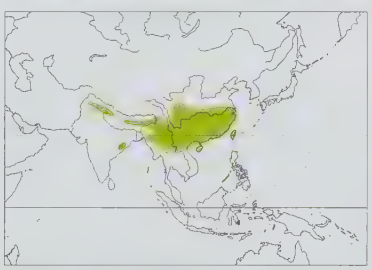
Genus *DENDROCITTA* Gould, 1833

55. **Rufous Treepie**

Dendrocitta vagabunda

French: Témia vagabonde **German**: Wanderbaumelster **Spanish**: Urraca Vagabunda
Other common names: (Indian) Treepie

Taxonomy. *Coracias vagabunda* Latham, 1790, Calcutta, India.
Formerly known as *D. rufa*. Perhaps has a distant relationship with *D. frontalis*. Recent investigations of type specimens have revealed that proposed name *vernayi* (hitherto used for SE Indian population, based on birds from Nallamalai Range, in S Kurnool) is a junior synonym of *pallida*; type locality of latter (originally given erroneously as W Himalayas) has been fixed to Chennai (in Tamil Nadu), and *behni* is a new name for W Indian population that formerly went under name *pallida*. Geographical variation clinal, races intergrading; some of listed races possibly of questionable validity. Nine subspecies tentatively recognized.
Subspecies and Distribution.
D. v. bristoli Paynter, 1961 – E Pakistan (S to Karachi) and E in Himalayan foothills to N India (Dehra Dun, in Uttarakhand).
D. v. vagabunda (Latham, 1790) – Uttarakhand E to Bangladesh and NE India, S in peninsula to N Andhra Pradesh.
D. v. behni Steinheimer, 2009 – W & C India from S Gujarat (E Surat District) S to C Karnataka and E to mountain ridges of E Western Ghats.
D. v. parvula Whistler & Kinnear, 1932 – SW India (S Karnataka and Kerala).
D. v. pallida (Blyth, 1846) – SE India S from Eastern Ghats (S of R Godavari).
D. v. sclateri Stuart Baker, 1922 – W & N Myanmar.
D. v. kinneari Stuart Baker, 1922 – C & E Myanmar, S China (SW Yunnan) and NW Thailand.
D. v. saturatior Ticehurst, 1922 – S Myanmar and SW Thailand.
D. v. sakeratensis Gyldenstolpe, 1920 – C, E & SE Thailand, Cambodia, S Laos and C & S Vietnam.



Descriptive notes. 46–50 cm; 90–130 g. Distinctive large treepie with long, strongly graduated tail, central feather pair somewhat broadening towards tip, rather short bill with strongly curved culmen and cutting edges. Nominate race has entire head to breast and upper mantle sooty blackish, blackest on face and throat; upperparts ginger-brown, paling to orange-buff on uppertail-coverts; secondary upperwing-coverts and tertials silvery grey, contrasting with black of rest of wing; central tail feathers light silvery grey, shading paler towards tip, and ending in wide black terminal band, remainder of tail feathers similar but progressively shorter, outermost (shortest) with terminal half black; lower underparts buffy rufous, paling to orange-buff on undertail-coverts; iris red or reddish-brown; bill and legs blackish-grey. Sexes similar. Juvenile has hood and mantle uniformly brown, rump, uppertail-coverts and underparts creamy buff, black areas of wings browner than adult and wingpanel pale grey with rusty-cream tinges, tail feathers (except central pair) with narrow rusty tips; first-year aged by retained worn, brown primaries. Races vary mainly in size and colour saturation, but complicated by clinal intergrading: *bristoli* is largest and longest-tailed, close to nominate in colour; *behni* is second largest and rather paler than previous, with greyish-buff belly and vent, ochre-buff mantle and scapulars, and cinnamon rump; *parvula* is smallest and most richly coloured race, with dark rufous-brown upperparts; *pallida* is similar in size to nominate, colours are paler but brighter, with belly almost creamy buff; *sclateri* has darker upperparts than nominate, nape and mantle colours diffusing; *kinneari* is similar to previous, but darker; *saturatior* is a little smaller and the darkest of all, with very dark reddish-brown upperparts; *sakeratensis* resembles nominate, but has darker nape. Voice. Advertising call difficult to describe, but one of most familiar sounds of Indian countryside, a loud, ringing, almost metallic "ko-kí-la"; another frequently heard call is a raucous chatter, similar to that of *Pica pica* but harsher and slower in delivery. Otherwise has wide vocabulary of various harsh notes, squawks and musical sounds, many of which shared by congeners.
Habitat. Open deciduous woodland of all kinds, from dry forest to moist broadleaf woodlands. Open agricultural country with scattered trees, town and city parks, large gardens and the like. Chiefly in lowlands, also in low hills, ascending as high as 2100 m.
Food and Feeding. Omnivorous, but primarily carnivorous. Recorded items include large variety of insects and their larvae, such as crickets and grasshoppers (Orthoptera), beetles (Coleoptera), moths (Lepidoptera), wasps and ants (Hymenoptera) and termites (Isoptera), also spiders (Araneae), centipedes (Chilopoda) and snails (Gastropoda); equally diverse variety of small vertebrates, including contents of bird nests, small birds, small rodents, small bats, small snakes, frogs and lizards. Recorded as killing sickly small birds, e.g. Indian Robin (*Saxicoloides fulicatus*), Common Tailorbird (*Orthotomus sutorius*), Oriental White-eye (*Zosterops palpebrosus*) and Purple Sunbird (*Cinnyris asiaticus*), and seen to tear open nests of weaver-birds to reach contents. Scavenges about villages for kitchen waste; feeds on carrion (roadkills), and even scavenges at tiger (*Panthera tigris*) kills. Very fond of wild figs (*Ficus*), including banyan and peepul, and variety of other fruits including neem (*Melia*) and the poisonous *Trichosanthes palmata*; raids orchards for cultivated fruits, especially figs, also mulberries and papaya. Visits flowering *Bombax* and *Erythrina* trees for nectar at appropriate season. Can be remarkably confiding about tourist attractions, even taking food from the hand at picnics. Usually in pairs or small family groups, although larger gatherings at exceptional food sources, such as swarming winged termites. Readily follows mixed-species groups of larger forest birds, especially Greater Racquet-tailed Drongos (*Dicrurus paradiseus*) and various woodpeckers (Picidae), nimbly catching moths or other insects disturbed from tree trunks or leaf litter by those species. Rides on backs of both domestic and wild large mammals, feeding on ectoparasites and anything that may be disturbed from underfoot. Forages on ground, with tail held raised, moving in short hops.
Breeding. Season varies according to rains, generally Mar–Jul, but mostly May–Jun in N India and Mar–Apr in S (Kerala). Solitary breeder. Nest built by both sexes, rather small for size of bird, a flimsy cup of thin, usually thorny twigs, lined with rootlets and smaller twigs, typically 6–8 m above ground, often in quite exposed position in often isolated or prominent tree such as sheesham (*Dalbergia*), acacia (*Acacia*), mango (*Mangifera*) or salai (*Boswellia*). Both sexes build nest, feed young, and are said to share incubation but this requires confirmation. Clutch 2–6 eggs, usually 4 or 5 (average in India larger in N than in S); incubation said to shared by sexes, but confirmation required; both parents feed the young; no information on duration of incubation and nestling periods.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Generally common and widespread throughout most of range; quite localized and uncommon in E, e.g. in Vietnam. The treepie most likely to be encountered in semi-open country, dry forest and farmland over most of Indian Subcontinent. A very adaptable species, omnivorous, and successful in its survival strategies of living alongside humans. Although reported as causing some damage to orchards and cereal crops, its diet includes high percentage of insects, many of which are detrimental to food crops; seems likely that any harm that it does is far outweighed by the quantity of insect pests that it consumes.
Bibliography. Ali & Ripley (1972, 1987b), Chen Fuguan *et al.* (1998), Dickinson *et al.* (2004), Goodwin (1986), Grimmett *et al.* (1998), Lekagul & Round (1991), Madge & Burn (1994), Paynter (1961), Rasmussen & Anderton (2005a, 2005b), Roberts (1992), Robson (2000), Steinheimer (2009), Stuart Baker (1928), Thomas & Poole (2003), Vaurie (1958a), Whistler (1949), Zafar-Ul-Islam *et al.* (2001).

56. **Grey Treepie**

Dendrocitta formosae

French: Témia de Swinhoe **German**: Graubrust-Baumelster **Spanish**: Urraca Gris
Other common names: Himalayan Treepie

Taxonomy. *Dendrocitta sinensis* var. *formosae* Swinhoe, 1863, Taiwan.
Forms a species group with *D. cinerascens*, *D. occipitalis* and *D. leucogastra*; sometimes thought to be conspecific with first two. Races fall into two groups, W group with greyish rump and some grey in tail (*occidentalis*, *himalayana*, *sarkari*, *assimilis*) and relatively shorter-tailed E group with darker, less patterned plumage, white rump and (except nominate) wholly black tail (*sinica*, *sapiens*, *insulae*, nominate). Isolated race *sarkari* often subsumed in *himalayana*. Race *himalayana* often listed as "*himalayensis*", but former has priority. Eight subspecies recognized.
Subspecies and Distribution.
D. f. occidentalis Ticehurst, 1925 – Himalayan foothills from Pakistan (Murree) E through NW India to W Nepal.
D. f. himalayana Jerdon, 1864 – C Nepal E to NE India, N Myanmar, S China (S Yunnan), NW Thailand, N & C Laos and N Vietnam (S to N Annam).
D. f. sarkari Kinnear & Whistler, 1930 – Eastern Ghats (Orissa and N Andhra Pradesh), in E India.
D. f. assimilis Hume, 1877 – SW & E Myanmar and N Thailand.
D. f. sapiens (Deignan, 1955) – C China (WC Sichuan).
D. f. sinica Stresemann, 1913 – E & SE China and NE Tonkin (extreme N Vietnam).
D. f. formosae Swinhoe, 1863 – Taiwan.
D. f. insulae E. J. O. Hartert, 1910 – Hainan I, in S China.

Descriptive notes. 36–40 cm; 89–121 g. Rather drab brownish-grey treepie with long, strongly graduated tail, central feather pair somewhat broadening towards tip, rather short bill with strong curve on culmen and cutting edges. Nominate race has forehead and side of crown blackish-brown, blackest on forecrown and above eye, shading lighter on rear ear-coverts and to breast, remainder of crown and nape light grey, becoming brownish on mantle; upperparts dark brown, lower rump and uppertail-coverts greyish-white; upperwing black, white bases of primaries (white patch); tail black, basal third of central feather pair pale grey; breast brownish-grey, shading paler on lower underparts, undertail-coverts chestnut; iris red or reddish-brown; bill and legs blackish-grey. Sexes similar. Juvenile is more uniformly grey-brown (little contrast between darker face and body colour), black areas of wings browner than when adult, tail (except central pair) with narrow rusty tips. Races differ mainly in size, rump and tail colour, and colour saturation, but complicated by intergrading between most forms: *sinica* is darker, less brown, than nominate, tail wholly black; *sapiens* is like previous but darker; *insulae* is slightly smaller and duller than *sinica*, with smaller white wing patch; *himalayana* has longer tail than previous races, is more tawny-brown above, rump and uppertail-coverts pale grey, central rectrices pale silvery grey, shading paler towards tip and with wide black terminal band, rest of tail feathers similar but progressively shorter, outermost almost entirely black; *occidentalis* is like previous, but on average larger; *sarkari* has smaller bill than *himalayana*; *assimilis* also is on average smaller, has stouter bill, relatively shorter tail and drabber underparts. Voice. Advertising call, typical of most treepie species, a loud, ringing, almost metallic, stumbling "klok-kli-klok-kli-kli…", uttered with explosive, undulating rhythm. Otherwise has wide vocabulary of various rattles, barks, burps, squawks, and various laughing and musical sounds.
Habitat. Deciduous montane woodland of all kinds, from tropical evergreen forest in foothills to oak–rhododendron (*Quercus–Rhododendron*) forest at higher elevations. Not fond of dense forest, but tolerates scrubby hillsides with scattered large trees; seems to prefer forest edge and clearings about villages, terraced slopes and wooded valleys. In S of range chiefly between 800 m and 2300 m; down to 550 m in China.
Food and Feeding. Very similar to *D. vagabunda*. Omnivorous, but primarily carnivorous. Prey items include large variety of invertebrates and their larvae, such as grasshoppers (Orthoptera), beetles (Coleoptera), moths (Lepidoptera), spiders (Araneae) and centipedes (Chilopoda); some small vertebrates, including lizards and small birds, and eggs and nestlings of small birds. Variety of fruits and seeds also taken, and very fond of nectar from flowering trees and shrubs such as *Bombax*, *Erythrina* and *Rhododendron*. Scavenges around villages for kitchen waste. Also raids

On following pages: 57. Bornean Treepie (*Dendrocitta cinerascens*); 58. Sumatran Treepie (*Dendrocitta occipitalis*); 59. White-bellied Treepie (*Dendrocitta leucogastra*); 60. Andaman Treepie (*Dendrocitta bayleii*); 61. Collared Treepie (*Dendrocitta frontalis*); 62. Racquet-tailed Treepie (*Crypsirina temia*); 63. Hooded Treepie (*Crypsirina cucullata*); 64. Ratchet-tailed Treepie (*Temnurus temnurus*); 65. Common Magpie (*Pica pica*); 66. Arabian Magpie (*Pica asirensis*); 67. Yellow-billed Magpie (*Pica nuttalli*); 68. Black-billed Magpie (*Pica hudsonia*).

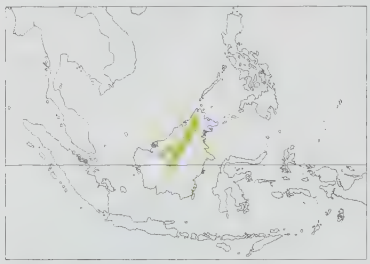
orchards for cultivated fruits, especially figs (*Ficus*), mulberries (*Morus*) and the like. Forages in pairs or small family groups; also larger gatherings of up to 20 individuals at exceptional food sources, such as fruiting figs or swarming termites (Isoptera). Readily follows mixed-species groups of larger forest birds, especially laughingthrushes (Timaliidae), for insects flushed by the flock moving through undergrowth. Briefly and clumsily hovers in canopy to reach fruits. Spends most of time in trees, but often feeds on ground, hopping about, with raised tail; often in open on terraced hillsides as it feeds on fallen grain.

Breeding. Season varies according to rains, generally Apr–Jul, but mostly May–Jun in N India and Myanmar. Solitary breeder. Nest built by both sexes, rather small for size of bird, a flimsy cup of thin sticks, shallow cup lined with rootlets and other soft plant material, placed 2–6 m above ground, sometimes in quite exposed position, inside canopy of small tree or shrub or in stand of bamboo, sometimes virtually on ground. Clutch 3–5 eggs, usually 3 or 4; incubation said to be shared by sexes, but this requires confirmation; both sexes feed young; no information on duration of incubation and fledging periods.

Movements. Sedentary.

Status and Conservation. Not globally threatened. Generally common and widespread throughout most of range; quite localized and uncommon towards W limits, e.g. in Pakistan and Kashmir. Although reported to cause some damage to orchards and cereal crops, its omnivorous diet includes a high percentage of insects, many of which would be detrimental to food crops; seems likely that any harm done is far outweighed by amount of insect pests that it consumes.

Bibliography. Ali (1949, 1962), Ali & Ripley (1972, 1987b), Chen Fuguan *et al.* (1998), Dickinson *et al.* (2004), Goodwin (1986), Grimmett *et al.* (1998), Lekagul & Round (1991), Liu Yang & Lei Jinyu (2005), Madge & Burn (1994), Owen (2003), Paynter (1961), Rasmussen & Anderton (2005a, 2005b), Roberts (1992), Robson (2000), Stuart Baker (1928), Vaurie (1958a), Whistler (1924).



57. **Bornean Treepie**

Dendrocitta cinerascens

French: Témia de Bornéo **German**: Borneobaumelster **Spanish**: Urraca de Borneo
Other common names: Sunda/Malaysian Treepie (when treated as conspecific with *D. occipitalis*)

Taxonomy. *Dendrocitta cinerascens* Sharpe, 1879, Mount Kinabalu, northern Borneo.
Forms a species group with *D. formosae*, *D. occipitalis* and *D. leucogastra*. Often treated as conspecific with *D. occipitalis*, and sometimes *D. formosae* included in same species. Monotypic.

Distribution. Mountains of N & C Borneo.

Descriptive notes. 40 cm; c. 125 g. Distinctive treepie with mostly pale face and throat, long, strongly graduated tail, central feather pair broadening somewhat towards tip (but a little narrower than in *D. formosae*), short bill with strong curve on culmen and cutting edges. Forehead, nasal tuft and lores rufous-buff; variable chocolate-brown bar over forecrown; mid-crown pale grey, almost white, shading to pale grey on nape, on hindneck becoming rufous-buff with light grey wash, often stronger grey on scapulars, mantle and back, narrow whitish line along outer scapulars, outlining wing; rump and uppertail-coverts very pale grey, almost white; upperwing black, white patch at base of primaries; central tail feathers light silvery grey with wide black terminal band, remainder of tail feathers black; most of face, throat, side of head and entire underparts rufous-buff, deeper orange-buff or ochraceous-buff on undertail-coverts; iris red or reddish-brown; bill and legs blackish-grey. Sexes similar. Juvenile has buffy fringes on body feathers and tertials, narrower central tail feathers; first-year aged by retained worn (brown) juvenile primaries and retained narrower tail feathers. Voice. Variety of typical treepie squawks, bell-like clangs, and other metallic and musical notes (which account for large percentage of bird sounds of Bornean hill forests). All call phrases shorter than those of *D. formosae*, and all rather explosive in delivery: a metallic clang sounding like old motor horn, "kil-awk"; a raucous squawk followed by metallic clunk, "squaaaaaak-tonk"; a metallic note followed by a ringing fading resonance, "b-clunk-eeeee"; and a liquid note followed by two harsh calls, "plonk, grah-grah". Also reported are a harsh chatter like that of *Pica pica*, and mimicry of other forest sounds.

Habitat. Hill and mountain forests, both primary and secondary; especially scrub-jungle, bamboo thickets, edges of villages and associated cultivation. Particularly in foothill valley forests. At 300–2600 m.

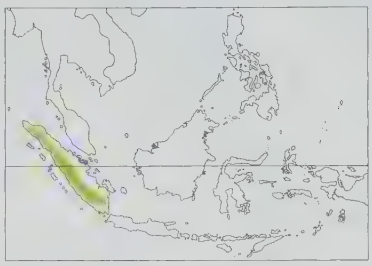
Food and Feeding. Omnivorous, primarily carnivorous. Prey items include large variety of invertebrates and their larvae, such as grasshoppers (Orthoptera), beetles (Coleoptera), moths (Lepidoptera), cockroaches (Blattodea). Variety of fruits and seeds also taken, including rice and fallen grain. Scavenges for food scraps around villages, and on Mt Kinabalu follows walkers for picnic scraps. Very sociable, typically found in noisy parties in tree canopy, but forages at all levels; often descends to ground, where it hops rather awkwardly, with raised tail.

Breeding. Little information. Eggs found early Jan to mid-Mar. Believed to be solitary breeder. Nest a shallow construction of fine twigs, cup lined with rootlets and other soft plant material, typically not very well hidden inside canopy of small tree or tall shrub. Clutch usually 2 eggs. No other information.

Movements. Sedentary.

Status and Conservation. Not assessed. Probably not globally threatened. Seems to be generally common and widespread throughout range in N & C Borneo. Oddly, is absent from hill forests of the Poi Range, Penrissen, and Kapuas and Mahakam drainage systems. Its tolerance, in some areas perhaps even its preference, for secondary forests bodes well for the future survival of this species.

Bibliography. Davison (1992), Dickinson *et al.* (2004), Goodwin (1986), MacKinnon & Phillipps (1993), Madge & Burn (1994), Sharpe (1879, 1889), Sheldon *et al.* (2001), Smythies & Davison (1999), Vaurie (1958a).



58. **Sumatran Treepie**

Dendrocitta occipitalis

French: Témia coiffée **German**: Sumatrabaumelster **Spanish**: Urraca de Sumatra
Other common names: Sunda/Malaysian Treepie (when treated as conspecific with *D. cinerascens*)

Taxonomy. *Glaucopis occipitalis* S. Müller, 1836, Sumatra.
Forms a species group with *D. formosae*, *D. cinerascens* and *D. leucogastra*. Often treated as conspecific with *D. cinerascens*, and sometimes *D. formosae* included in same species. Monotypic.

Distribution. Sumatra.

Descriptive notes. 40 cm; 88–102 g. Distinctive treepie with long, strongly graduated tail, central pair of feathers somewhat broadening towards tip, rather short bill with strongly curved culmen and cutting edges. Has forecrown, face, throat and side of head liver-brown, darkest on crown, contrasting white upper nape, shading into light grey lower nape; upperparts tawny-brown, rump and uppertail-coverts pale grey (almost whitish); upperwing black, white patch at base of primaries; central tail feathers light silvery grey with wide black terminal band, remainder of tail black; lower throat dark brown fading to buffy rufous on breast and belly, becoming richer tawny-orange on undertail-coverts; iris red or reddish-brown; bill and legs blackish-grey. Sexes similar. Juvenile has crown, face and throat more sooty than adult, buffy fringes on body feathers and tertials, and narrower central tail feathers; first-year aged by retained worn (brown) juvenile primaries and retained narrower tail feathers. Voice. Little information. Said to be noisy, uttering bell-like calls. Vocalizations probably very much as *D. cinerascens*, which is similar vocally to other treepies.

Habitat. Hill and mountain forests, both primary and secondary; also tolerates coniferous forest, bamboo stands in gulleys, and plantations. Generally between 400 m and 2300 m.

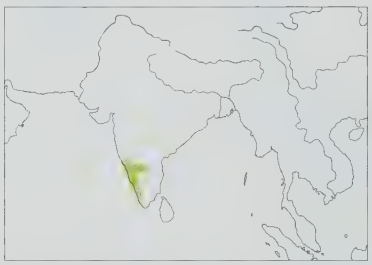
Food and Feeding. Little specific information; this species was for long regarded as conspecific with *D. cinerascens*, and division of data between the two taxa confused. Often perches quite low down, waiting for movements in undergrowth which may flush insects from leaf litter. Also feeds in upper canopy of trees, its methodical searching reminding some observers of a malkoha (*Phaenicophaeus*). Usually in pairs or small family groups, although larger gatherings at exceptional food sources, such as swarming winged termites (Isoptera).

Breeding. No specific information.

Movements. Sedentary.

Status and Conservation. Not assessed. Probably not globally threatened. Seems to be generally common and widespread throughout range. Tolerance of secondary forests bodes well for the future survival of this species.

Bibliography. Dickinson *et al.* (2004), Goodwin (1986), MacKinnon & Phillipps (1993), Madge & Burn (1994), van Marle & Voous (1988), Paynter (1961), Vaurie (1958a).



59. **White-bellied Treepie**

Dendrocitta leucogastra

French: Témia à ventre blanc **German**: Weißbauch-Baumelster **Spanish**: Urraca Ventriblanca
Other common names: Southern Treepie

Taxonomy. *Dendrocitta leucogastra* Gould, 1833, "Eastern Asia" = Malabar coast, India.
Forms a species group with *D. formosae*, *D. cinerascens* and *D. occipitalis*. Monotypic.

Distribution. Western Ghats from N Karnataka S to S Kerala and E to W Tamil Nadu (Nilgiris), in SW India.

Descriptive notes. 45 cm; c. 125 g. Unmistakable treepie with much white in plumage; long, strongly graduated tail, central pair of feathers somewhat broadening towards tip; rather stout bill with strong curve on culmen and cutting edges. Most of crown, side of head, throat and upper breast are black, rear crown, nape, hindneck and most of underparts below breast strikingly white, feathered portion of tibia black, undertail-coverts chestnut; mantle, back and scapulars chestnut-brown, rump and uppertail-coverts white; upperwing black, white patch at base of primaries; central tail feathers light silvery grey with wide black terminal band, rest of tail black; iris red or reddish-brown; bill and legs blackish-grey. Sexes similar. Juvenile has buffy fringes of body feathers and tertials, and narrower central tail feathers; first-year aged by retained worn (brown) juvenile primaries and retained narrower tail feathers. Voice. Variety of vocalizations, many calls louder, harsher and more metallic than those of *D. vagabunda* and surprisingly similar to those given by Greater Racquet-tailed Drongo (*Dicrurus paradiseus*), with which it often loosely associates; this likely due to mimicry. Vocalizations include short, dry rattle terminating in frog-like croak, lower, coarser dry rattle ending in sharp note, "krrrrrrrrrrrrrr, quit", castanet-like rattling "kt-kt-kt-kt-kt", high-pitched clanging "quang, quang, quang" (3–5 notes), liquid "ko-koo" (in display), harsh "kraa" (perhaps an alarm call), throaty "chuff-chuff-chuff" (by two birds facing each other and jumping up and down), rapid "took- took-took", and remarkable series of 7 very deep "clunky" knocking notes. Significance of many of these uncertain.

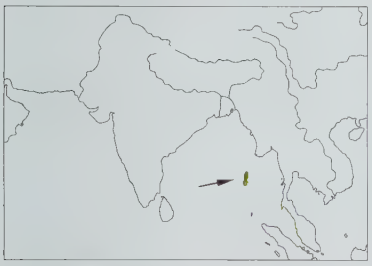
Habitat. Humid evergreen hill forests, both primary and relict patches within secondary forests; especially sholas (small ravines) with cardamom plantations, overgrown abandoned rubber plantations, large roadside trees and so on. Avoids human habitation and human contact in general. Foothills to mountain forest-line, from 60 m to 1500 m. Overlaps in range with *D. vagabunda*, but prefers lusher evergreen forest, whereas latter species found in dry deciduous woodland.

Food and Feeding. Omnivorous, primarily carnivorous. Prey items include variety of invertebrates and their larvae, also small vertebrates such as small lizards and rodents, and eggs and nestlings of small birds. Fond of flower nectar and a variety of fruits and seeds, particularly ripe seeds of *Sterculia villosa*, which it devours by stripping the orange pods. Typically in pairs or family parties. Often with mixed foraging parties of other forest birds, particularly Greater Racquet-tailed Drongos; when associating with these mixed flocks, it readily comes down to bushy undergrowth, and more rarely descends to ground.

Breeding. Eggs recorded in Feb–Apr, chiefly Mar and Apr. Solitary breeder. Nest a rather deep construction of prickly twigs, cup lined with smaller twigs, rootlets and other soft plant material, well hidden inside canopy of large forest tree or tall shrub, generally well away from human habitation. Clutch 3 or 4 eggs. No other information.

Movements. Sedentary, as far as is known. Some old reports from SE Gujurat, Goa, Bangalore and particularly S Andhra Pradesh (E to Palmaner).

Status and Conservation. Not globally threatened. Restricted-range species: present in Western Ghats EBA. Locally quite common in lush tropical evergreen forests. Present in a number of pro-



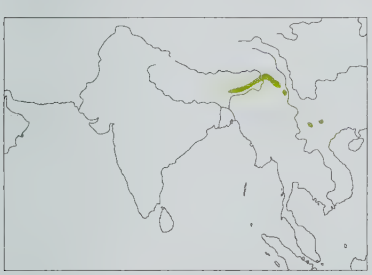
tected areas, including Periyar and Silent Valley National Parks, Thattakad (Salim Ali) Bird Sanctuary, and Topslip. Most remarkable is an old specimen purportedly from Gawilgarh Hills, in C India, which is not only well outside this species' known range but also the wrong habitat (dry scrub-forest); report probably erroneous, but, if genuine, would suggest either propensity to extensive wandering or a subsequent massive range contraction.
Bibliography. Ali & Ripley (1972, 1987b), Dickinson *et al.* (2004), Goodwin (1986), Grimmett *et al.* (1998), Madge & Burn (1994), Rasmussen & Anderton (2005a, 2005b), Stuart Baker (1928), Vaurie (1958a).

60. **Andaman Treepie**

Dendrocitta bayleii

French: Témia des Andaman **German**: Andamanenbaumelster **Spanish**: Urraca de Andamán

Taxonomy. *Dendrocitta bazlei* [sic] Tytler, 1863, Andaman Islands.
Original description first used name "*bazlei*" but publisher's corrigendum explicitly corrected this to "*bayleii*"; as all falls within same volume of same journal, the emendation stands. Species name sometimes erroneously given as *bazlei*, *bayleyi* or *baileyi*. Monotypic.
Distribution. Andaman Is.



Descriptive notes. 32 cm; 92–113 g. Unmistakable small treepie, the smallest of genus, with large white wing patch and pale eyes; long, strongly graduated tail, central pair of feathers little longer than the next, rather short bill less stout than others of genus and with more gently curved culmen. Head and neck are dark bluish-grey, shading into blackish on face and forecrown; upperparts dark tawny-brown, brighter rufous on rump, becoming grey on uppertail-coverts; upperwing black, white patch at bases of primaries and inner secondaries; tail blackish, shading to dark grey over basal half of central feathers; underparts bright rufous, shading into greyish on upper breast and chestnut on undertail-coverts; iris yellow; bill blackish; legs blackish-grey. Sexes similar. Juvenile has sooty reddish-brown hood, darker and redder upperparts (reddish feather margins), greyish-brown fringes of wing-coverts, rather shorter and greyer tail, and olive iris; iris becomes brighter green before turning into yellow of adult. Voice. Poorly documented. Said to have repeated harsh alarm note, and metallic sound likened to "a coarse file being drawn across the teeth of a saw"; also a fluty whistle "kiu-duu" like that of an Old World oriole (*Oriolus*), and harsh, rasped "kyow". Some calls similar to those of Andaman Drongo (*Dicrurus andamanensis*), with which it often associates.
Habitat. Dense, humid evergreen forests, where it favours the largest trees.
Food and Feeding. No information on diet; presumably omnivorous. Typically encountered in small parties, with as many as 12–20 in loose company following mixed-species bird waves. Usually works its way through mid-canopy level, especially in company of Andaman Drongos. General behaviour assumed to be much as that of congeners.
Breeding. Eggs recorded Mar–May. Solitary breeder. Nest a rather flimsy structure of fine twigs and grasses, smaller and neater, more compact, than that of *D. formosae*, lined with fern rootlets and other soft plant material, well hidden c. 5 m above ground inside dense foliage of small forest tree. Clutch 3 eggs. No further information.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in Andaman Islands EBA. Not uncommon in suitable forest habitat. Transect surveys undertaken in 1993 and 1994 located 36 individuals on a total of nine islands, including main islands of Middle Andaman and South Andaman and smaller Baratang I. Forest destruction is widespread on the larger, most populated island of South Andaman. Several forest reserves and protected areas have been created on the islands. The future of this forest species depends on enforcement of logging restrictions.
Bibliography. Abdulali (1965), Ali & Ripley (1972, 1987b), Anon. (2008p), Butchart & Stattersfield (2004), David *et al.* (2009), Davidar *et al.* (1997), Dickinson *et al.* (2004), Goodwin (1986), Grimmett *et al.* (1998), Madge & Burn (1994), Rasmussen & Anderton (2005a, 2005b), Stattersfield & Capper (2000), Vaurie (1958a).

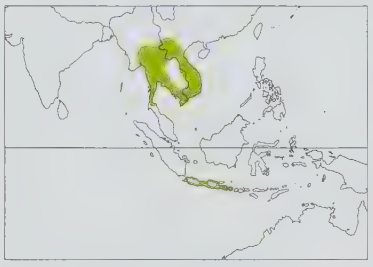
61. **Collared Treepie**

Dendrocitta frontalis

French: Témia masquée **German**: Maskenbaumelster **Spanish**: Urraca Acollarada
Other common names: Black-faced/Black-browed/White-naped Treepie

Taxonomy. *Dendrocitta frontalis* Horsfield, 1840, Assam, India.
Birds from N Vietnam (Tonkin) described as a race, *kurodae*, but differences from birds in rest of species' range appear minimal. Treated as monotypic.
Distribution. E Himalayas in Bhutan and NE India (Arunachal Pradesh and E Assam), N Myanmar, S China (extreme SE Xizang and W Yunnan), and apparently isolated population in N Vietnam (N Tonkin).

Descriptive notes. 38 cm; c. 100 g. Richly coloured little treepie with chestnut rear body and uniformly black long, strongly graduated tail, central pair of feathers considerably longer than the next, rather short and stout bill with strongly curved culmen and cutting edges. Has front half of head back to level of mid-crown, middle ear-coverts and upper breast black, separated by very narrow whitish-grey border from clean light grey nape, side of neck, hindneck and lower breast; upperparts are chestnut-brown, upperwing black, chestnut lesser coverts and grey median and greater coverts (forming band across closed wing), tail black; underparts below breast rich chestnut; iris red or reddish-brown; bill and legs blackish-grey. Sexes similar. Juvenile has buffy fringes of body feathers and tertials, and narrower central tail feathers; first-year aged by retained worn (brown) juvenile primaries and retained narrower tail feathers. Voice. Poorly documented. Said to have variety of typical treepie vocalizations, some quite musical, others harsh and grating.
Habitat. Humid evergreen foothill forests, preferably with extensive stands of bamboo. From foothills to 2100 m.
Food and Feeding. Omnivorous, primarily carnivorous. Prey items include variety of invertebrates and their larvae, also small vertebrates such as small lizards and rodents, and eggs and nestlings of small birds. Also variety of seeds and berries. Typically in pairs or family parties, with up to 20 individuals reported on occasions at rich food source, e.g. sudden emergence of winged termites (Isoptera); observed to make flycatching sallies from tops of tall bamboos in manner of drongos (Dicruridae) during such a termite swarm. General behaviour much for others of genus.
Breeding. Season Apr–Jul. Solitary breeder. Nest smaller and neater, more compact, than that of *D. formosae*, lined with fern rootlets and other soft plant material, well hidden inside bamboo thicket or in top of large prickly shrub at edge of forest. Clutch 3 or 4 eggs; no information on incubation and fledging periods.
Movements. Sedentary, as far as is known.
Status and Conservation. Not globally threatened. Not well known; rare to locally fairly common. Local in Bhutan; parties of up to 20 individuals located in Namning area of EC Bhutan in 1991. Apparently not uncommon in extreme NE India, but recent reports from Arunachal Pradesh and E Assam do not support this. Rare in China, and recorded only in extreme SE Xizang and on Yunnan–Myanmar border (in Gaoligong Mts). Isolated population in N Vietnam very little known. Old reports from Sikkim, but no recent records, and habitat in S Sikkim perhaps now too degraded to support a breeding population. No reliable evidence that it ever occurred in Nepal or Darjeeling. In view of the low level of sightings, it seems prudent to suggest that the conservation status of this species be reassessed.
Bibliography. Ali (1949, 1962), Ali & Ripley (1972, 1987b), Chen Fuguan *et al.* (1998), Dickinson *et al.* (2004), Goodwin (1986), Grimmett *et al.* (1998), Inskipp *et al.* (1999), Katti *et al.* (1992), King *et al.* (2001), MacKinnon & Phillipps (2000), Madge & Burn (1994), Rasmussen & Anderton (2005a, 2005b), Robson (2000), Tymstra *et al.* (1997), Vaurie (1958a).



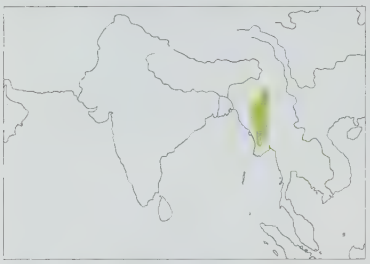
Genus *CRYPSIRINA* Vieillot, 1816

62. **Racquet-tailed Treepie**

Crypsirina temia

French: Témia bronzée **German**: Spatelbaumelster **Spanish**: Urraca Bronceada
Other common names: Black Racquet-tailed Treepie, Black/Bronzed Treepie

Taxonomy. *Corvus temia* Daudin, 1800, Africa; error = Java.
Monotypic.
Distribution. Lowlands of S & SE Myanmar, Thailand, extreme S China (S Yunnan), Laos, Vietnam and Cambodia; also Java and Bali.



Descriptive notes. 31–33 cm; 114–145 g. Rather small, slender all-dark treepie with very long, graduated tail (of ten, not twelve, rectrices) which has spatulate expansion at tip, rather short but stout bill with curved culmen; feathers of forecrown and lores soft and velvet-like, forming cushion over nares. Entire plumage is blackish with bronze-green sheen (in good light, matt black of face and throat contrasts with shiny remainder of plumage); tail and flight-feathers blacker-looking, only slightly glossed; iris dull blue or pale blue; bill and legs black. Sexes similar. Juvenile has brown iris, is dull greyish-black overall, lacks contrasting velvety black appearance of forehead and lores, and tail lacks expansion at tip. Voice. Nasal mewing call. Also, often utters high-pitched but gruff "chu"; deep rasping "churg-churg", often rising to enquiring finish, "churrrk?", or given at higher pitch as "chrrrk-chrrrk" or "gasp-gasp".
Habitat. Lowland open forests to 1000 m in altitude, with clearings about villages and plantation edges, also mixed secondary growth, including fringes of mangroves.
Food and Feeding. Omnivorous. Surprisingly poorly known, with little precise information. Known to feed on variety of invertebrates, with fondness for large beetles (e.g. Scarabaeidae), and doubtless also fruits and berries. Forages almost entirely inside foliage of bushy growth and in lower to middle canopy of larger trees. Usually encountered singly, in pairs or in family parties, moving through cover. Hops and climbs up through hanging tangles with agility, using tails as a counterbalance; in this repect, reminiscent of malkohas (*Phaenicophaeus*). Rarely seen on the ground, except when bathing. Seldom flies far.
Breeding. Poorly studied. Eggs reported in Apr–Aug in Myanmar and Thailand and Apr in N Vietnam (Tonkin). Solitary breeder. Nest constructed from twigs, tendrils and creeper stems, cup lined with finer tendrils and rootlets, generally well hidden in dense cover 2–5 m above ground inside shrubby cover, preferably in isolated shrubby thicket or bamboo clump, hanging creepers, surrounded by open grassy area. Clutch 2–4 eggs. No other information.
Movements. Sedentary, as far as is known.
Status and Conservation. Not globally threatened. Not uncommon in most of range. Formerly occurred in extreme NW Peninsular Malaysia (Kedah), but apparently extirparted there; was quite frequent in 1930s and 1940s, but only one report since, in 2003; reasons for this local disappearance unclear. A 19th-century specimen said to have been taken at S tip of Sumatra and two from Borneo are regarded as erroneous; at least one of these considered to have originated from Java. Reliance on lowland forest makes this species vulnerable to habitat destruction and distributional fragmentation. Main factor in its favour for future survival is its tolerance of secondary forest, and the fact that it is often seen around forest clearings with human habitation.
Bibliography. Dickinson *et al.* (2004), Glenister (1951), Goodwin (1986), Lekagul & Round (1991), MacKinnon & Phillipps (1993), Madge & Burn (1994), Robson (2000), Thomas & Poole (2003), Vaurie (1958a), Wells (2007).

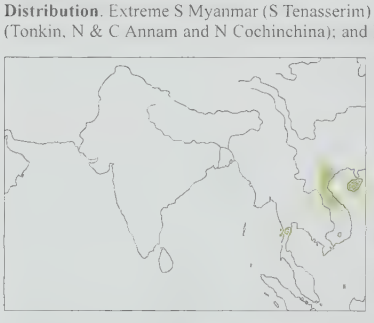
63. **Hooded Treepie**

Crypsirina cucullata

French: Témia à collier **German**: Kapuzenbaumelster **Spanish**: Urraca Encapuchada
Other common names: Hooded Racket-tailed Treepie

Taxonomy. *Crypsirina* (*Temia*) *cucullata* Jerdon, 1862, Thayetmyo, Myanmar.
Monotypic.
Distribution. Lowlands of C & S Myanmar.

Descriptive notes. 29–31 cm; c. 130–135 g. Small, slender light grey treepie with distinctive black hood and wings and very long black tail (of ten, not twelve, rectrices) which has almost spoon-shaped expansion at tip, rather short but stout bill with curved culmen; feathers of forecrown and lores soft and velvet-like, forming cushion over nares. Hood from upper nape down to throat black with oily green sheen, narrow whitish-grey border surrounding hood, being most noticeable on nape; body plumage almost uniformly light grey, washed bluish-grey above and mauve-fawn below; upperwing-coverts and tertials fawn-grey, greater coverts fringed whitish, tertials tipped whitish, primaries and primary coverts black, outer secondaries blackish with whitish outer webs (forming narrow white panel on folded wing); central tail feathers black, remainder pale fawn-grey (these normally concealed when tail closed; iris dark blue, orbital ring blackish; bill and legs black. Sexes similar. Juvenile is duller and browner grey than adult, with dark brown hood, tail tip narrow (not spoon-shaped), bill blackish, with extensive orange inside mandibles and at base of lower mandible, iris probably dark brown, narrow light blue orbital ring; after first moult, differs from adult in being darker grey above, lacking narrow pale border to hood, retains narrow-tipped tail feathers, gape patch smaller and yellower than juvenile; some yellow may be visible on gape into second year. Voice. Poorly documented. Contact call a quiet purring "drrrriiii'k"; said also to give several harsh, discordant calls.
Habitat. Lowland open dry forests to 950 m, in plains of R Irrawaddy and R Sittang; little of this forest remains, but it seems to survive in remaining patches of deciduous woodland. Also about stands of bamboo and in thorn-scrub jungle, with clearings surrounding villages, and mixed secondary growth.
Food and Feeding. Little precise information. Reported prey items included grasshoppers and locusts (Orthoptera), mantids (Mantidae) and winged termites (Isoptera). Feeds almost entirely inside foliage of bushy growth and in lower to middle canopy of larger trees. Usually encountered singly, in pairs or in family parties, moving through cover; flocks of up to 30 recorded on occasion.
Breeding. Poorly studied. Eggs reported May and Jul. Solitary breeder. Nest described as resembling small, neat version of that of *Pica pica*, based on protective exterior of thorny twigs, which are continued over nest as partial dome; well hidden inside dense thicket or small tree. Clutch (three known) 2–4 eggs. No other information.
Movements. Sedentary, as far as is known.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Irrawaddy Plains EBA. Recently found to be not uncommon in suitable habitats. Partial reliance on lowland dry forest could render it vulnerable to habitat destruction. Main factor in its favour for its future survival is its tolerance of secondary forest and even scrub-jungle, and the fact that it is often seen around clearings with human habitations.
Bibliography. Anon. (2008p), Butchart & Stattersfield (2004), Goodwin (1986), Madge & Burn (1994), Robson (2000), Robson *et al.* (1998), Smythies (1953), Stattersfield & Capper (2000).



Genus *TEMNURUS* Lesson, 1831

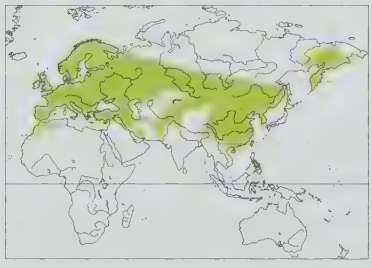
64. Ratchet-tailed Treepie

Temnurus temnurus

French: Témia temnure **German**: Leiterschwanzelster **Spanish**: Urraca de Raquetas
Other common names: Notch-tailed Treepie

Taxonomy. *Glaucopis temnura* Temminck, 1825, Cochinchina, Vietnam.
Monotypic.
Distribution. Extreme S Myanmar (S Tenasserim) and adjacent SW Thailand; C Laos and Vietnam (Tonkin, N & C Annam and N Cochinchina); and Hainan I (S China).

Descriptive notes. 32–35 cm; c. 138 g. Rather small, dark treepie with fairly long, graduated tail (of ten, not twelve, rectrices), rather stout bill with curved culmen; feathers of forecrown and lores soft and velvet-like, forming cushion over nares. Entire plumage is blackish, with weak sheen on head, wing and tail; tip of each rectrix notched into a pair of pointed extensions, which project sideways down each side of tail (points not always obvious); iris dark brown or red; bill and legs black. Sexes similar. Juvenile undescribed; first-year has retained juvenile tail feathers, which narrower than those of adults and with terminal points shorter or perhaps lacking. Voice. Quite varied vocabulary. Pair-members often call in duet, one giving incisive start followed by a ringing terminal note, "clipeeee", mate coming in with rapid double hollow "pupu" at start, "pupueeee". Variations on a similar theme are a ringing double "clee-clee" and a constantly repeated squeaky two-syllable call, ringing and with rising inflection, "eeup, eeup, eeup…". Also gives short, high-pitched rasping "rrrrrrrrr" and harsh grating, but very slow chatter, "graak graak graak".
Habitat. Lowland and hill forests, chiefly dry broadleaf evergreen forests to at least 1200 m; also mixed secondary growth with stands of bamboo, forest edges and scrubby, grassy clearings, even around villages.
Food and Feeding. Surprisingly poorly known, with little precise information. Known to feed on variety of insects and other invertebrates. Observed singly, in pairs and in family groups, often with mixed foraging parties of other birds, especially Greater Racquet-tailed Drongos (*Dicrurus paradiseus*). Often sits rather upright at mid-canopy level.
Breeding. Little known. Eggs reported Apr–Jun. Solitary breeder. Nest built from twigs, with shallow cup; few nests found have been inside bamboo thickets. Clutch 2 eggs. No other information.
Movements. Sedentary, as far as is known.
Status and Conservation. Not globally threatened. Widespread and not uncommon in Laos and Vietnam; little known in rest of range. Easily overlooked, being quite sluggish and rather unobtrusive in habits, but draws attention to itself by persistent calling. In 1991, population discovered unexpectedly in Kaeng Krachan National Park, in SW Thailand; habitat there is continuous with forest in Myanmar, and part of one of largest remaining stretches of forest in SE Asia. Reliance on lowland forest makes it vulnerable to habitat destruction. Loss of forest on Hainan does not bode well for its future there.
Bibliography. Chen Fuguan *et al.* (1998), Dickinson *et al.* (2004), Duckworth *et al.* (2002), Ericson *et al.* (2005), Goodwin (1986), Hartlaub (1899), Kalyakin (1996), MacKinnon & Phillipps (1993), Madge & Burn (1994), Robson (2000), Robson *et al.* (1993).



Genus *PICA* Brisson, 1760

65. Common Magpie

Pica pica

French: Pie bavarde **German**: Elster **Spanish**: Urraca Común
Other common names: Eurasian/Pied Magpie; Black-billed Magpie (when treated as conspecific with *P. hudsonia*); Maghreb Magpie (*mauritanica*); Kamchatka Magpie (*camtschatica*); Tibetan/Black-rumped Magpie (*bottanensis*); Oriental Magpie (*serica*)

Taxonomy. *Corvus pica* Linnaeus, 1758, Uppsala, Sweden.
Forms a superspecies with *P. asirensis*, *P. nuttalli* and *P. hudsonia*, and often treated as conspecific with first and/or last of those. Several races possibly warrant elevation to species rank, pending further research into comparative vocalizations and social behaviour as well as DNA molecular studies: N African *mauritanica* may have reached species level, but Spanish *melanotos* approaches it in several respects and may be more closely allied to it than to nominate race; distinctive *camtschatica* of NE Siberia is also isolated, while *bottanensis* of Tibetan region differs strongly from neighbouring forms, but is said to intergrade with *anderssoni* in N of its range; SE Asian *serica* exhibits interesting similarity to European races, although it seems that such superficial similarity may not be supported by findings of DNA studies. Many intergrading populations exist. A number of other races have been described, but situation complicated by intermediates (e.g. *anderssoni* is possibly an intermediate series of populations): *galliae* (from France) and *germanica* (Germany) are included in nominate race; *kot* (E Ukraine), *laubmanni* (Kelat, in Pakistan) and *hemileucoptera* (C Siberia) in *bactriana*; *japonica* (Japan), *amurensis* (near Khabarovsk, in Ussuriland) and *jankowskii* (near Vladivostok) in *anderssoni*; and *hainana* (Hainan I) and *alashanica* (Ala Shan, in C China) in *serica*. Race *serica* often misspelt "*sericea*". Ten subspecies currently recognized.
Subspecies and Distribution.
P. p. fennorum Lönnberg, 1927 – N Scandinavia, Finland and NE Baltic region E to W Siberia.
P. p. pica (Linnaeus, 1758) – from British Is and S Scandinavia E to E Europe, S to Mediterranean, including most islands.
P. p. melanotos A. E. Brehm, 1857 – Iberian Peninsula.
P. p. mauritanica Malherbe, 1845 – N Africa (Morocco, N Algeria and Tunisia).
P. p. bactriana Bonaparte, 1850 – Siberia E to L Baikal, S to Caucasus, Iraq, Iran, C Asia and Pakistan.
P. p. leucoptera Gould, 1862 – S Transbaikalia (Russia), Mongolia and NE China (Inner Mongolia and NW Heilongjiang.
P. p. camtschatica Stejneger, 1884 – N Sea of Okhotsk, Kamchatka and Anadyrland (in Russian Far East).
P. p. anderssoni Lönnberg, 1923 – SE Russia (Ussuriland), extreme NE China and Korea.
P. p. bottanensis Delessert, 1840 – WC China (Qinghai and W Sichuan S to S & E Xizang) and C Bhutan.
P. p. serica Gould, 1845 – E & S China, Taiwan, N Myanmar, N Laos and N Vietnam.
Introduced (race *serica*) on Kyushu (Japan).

Descriptive notes. 46–50 cm; 200–270 g (various races), male 185–247 g and female 161–240 g (nominate), male 214–268 g and female 208–232 g (*leucoptera*). Very distinctive magpie, mainly black and white, with long, graduated tail, medium-sized bill relatively wide at base, culmen downcurved distally. Nominate race has head down to breast and most of upperparts black with inconspicuous purple and green sheen; scapulars white, narrow greyish band across rump; upperwing black, highly glossed green or greenish-blue on secondaries and tertials, inner webs of primaries white with black tips and bases, white usually concealed when bird at rest (but forming huge band on opened wing); tail black, highly glossed with green and reddish-purple, becoming almost matt black at very tip; flanks and central underparts white, lower belly, tibia feathering and undertail-coverts black; iris dark brown; bill and legs black. Sexes similar. Juvenile is similar to adult but duller, with black areas of plumage unglossed and sooty black, white areas tinged buffy, when recently fledged has patches of bare grey or grey-blue skin around eye and on malar, becoming much as adult by late summer. Races differ mainly in intensity of gloss in black areas of plumage, extent of white in wing, prominence or absence of white in rump, comparative tail length and size: *fennorum* is larger and has more extensive white on rump than nominate; *bactriana* has prominent white rump, more extensive white in primaries (showing as white tips on closed wing); *serica* is small and dark, remarkably similar to nominate but with relatively shorter tail and greener gloss on secondaries; *anderssoni* resembles previous, but is somewhat larger and paler; *bottanensis* is very distinctive, having black rump, relatively short tail, stout bill, and very little gloss in plumage; *leucoptera* has very extensive white in primaries, and tail gloss is yellowish brass-green; *camtschatica* has most extensive white in primaries, showing as white tips down folded wing, also has brightest and most extensive green gloss of all races; *melanotos* has black rump, extent of white in primaries much as nominate, in S of range sometimes a blue spot of bare skin behind eye; *mauritanica* has black rump, bronze gloss on wings and tail, is relatively longer-tailed than others, and has relatively large blue patch of bare skin behind eye. Voice. Typical call a raucous, explosive rapid chatter, "chak-chak-chak-chak-

chak-chak-chak"; also a single, more relaxed, almost enquiring "ch-tak?" and high-pitched, squealed "keee-uk". Some geographical variation in pitch and speed of delivery of the chattering call, e.g. SE Asian *serica* has a somewhat softer chatter than that of European birds. N African *mauritanica* has higher-pitched chatter, uttered with more undulating rhythm compared with nominate; said also to have a more varied vocabulary than nominate, but seemingly these remarks apply to S Moroccan birds (those in N Morocco seem to be vocally closer to nominate). Like many other corvids, utters a subdued warbling song, interspersed with high-pitched notes and even some mimicry; such songs uttered mainly by unpaired individuals and audible only at close range.
Habitat. Inhabits a tremendous variety of open country, preferably with at least scattered trees. Avoids both tracts of treeless country and extensive woodland or forests. In man-modified landscapes, favours mixed farmland, parks and gardens, with overgrown hedges and small stands of trees. In recent decades increasingly common in urban areas, especially in places with avenues of trees; can reach very high densities in parts of urbanized Europe.
Food and Feeding. Omnivorous, but chiefly a carnivorous scavenger. Diet varies according to local habitats, basically of invertebrates, especially beetles (Coleoptera), and small mammals and lizards, frogs, bird eggs and nestlings, as well as carrion. Pairs patrol roadsides in the early mornings, exploiting overnight roadkills. In addition, various seeds, berries and fruits are taken seasonally. Takes a variety of food scraps, and where unmolested can become cautiously confiding around picnic sites and in city parks, regularly visiting refuse bins. Feeds almost entirely on ground, walking with bold, strutting gait, carrying tail upwards as it searches for insects; side-hops to catch prey. Perches on cattle and sheep to feed on ectoparasites, such actions sometimes resulting in aggravated sores for the host animal. Freely stores food, but usually retrieves items within a few days. Although not known for its agility in the air, will pursue other birds to force them to drop or regurgitate food items; exceptionally, recorded as capturing small birds in flight, including a House Sparrow (*Passer domesticus*). Normally utilizes lowest air-space, flying between trees with undulating flight action, sweeping up to perch just inside canopy. Although often encountered in pairs or family parties, larger groups are not uncommon, and assemblages of 20 or more gather for communal roosts. In Turkmenistan as many as 2000 have been estimated at one winter gathering, and in the Tibetan region of Asia ten magpies were counted as they left a single roosting nest; it seems that Tibetan individuals build several roosting nests, very close to or contiguous with one another, for added warmth. Biggest known urban roost is in L'viv (Lwow), in W Ukraine, where 1700 individuals recorded. Roosts in towns tend to be larger than those in farmland.
Breeding. Season commences with nest-building as early as Dec in Britain, mid-Apr being peak time for first egg-laying; dates similar elsewhere in Europe and, surprisingly, in Turkmenistan, but later, with laying chiefly last week Apr, in C Siberia; single-brooded. Monogamous long-term pair-bond, partners keeping together throughout year, even when flocking. Solitary nester. Nest construction undertaken by both sexes, female doing bulk of building, male supplying most of materials, work takes 1–8 weeks (depending on experience of builders and availability of materials); nest a rather large, distinctively domed structure (occasionally undomed, especially in urban areas, where up to 32% of nests may be open), made from sticks and twigs, with side entrance protected by thorny twigs (in areas where twigs hard to come by, nest occasionally made entirely from wire), deep cup thickly lined with soft materials such as wool, animal fur, soft grasses and feathers, usually placed at variable height in crown of tall tree; normally a fresh nest built each year, although in some cases (e.g. where availability of nest-sites limited) an old nest may be repaired; in more open habitats electricity pylons also used as nest-site (nests on pylons in Khabarovsk region of Amurland/Ussuriland reach massive proportions, as fresh nest built each year on top of previous), and in habitats with few trees a stunted shrub may be used, or nest built on antenna mast or old building or even on ground, sheltered by heather (Ericaceae), stone wall or rocks. Clutch 2–8 eggs, chiefly 5–7; incubation entirely by female, fed at nest by male, period 21–22 days; chicks fed by both sexes, mainly by male, leave nest after 24–30 days, dependent on adults for several weeks further; in autumn, young join up with flocks of non-breeders. Nests parasitized by Great Spotted Cuckoo (*Clamator glandarius*). Able to breed for first time when 15–17 months old.
Movements. Essentially resident; few ringing recoveries of more than 30 km. Those in N Scandinavia move S following adverse weather conditions, in some years flocks gathering in S Sweden and attempting sea crossing to Denmark (apparently relatively few succeed, the majority turning back). Finnish birds, presumably from far N, may move farther than assumed, as indicated by several ringing recoveries of more than 100 km, including one of 450 km. In Siberia, populations in extreme N of range shift S during severe weather, joining gatherings of magpies which are attracted towards towns and settlements from the open countryside. Being in general remarkably sedentary, the species is not prone to vagrancy, but vagrants reported from Singapore, Israel, Lebanon, and Isles of Scilly (off extreme SW England).
Status and Conservation. Not globally threatened. Widespread and common in much of range; locally abundant. In most European countries has apparently increased over recent decades, most notable being its spread into cities from the countryside. Following estimates (territories/pairs) made for countries within W Palearctic: Britain 590,000, Ireland 320,000, France 200,000–700,000, Belgium 19,000, Luxembourg 8000–10,000, Netherlands 60,000–120,000, Germany 280,000–360,000, Denmark 31,000–320,000, Norway 200,000–500,000, Sweden 300,000–600,000, Finland 150,000–200,000, Estonia 50,000–100,000, Latvia 10,000–20,000, Lithuania 70,000+, Poland 400,000–800,000, Czech Republic 40,000–80,000, Slovakia 30,000–60,000, Hungary 100,000–140,000, Austria 4000–5000, Switzerland 20,000–40,000, Italy 100,000–500,000, Spain 220,000–1,200,000, Portugal 10,000–100,000, Greece 30,000–80,000, Albania 10,000–30,000, Croatia 60,000–80,000, Slovenia 8000–12,000, Bulgaria 1,000,000–5,000,000, Romania 100,000–200,000, Russia 1,000,000–10,000,000, Belarus 480,000–500,000, Ukraine 1,300,000–1,500,000, Moldova 60,000–70,000, Azerbaijan 2000+, Turkey 1,000,000–10,000,000; in N Africa, widespread but localized in Morocco and Algeria and few in Tunisia. Densities often high, the highest being 32 pairs/km²; in prime habitat in N England 4–16 pairs/km². In N Africa patchily distributed, nests on average 264 m apart within "patches". Has for long been persecuted as "vermin" by gamekeepers and farmers owing to its egg-stealing and nest-robbing habits; also, its habit of feeding on ectoparasites on livestock sometimes results in aggravated sores for the host animal. A reduction in keepering intensity, especially in W of range, since 1920s, however, has allowed a steady increase, which accelerated in 1950s as the creation of larger suburban gardens and city and town parks provided safer habitats from human persecution; over much of its European range it is still increasing, as urban and suburban areas also provide easy scavenging. Rapid increase noted in 1970s and 1980s in European urban areas, and later in Asian parts of former USSR; colonization of new areas in S (deserts) and N (within Arctic Circle) closely associated with human economic activity in these otherwise inhospitable landscapes. Members of the general public now witness its nest-raiding habits in their own gardens, although extent of damage done by this species to garden bird populations is minimal compared with that inflicted by domestic cats. In SE of its global range, there have been no recent records from Laos and it could well be extinct there; has also become very rare in adjacent Vietnam. As with other corvids, old nests of this species are used by a number of other birds, including Long-eared Owls (*Asio otus*), sparrowhawks (*Accipiter*) and various falcons (*Falco*).

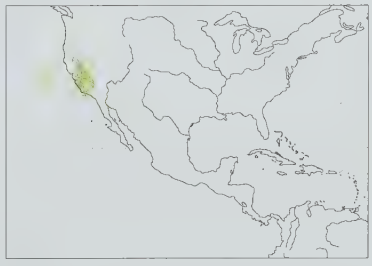
66. Arabian Magpie

Pica asirensis

French: Pie d'Arabie **German**: Asirelster **Spanish**: Urraca Árabe
Other common names: Asir/Asian Magpie

Taxonomy. *Pica pica asirensis* Bates, 1936, Asir Mountains, south-western Arabia.
Forms a superspecies with *P. pica*, *P. nuttalli* and *P. hudsonia*; often treated as conspecific with first of those, but isolation within very restricted range and differences in vocalizations and structural features suggest that treatment as a separate species warranted. Monotypic.
Distribution. Asir massif, in SW Saudi Arabia.



Descriptive notes. 46 cm; 200 g. Unmistakable within its range; distinctive black-and-white corvid with long, graduated tail. Head to breast and upperparts are black with, at most, slight sheen (not obvious), only a little white on outer scapulars, upperwing black, glossed dark purplish-blue on coverts and tertials, inner webs of primaries with white centrally, tail black with dark greenish-purple or bronze-purple gloss; flanks and central underparts white, undertail-coverts, lower belly and tibia feathering black; plumage prone to bleaching when worn (exposed glossy parts of wings and tail become dull bronze-brown); iris dark brown; bill and legs black. Differs from *P. pica* mainly in having more extensive black in plumage, wholly black rump, narrower white scapular patch, less extensive white in primaries, also tail relatively shorter, bill relatively larger, foot stronger. Sexes similar. Juvenile is similar to adult but duller, with black areas of plumage unglossed, and white areas washed with brown. Voice. Calls very different from those of *P. pica*. Three types of call described: a full, loud "quaynk-quaynk" given from top of bush or when a party is on the move; weaker "quenk, quenk" when bird alarmed or stressed during foraging; and soft "qua, qua" by food-begging young. Seems to be very vocal, group-members keeping in contact as they forage.
Habitat. Restricted to juniper (*Juniperus*) forest and well-vegetated wadis, at 2400–3000 m.
Food and Feeding. Omnivorous, but few details. Recorded food items "insects", caterpillars, juniper berries, also food scraps from picnic sites, including boiled rice, also fallen grain and fruiting figs (*Ficus*). Forages in small groups of up to seven individuals, presumably family parties; rarely seen alone. Roosts in trees in well-vegetated wadis, foraging ceaselessly from dawn to dusk (can be from 05:20 to 19:20 hours) over area 2–3 km from roost-site. At first light group leaves roost and scatters into nearby trees, moving on after a few minutes.
Breeding. Egg-laying in early Feb. Nest typical of genus, a somewhat oval mass of twigs with side entrance, interior cup lined with soft plant materials (chiefly rootlets) and feathers, placed c. 5–6 m above ground at base of fork in juniper tree, rarely in acacia (*Acacia*); seems to build fresh nest each year. Both sexes feed the young. No other information.
Movements. Sedentary.
Status and Conservation. Not assessed. Hitherto treated as a race of *P. pica*. Possibly globally Near-threatened or threatened. Research indicates that perhaps fewer than 500 individuals survive; these now restricted to Abha and 120 km to N, and at Jibal al Qahr. Older reports indicate that range once extended throughout the Asir, even as far N as Taif. The lush vegetation in this part of Arabia is under threat from development for tourism, and climatic change is producing hotter and drier weather, forcing this species into pockets of remaining suitable habitat.
Bibliography. Bates (1936), Birkhead (1991), Cramp & Perrins (1994), Ebels (2003), Goodwin (1986), Madge & Burn (1994), Yahya (1998), Yahya & Salamah (1996).

67. Yellow-billed Magpie

Pica nuttalli

French: Pie à bec jaune **German**: Gelbschnabelelster **Spanish**: Urraca de Nuttall

Taxonomy. *Corvus nutalli* [sic] Audubon, 1837, Santa Barbara, California, USA.
Forms a superspecies with *P. pica*, *P. asirensis* and *P. hudsonia*. Sometimes treated as conspecific with first and/or last of those; recent analysis of mitochondrial genome suggests that *P. hudsonia* and present species are sister-taxa, closely related to *P. pica*, the three exhibiting low average divergence (only 2·35%), suggesting that they may be better considered conspecific. Emended spelling of species name has prevailing usage. Monotypic.
Distribution. California W of Sierra Nevada Mts (Sacramento Valley, San Joaquin Valley, and valleys of S Coast Ranges), in SW USA.

Descriptive notes. 43–54 cm; male 151–189 g, female 126–158 g. A medium-sized black-and-white corvid with long, graduated tail and yellow bill; most black areas strongly glossed blue. Head to upper breast and upperparts are black, head with slight green gloss, scapulars white, upperwing and tail black with conspicuous blue-green iridescence, inner webs of primaries white with black tip; lower breast to upper belly and flanks white, lower belly and undertail-coverts black; iris dark brown, variable patch of yellow skin above and below eye (sometimes fully around eye); bill yellow; legs black. Differs from *P. hudsonia* mainly in noticeably smaller size, proportionately longer wing, yellow bill. Sexes alike in plumage, male 10–17% larger than female. Juvenile is duller than adult, dark areas of plumage browner, looser in texture, and with less iridescence than adult; mouth lining fully black by second year. Voice. Not well studied. Stacatto, harsh "chatter" alarm call similar to that of *P. hudsonia*, but slower and higher-pitched (208 KHz) than chatter of *P. pica*. Soft, babbling song by male (may help to bring

female into breeding condition). Fertile female gives "clear" call, which is a begging call with rising inflection directed at mate with accompanying wing-flapping from two days prior to egg-laying. Accomplished mimic.

Habitat. Oak (*Quercus*) savanna where large trees are scattered among broad expanses of open grassland and pasture; forages also in cultivated fields and orchards. Water and large insects must be present throughout year. Increasing in abundance in some suburban settings, notably those in Sacramento Valley. Tolerates temperatures considerably warmer than those within range of *P. hudsonia*.

Food and Feeding. Omnivorous. Eats grasshoppers (Orthoptera), Lepidoptera, bees, ants and wasps (Hymenoptera), beetles (Coleoptera), true bugs (Hemiptera), and flies (Diptera), also (and observed to drown) mice (Muridae) and voles (Cricetidae); preys on bird eggs and nestlings, likely also small reptiles; readily consumes carrion (especially roadkills), and human handouts and offal. Variety of cultivated grains, fruits, and nuts also taken. Caches acorns (in trees and ground) in autumn, and supplements diet with large variety of other native fruits and seeds. More insectivorous and less of a predator and scavenger than *P. hudsonia*. Forages in flocks (often with other species), mainly on ground, for invertebrates (especially large Orthoptera and Lepidoptera). Forages with cattle, perhaps taking insects flushed by grazing herd; gleans insects from backs of ungulates and horses. Picks food from ground, or digs into soil and litter; flips over cow dung, makes flycatching sorties, and hunts from perches.

Breeding. Nest-building from late Dec to Mar, egg-laying mid-Mar to early May. Monogamous, apparently lifelong pair-bond. Male and some females pursue extra-pair copulations, male guards mate during fertile period, but female alone in nest or nest tree during egg-laying period. Loosely colonial, in groups of 3–30 pairs with average inter-nest distance 38 m (coloniality may account for nore frequent extra-pair copulations compared with *P. pica*), defends small core area (0·6–1·9 ha) around nest. Nest built by both sexes, female doing most of shaping of bowl and lining, construction work taking up to two months, a large, globe-shaped dome (up to 0·9 m in diameter), including a platform and domed roof of coarse twigs (less than 30 cm long), and a mud bowl lined with animal hair, grass, shredded bark or rootlets, placed high up (average 14·2 m) in large tree, typically oak, generally in mistletoe (Loranthaceae) clump and at end of long branch (to thwart predators); sometimes a refurbished old nest reused; Bullock's Oriole (*Icterus bullockii*) appears to nest preferentially within colonies of present species (benefiting from latter's effective anti-predator defence, thus achieving lower nest-predation rates). Clutch 4–9 eggs, usually 6–7; incubation by female alone, starting before clutch complete, period 16–18 days; hatching often asynchronous, chicks brooded by female, fed by both sexes, nestling period 30 days; young fed by both parents for up to 16 days after fledging; young from nests within colony may gather in crèche, but quickly form larger flocks containing young from several colonies. Majority of successful nests fledge only two or three young; starvation is major source of chick death (asynchronous hatching facilitates brood reduction).

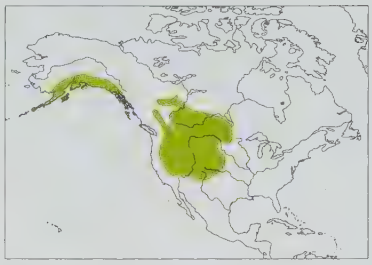
Movements. Resident. Most juveniles not seen after they disperse, but a few males known to have obtained breeding territory within natal colony or in nearby colony (average 1260 m from natal territory); young females apparently disperse more widely. Occasional casual wandering, straying N almost as far as Oregon.

Status and Conservation. Not globally threatened. Restricted-range species: present in California EBA. Inhabits area of c. 240 × 800 km of bottomland and adjacent low foothills of Sacramento Valley (S from Redding) and San Joaquin Valley (S to base of Breckenridge Mt), and valleys of Coast Ranges from San Francisco Bay S to Goleta, Santa Barbara County. Home range during breeding averages 22·8 ha, expanded slightly to average 33·1 ha during non-breeding season. Small historical range, in which formerly common. Overall population drastically reduced since introduction of West Nile Virus to range in 2004: population of 180,000 birds in 2003 thought to have been reduced by 49% by 2006; presence in urban roosts greatly declined due to extreme mortality from the virus. Prior to 2004, locally abundant in some areas, e.g. Sacramento, although already declining in other areas as oak savanna was exploited for development, e.g. Salinas Valley and sprawling areas S of San Francisco. Vulnerable to poisons used for killing ground squirrels (Sciuridae), but able to learn by observation to avoid tainted baits and dangerous situations. Current threats, in addition to West Nile Virus and habitat loss to development and agriculture, include summer droughts, which reduce abundance of large insects, and Sudden Oak Death, which can reduce oak trees characterizing preferred habitat. Colony resilience dependent on low adult mortality (70% annual survival normal) and dispersal from other colonies to fill breeding vacancies.

Bibliography. Anon. (2000a), Birkhead (1991), Birkhead *et al.* (1992), Blackburn (1968), Bolen (1999), Bolen *et al.* (2000), Crosbie (2004), Crosbie *et al.* (2008), Enggist-Dublin & Birkhead (1992), Hayworth & Weathers (1984), Hope (1989), Kalmbach (1927), Klicka & Zink (1997), Koenig & Reynolds (1987), Lee Sang-Im *et al.* (2003), Linsdale (1937), Reynolds (1990, 1995), Richardson & Bolen (1999), Saunders & Edwards (2000), Verbeek (1972a, 1972b, 1973), Wiggins (1947), Zink *et al.* (1995).

68. Black-billed Magpie

Pica hudsonia



French: Pie d'Amérique **German**: Hudsonelster **Spanish**: Urraca de Hudson
Other common names: American Black-billed Magpie

Taxonomy. *Corvus hudsonia* Sabine, 1823, Cumberland House, Saskatchewan, Canada.

Forms a superspecies with *P. pica*, *P. asirensis* and *P. nuttalli*, and often treated as conspecific with first or all of those; recent analysis of mitochondrial genome suggests that *P. nuttalli* and present species are sister-taxa, closely related to *P. pica*, the three exhibiting low average divergence (only 2·35%), suggesting that they may be better considered conspecific. Monotypic.

Distribution. Coastal S Alaska (E from Alaska Peninsula and Shumagin Is) and SW Canada (SW Yukon, extreme NW & E British Columbia, N Alberta, C Saskatchewan, C Manitoba, extreme SW Ontario) S in W USA to NE & EC California (to Inyo County), SC Nevada, Utah, extreme NE Arizona (Apache County), N New Mexico, W (casually also NE) Oklahoma, C Kansas, and Nebraska (except SE).

Descriptive notes. 45–60 cm; 135–210 g, male 176–216 g and female 141–173 g (Idaho). A medium-sized, black-and-white corvid with long iriscent tail and a black bill. Has head to upper breast and upperparts black, scapulars white, upperwing and tail with metallic blue-green iridescence, primaries with black outer web, white inner web and black tip (large white wing patch in flight); lower breast to upper belly and flanks white, lower belly and undertail-coverts black; iris dark brown; bill and legs black. Differs from *P. nuttalli* mainly in noticeably larger size, longer tail, proportionately shorter wing, black bill. Sexes alike in plumage, male 6–9% larger and 16–20% heavier than female. Juvenile is duller and buffier than adult, plumage looser in texture, with less iridescence, tail feathers more rounded at tips; after first moult (Jul–Oct), immature similar to adult but with smaller white wing patches, mouth lining fully black by second year. Voice. At least 15 distinct calls identified. Only well-studied call the alarm call, or "chatter", a graded call of variable

length and intensity that reflects caller's motivation: "basic chatter" a harsh rattle lasting minimum of 0·12 seconds, used for assembling individuals around ground or perched predator or dead conspecific; "staccato chatter" a more general alarm that disperses magpies from immediate area, given to warn of aerial predator. Many other tweets, trills, coos, purrs, squawks, shrieks, screams and yelps described for *P. pica* and likely used by present species. A soft "shrill" call given only by female in response to mate returning with food. Female utters (from two days before egg-laying) loud, high-pitched whining cries ("clear call") while crouched and flapping wings to beg from mate. Three renditions of singing are recognized (babble, soft, and rhythmic singing); song given mostly by male during courtship or assertive behaviour, even towards intruding predators or people. Between partners a "chirp" (female) and "crunch" (male) given. Mimicry recorded in captivity, but apparently not in wild.

Habitat. Arid shrub-steppe, favouring landscapes with clumps of shrubs and trees along rivers and streams, on islands, or interspersed in more open meadow, grassland and sagebrush (*Artemisia*) areas. Dry, open pine (*Pinus*) forests and suburban areas in and adjacent to shrublands readily used. Forest edges and suburban or agricultural settings used, especially in N part of range. Common in farm and rangelands that maintain scattered trees and hedgerows. Generally in cooler climate than that tolerated by *P. nuttalli*.

Food and Feeding. Omnivorous. Eats carrion, also invertebrates, including ground beetles (Coleoptera), grasshoppers (Orthoptera), worms (Oligochaeta), also small vertebrates, occasionally as large as rabbits (Leporidae); preys on bird eggs and nestlings, and occasionally catches small adult birds on the wing; some plant material taken. Generally considered more of a scavenger and predator than is *P. nuttalli*. Nestling diet primarily ground-dwelling invertebrates. Scatterhoards abundant foods, mainly carrion and plant material, for short periods (behaviour possibly facilitated by well-developed hippocampus); olfaction utilized to recover and steal caches. Forages alone or in small flocks, mainly on ground. Picks food from ground, or digs into soil and litter, flips over cow dung; also flycatches, and hunts from perches; gleans insects, especially winter ticks (Ixodoidea), from backs of ungulates. Closely associated with predators, from which it scavenges and steals. Precedes and outmanoeuvres larger scavengers such as ravens (*Corvus*) and canids at roadkills and at kills made by grey wolves (*Canis lupus*).

Breeding. Nest-building from late Jan/Feb (later in higher and more N parts of range; relatively earlier in suburban areas than in wild lands), and egg-laying from late Mar to early Jun (mostly in mid-Apr). Pair formation occurs in autumn and winter, when many individuals flock together. Forms monogamous, sometimes lifelong pair-bond (divorce rate varies geographically, 8–63%); female solicits extra-pair copulations, against which mate guards, and which other mated males regularly pursue, but extra-pair copulations less frequent than in *P. nuttalli*. Solitary nester, but nests more clumped than those of *P. pica*, average inter-nest distance varies within range 55–300 m (much shorter than that of most *P. pica* populations); defends area of 30–50 m around nest. Nest built by both sexes, female doing most of shaping and lining of bowl, construction work taking c. 43 days, a platform and usually a domed roof of coarse twigs, interior mud bowl lined with animal hair, grass, shredded bark or rootlets (fewer than 2% of nests undomed), placed in great variety of locations typically 1–9 m above ground, depending on available trees or artificial structures (where human persecution exists, nests higher in trees if alternatives available); nest placement may involve local traditions such as use of utility poles and abandoned buildings, coniferous as opposed to deciduous trees, and sites overhanging water; sometimes refurbished old nest reused. Clutch 1–9 eggs, usually 6–7 (number increasing with female age and pair-bond duration); incubation by female alone, starting before clutch complete, period c. 18 days; hatching often asynchronous, chicks brooded by female, fed by both sexes, nestling period 24–31 days; young fed by both parents for up to 6–8 weeks after fledging; in late summer and autumn, juveniles form large flocks of several hundred individuals. Majority of successful nests fledge 3–4 young; starvation is major source of chick death (asynchronous hatching facilitates brood reduction).

Movements. Primarily resident. Some extensive movements outside breeding season, breeders returning each year to within a few hundred metres of previous nest; wanders in some winters to Pacific coast, upper Midwest, and S Texas. Local post-breeding movements include altitudinal shift (upslope in Idaho, downslope in British Columbia) or movement from inland to coast (e.g. British Columbia). Large flocks observed unpredictably in new areas (e.g. 1500 individuals in Death Valley in 1919). Dispersal of juveniles greater than for *P. pica*, and similar to that of *Perisoreus canadensis* in that dominant siblings disperse less than do subordinates; thus, in S Idaho, males (dominant over females) disperse on average 560 m and females 1034 m; dispersers may travel widely, movements of 354 and 580 km recorded.

Status and Conservation. Not globally threatened. Locally common. Populations currently stable or slightly declining. Range appears limited by climatic factors, especially temperature and humidity; high temperature and high humidity keep species W of 100° W, and extreme heat in S part of range limits species to elevations above 480 m. Breeding density varies, generally 2–35 pairs/km², but up to 200/km² in parts of S Idaho; home range c. 40 ha. In last several centuries, this species has certainly declined and its range contracted as wild bison (*Bison bison*) were nearly extirpated, poisons were widely dispersed to kill wolves and coyotes (*Canis latrans*), and extensive areas of shrub-steppe were converted to monocultures of intensively farmed row crops. Locally, some populations have increased in areas where grasslands have become savannas with trees, contiguous forests have become fragmented, and agriculture and urban sprawl have supplemented food availability while maintaining nesting habitat (e.g. in Minnesota, Arizona, Alberta, and Owens Valley of California). Despite being widely distributed, this corvid is vulnerable to poisons, habitat loss through development and agriculture, and exotic and increasingly common diseases (e.g. West Nile Virus) throughout range.

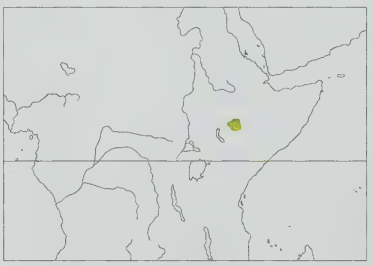
PLATE 35 ➤



Genus *ZAVATTARIORNIS* Moltoni, 1938

69. **Stresemann's Bushcrow**

Zavattariornis stresemanni

French: Corbin de Stresemann **German**: Akazienhäher **Spanish**: Urraquita de Stresemann
Other common names: Bush-crow, Ethiopian/Abyssinian Bushcrow, Zavattariornis

Taxonomy. *Zavattariornis stresemanni* Moltoni, 1938, Yabelo, region of Borana, southern Ethiopia.
Although long regarded as a member of present family, possesses a number of atypical features, notably its sucking-lice (Mallophaga), and several anatomical peculiarities (including mobility of bare facial skin and structure of palate); has occasionally been placed in monotypic family, Zavattariornithidae, but more recently has been included in starling family, Sturnidae, its small size and sociable behaviour being suggestive of, especially, Wattled Starling (*Creatophora cinerea*). DNA-sequencing analysis, however, supports its inclusion in present family, with closest relatives *Podoces*, *Pica* and the peculiar *Ptilostomus afer*; also, its large domed stick nest is reminiscent of that of some *Pica* species; similarities in plumage colour and pattern have been noted with *Nucifraga columbiana* and *Podoces panderi*, but taxonomic significance doubtful. Monotypic.
Distribution. Small area circumscribed by towns of Yabello, Meega and Arero, in S Ethiopia.

Descriptive notes. 28 cm; c. 130 g. An unmistakable pale grey corvid with striking black tail and wings; relatively long square-ended tail, relatively slight bill with culmen decurving to pointed tip; chin feathers finely hair-like, can form small tuft when erected; bare skin around eye "inflatable" so that eye narrows to horizontal slit, and surrounding feathers and bristles move to expose oblong patch of pinkish skin behind eye. Has head, mantle, scapulars, back, rump and uppertail-coverts delicate light grey, shading whitish on forehead, upper ear-coverts and throat; lesser and median upperwing-coverts grey, contrasting with slightly

glossed blue-black remainder of wing; tail wholly blue-black; chin and throat whitish, breast and flanks pale grey, becoming whitish on rear flanks, tibia, belly and undertail-coverts; iris blackish-brown, bare skin on lores and around eye bright azure-blue, triangular patch of reddish skin behind eye; bill and legs black. Sexes similar. Juvenile is slightly duller than adult, with creamy-fawn fringes on body feathers and lesser and median upperwing-coverts, duller and greyer facial skin, bill and legs. Voice. Very vocal, calling regularly during foraging. Most frequent calls include single metallic "kej" as main contact call, also a nasal, rapid "kerr kerr kerr..." often given in flight. Other vocalizations less obvious or less frequently uttered, include metallic "kaw, kaw, kaw..." by allopreening adults, rapid "how, how, how...", single quiet "quak" notes and low, soft, variably repeated "guw", all given occasionally by foraging flocks; nest-building adults give occasional low "keh", and a single deep "waw" has been heard from adults when rubbing bills together.
Habitat. Flat savanna with mature acacia (*Acacia*) and *Commiphora* thornbush at c. 1300–1800 m. Favours stands of mature thornbush with intervening open short-grass savanna; densities greatest where large stands of acacias close to grazing pasture or cultivated fields. Very scarce in broadleaf *Combretum–Terminalia* woodland. Important factor for this species is presence of relatively deep, rich soil.
Food and Feeding. Almost entirely invertebrates, particularly insects, including larvae and pupae. Forages on ground, strutting about alone, in pairs or in parties of five or six individuals; larger gatherings of up to 20 or even 30 perhaps of a temporary nature. Digs vigorously in soil, with bill held slightly open, often carrying prey item (usually Coleoptera larva or pupa) to nearest tree or bush, where it uses foot to hold down food and then kills and eats it. Also hacks into rotten wood in manner of woodpecker (Picidae) to extricate food items. Inspects cattle dung, but not seen to turn dung over. Once seen to alight on back of cow, presumably to search for parasites. Also forages among village rubbish dumps. During emergences of flying insects, chases insects on foot, running with abrupt changes of direction, and repeatedly undertaking flying jumps; on such occasions mixes with other savanna birds, including Red-billed Hornbill (*Tockus erythrorhynchus*), Red-billed Buffalo Weavers (*Bubalornis niger*), Superb Starlings (*Lamprotornis superbus*) and White-crowned Starlings (*Lamprotornis albicapillus*). Also surprisingly agile in trees, walking along horizontal branches and ascending to crown by quickly hopping from branch to branch; parties glide from crown of tree down to ground. Begins foraging around sunrise.
Breeding. Nest-building seems to be triggered suddenly by first rains of the season in late Feb and early Mar; eggs reported latter part of Mar and early Apr, and large nestlings and many fledglings in early Jun. Monogamous, perhaps with lifelong pair-bond. Solitary or semi-colonial nester; 3–5 pairs nesting within 30–100 m of each other, whereas other nests are more distantly scattered (significance of this variation unclear). An additional individual or, rarely, 2–4 more may join in (or be loosely associated) with nest construction and/or help with feeding of young, but such helpers may not be tied exclusively to one nest as have been seen to fly from one nest to another. Complex social relationships, with frequent allofeeding and allopreening not only between partners, but also among other members of group; further study needed. Once initial twig inserted into crown of an acacia, there is much excited commotion from the paired adults, bare blue facial skin being engorged to alter facial expression, this followed by almost ritualistic picking and dropping of acacia leaves, small twigs and bits of soil, before partners chase each other through tree canopy, carrying nesting material. Nest an untidy globular structure c. 30 cm in height and 60 cm wide, entrance at top, made from thorny twigs, first few twigs fixed in place with clumps of damp soil, cattle dung incorporated later, internal chamber c. 30 cm in diameter, lined with dry grass and cattle dung and connected by vertical tunnel to the tapered roof point; placed 2·5–10 m from ground in crown of acacia; often an old nest repaired and enlarged for reuse. Clutch 6 eggs reported; no information on incubation and fledging periods.
Movements. Sedentary.
Status and Conservation. ENDANGERED. Restricted-range species: present in South Ethiopian Highlands EBA. Fairly common but local, with very small global range. Total population fewer than 10,000 individuals. Extremely limited range, and dramatic decrease over recent decades has prompted the upgrading of this species from Vulnerable to present status. Long considered relatively common in patches over its small range, but it has become evident that habitat destruction is escalating. Increasing human population and settlement of formerly nomadic tribes into permanent villages with private land ownership have led to destruction of natural grassland by overgrazing and intensive planting of cash-crops such as maize (*Zea mays*). Many stands of large acacias have been cut for firewood, and many also cleared for the deep, rich soil in which they grow; this soil is optimum for farming, but also crucial for the bush-crow for foraging. Even at Yabello town, widely considered this species' stronghold, it is now found only in surrounding countryside, whereas only a few years previously it could be found in town centre (town has mushroomed in size to become administrative centre for S Ethiopia). Part of the species' range is within Yabello Wildlife Sanctuary, where tree-felling and tree-cutting prohibited, but such regulations impossible to enforce and are widely flouted. Roadside counts suggest an 80% decrease between 1989 and 2003, which does not bode well for this interesting corvid. Although this dramatic decline possibly in part a reflection of habitat alteration along roads themselves, the species remains under threat from habitat transformation caused by agricultural expansion, tree-felling and bush encroachment.

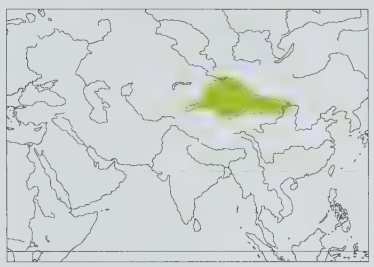
Genus *PODOCES*

J. G. Fischer von Waldheim, 1821



70. Henderson's Ground-jay

Podoces hendersoni

French: Podoce de Henderson **Spanish**: Arrendajo Terrestre Mongol
German: Mongolenhäher

Other common names: Mongolian/Black-tailed Ground-jay, Henderson's Ground-chough, Mongolian Desert Jay

Taxonomy. *Podoces Hendersoni* Hume, 1871, no locality = between Sanju and Koshtak, Xinjiang, China. Forms a species pair with *P. biddulphi*; the two are sometimes united in a separate genus, *Eupodoces*, differing from other two members of genus in having black on crown, relatively long uppertail-coverts and dark legs, and lacking blackish breast patch. Monotypic.
Distribution. SC Russia (Tuva) and W & S Mongolia S to NW & N China (S to Tien Shan, E to NE Qinghai, N Gansu, W Inner Mongolia and Ningxia).

Descriptive notes. 28 cm; 104–140 g. Beautifully patterned little corvid with gently decurved bill, slightly ruffled rear crown, and rather long uppertail-coverts concealing basal half of tail. Centre of crown and nape are glossy black, lores and superciliary area pale sandy; upperparts sandy brown, richest and washed with vinous on scapulars, rump and uppertail-coverts (becoming bleached to sandy-buff overall); apart from sandy-buff lesser and median upperwing-coverts, wing glossy blue-black over inner half (secondaries and coverts, including primary coverts), contrasting with largely white primaries, latter tipped with black and with black bases (some have white tips on outermost secondaries); tail glossy blue-black, outermost feathers with sandy fringes when fresh; sandy buff below, lightest on throat and undertail-coverts; iris dark brown; bill and legs black. Differs from somewhat similar *P. biddulphi* in black (not mostly white) tail, pale (not blackish) face and chin, also (in flight) lack of white trailing edge of secondaries. Sexes similar. Juvenile is similar to adult, but wing dull (not glossy) black, has buff tips on greater coverts in fresh plumage, and black of crown sometimes obscured or dulled by sandy-buff feather tips. Voice. Hardly studied. Calls include harsh penetrating whistle, and a sound likened to the "clack-clack-clack" of a wooden rattle.
Habitat. Flat extensive stony or gravel desert or semi-desert with scattered bushes, e.g. peashrub (*Caragana*), almond (*Amygdalus*) and saxaul (*Haloxylon*), also more locally in sandy deserts with tamarisk (*Tamarix*) thickets. Chiefly between 1000 m and 1700 m, but recorded also down to 200 m in the basins and as high as 3800 m (Xinjiang).
Food and Feeding. Omnivorous. Food during breeding season mainly insects, especially beetles (Coleoptera), and even small lizards recorded; at other times also variety of seeds and other plant materials, and in winter in Mongolia sometimes feeds on meat left to dry on roof of yurt. Digs in soil for insects, especially beetles, for which strong decurved bill useful; also picks seeds from ground or from among animal droppings, and searches along roadsides for spilt grain, maize, wheat, etc. Gait a strutting, almost swaggering walk with upright stance, but, if potential danger threatens, assumes more horizontal posture as it suddenly starts to run; runs well on relatively long legs. Prefers to run, rather than to fly, from potential danger, but will take to the air if hard pressed, flying low just over bushtops, landing and running on again when out of sight.
Breeding. Few nests found. Eggs laid late Mar in W Xinjiang (Kashi) and early Apr in Inner Mongolia (Junggar basin), in China, and late Apr to early May in S Mongolia. Nest a compact bowl of twigs and rootlets, lined with animal hair, feathers and soft plant fibres, well hidden 50–75 cm above ground inside desert bush, more rarely among boulders; one found in Mongolia in Apr 2009 had outer diameter 25 cm, inner diameter 10 cm, exterior made from coarse twigs, interior a neat bowl of fine twigs lined with gazelle hairs, plant fibres and feathers of Pallas's Sandgrouse (*Syrrhaptes paradoxus*), placed 65 cm above ground in saxaul bush. Clutch 3 or 4 eggs; no information on incubation and nestling periods.
Movements. Sedentary, as far as is known. Vagrant to Kazakhstan, with single reliable record in Oct 1962.
Status and Conservation. Not globally threatened. Generally uncommon. In Mongolia not rare, but thinly spread over Gobi desert and in semi-deserts farther north. In China, population studies undertaken in Xinjiang suggest density of c. 5–8 birds/100 km², with estimate of entire Xinjiang population somewhere in region of 50,000 individuals. In Kazakhstan, claimed breeding at L Zaysan is insufficiently documented, and species considered vagrant. Although this corvid's natural predators include large birds of prey, e.g. Long-legged Buzzard (*Buteo rufinus*), Golden Eagle (*Aquila chrysaetos*) and Saker Falcon (*Falco cherrug*), greatest threats involve various human activities. In Xinjiang habitat degradation perhaps the most important overall threat, mining for minerals resulting in destruction of large areas of desert. Overgrazing by domestic camels and goats, and the cutting of scrubby bushes for firewood by nomadic and settled people are also contributing to apparent decline in the species' numbers. Creation of better-quality roads has also taken its toll, as ground-jays forage along roadsides, feeding on roadkill victims and on grain spilt from trucks. Nevertheless, extensive tracts of suitable habitat remain, ensuring its continued survival.

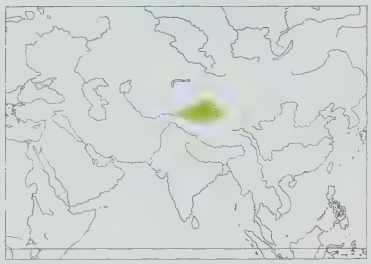
71. Biddulph's Ground-jay



Podoces biddulphi

French: Podoce de Biddulph **Spanish**: Arrendajo Terrestre de Xinjiang
German: Weißschwanzhäher

Other common names: Xinjiang/Sinkiang/Tarim/White-tailed Ground-jay, Biddulph's Ground-chough

Taxonomy. *Podoces Biddulphi* Hume, 1874, Maralbashi, Xinjiang, China.
Forms a species pair with *P. hendersoni*; the two are sometimes united in a separate genus, *Eupodoces*, differing from other two members of genus in having black on crown, relatively long uppertail-coverts and dark legs, and lacking blackish breast patch. Monotypic.
Distribution. Taklimakan Desert (from Yarkand E to Lop Nur) in Xinjiang, NW China.
Descriptive notes. 26·7–31·2 cm cm; male 134–141 g, female 120–132 g. Attractive small corvid with gently decurved bill, slightly ruffled rear crown, and rather long uppertail-coverts conceal-

On following pages: 72. Pander's Ground-jay (*Podoces panderi*); 73. Pleske's Ground-jay (*Podoces pleskei*); 74. Kashmir Nutcracker (*Nucifraga multipunctata*); 75. Spotted Nutcracker (*Nucifraga caryocatactes*); 76. Clark's Nutcracker (*Nucifraga columbiana*).

ing basal half of tail. Centre of crown and nape are glossy black, lores and superciliary area pale sandy; upperparts sandy buff, browner-tinged on scapulars, rump and uppertail-coverts (all becoming bleached to sandy buff); apart from sandy-buff lesser and median upperwing-coverts, wing glossy blue-black over inner half (secondaries and coverts, including primary coverts), contrasting with largely white primaries, latter tipped black and with black bases, secondaries white-tipped (white trailing edge in flight); tail white, some dark markings near feather shafts (appearing essentially white in flight); chin, upper throat and malar region (extending to rear of eye) blackish, finely mottled with pale feather tips (appearing black-throated in field, especially when pale feather tips are worn away), underparts pinkish sandy buff, lightest on undertail-coverts; iris dark brown; bill and legs black. Differs from similar *P. hendersoni* in having black on throat, white tail, white trailing edge of secondaries, slightly slimmer but larger bill. Sexes similar, male somewhat heavier than female. Juvenile is similar to adult, but tail has more extensive, but diffuse, dusky markings and wings are dull (not glossy) black, with buff tips on greater coverts in fresh plumage, the black of crown sometimes obscured or dulled by sandy-buff feather tips. Voice. Hardly studied. Calls include succession of low whistles on rapidly descending scale and a trisyllabic "chui-chui-chui", last syllable of which higher in pitch.

Habitat. Well-vegetated low-lying sandy desert, between 900 m and 1200 m. Favoured habitat is soft sand, forming dunes of varying height (largest exceeding 150 m). Hollows between dunes and dry riverbeds allow access to groundwater in places, permitting growth of desert poplars (*Populus*), tamarisk (*Tamarix*) and even reeds (*Phragmites*), as well as other low-growing plants and shrubs. Readily attends human settlements, including roadworkers' camps, refuse dumps and desert roadsides.

Food and Feeding. Omnivorous, but little studied. Takes variety of seeds, grain and other plant materials; also uses strong decurved bill to dig vigorously in sand for insects, especially beetles (Coleoptera). Picks seeds from among animal droppings, and searches along roadsides for spilt grain and roadkills. Has been observed to cache food items in holes in ground. Observed while drinking from rivers. Perches atop shrubs and trees, dropping to catch a beetle or some other invertebrate before flying off to another bushtop. Normally in pairs or in family parties of up to six individuals; no larger gatherings reported. Gait a typical corvid swaggering walk. Readily takes to air in face of potential danger; flight action rather weak, but often flies considerable distances when flushed.

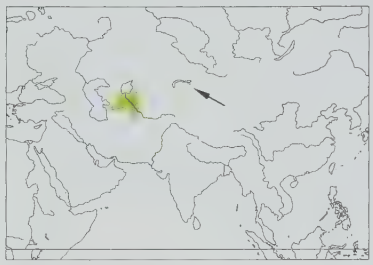
Breeding. Eggs laid late Mar and Apr. Nest a compact bowl of twigs and rootlets, lined with animal hair, feathers and soft plant fibres, outer diameter 14–55 cm, height 12–35 cm, internal diameter 9–20 cm, depth 5–16 cm, placed 10 cm to 2 m above ground in tree 1·5–10 m tall, exceptionally on ground; one nest was well hidden c. 10–12 cm from ground in a 3-m tamarisk. Clutch 1–3 eggs, usually 3; no information on incubation and nestling periods; both parents seem to accompany family groups for 4–6 weeks after fledging, groups generally breaking up during Jul.

Movements Sedentary, as far as is known.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Taklimakan Desert EBA. Described as "common" in Taklimakan Desert during 1929–1930; c. 60 years later, on a visit to several of same sites in Jun 1988, only one group, of six individuals, was observed, perhaps indicating a considerable drop in population. It should be borne in mind, however, that ground-jays are sometimes rather difficult to locate, even in areas where they breed. In recent decades, Tarim Basin is no longer quite so wild and uninhabited as it was in c. 1930. Chinese government's "Go West Campaign" has led to increase in the region's human population from 1,000,000 in 1950 to c. 20,000,000 by 2000. Such fragile habitats as existed in the Taklimakan (a harsh environment, with temperatures ranging from –30°C in Jan to 48°C in Jul) have been heavily degraded by water extraction for irrigation schemes, and by overgrazing by goats and camels. Pressures are numerous, from the collection of medicinal plants and firewood to the numerous traffic kills of the species along the newly constructed Tarim Highway; additional threats include conversion of habitat to cotton and melon fields, direct hunting by migrant workers, and destruction of nests by children and herders. Surveys carried out between 1988 and 2003 indicate, however, a population of c. 8 birds/100 km²; with only c. 40% of the Taklimakan suitable, this suggest a total population of c. 10,700 birds, which is far healthier than had been imagined. Possibly occurrence farther E suggested by a sight record from Golmud, in Qinghai. Such a striking bird would be an ideal figurehead for programmes aimed at conserving parts of the Taklimakan, which has hitherto received no protection. Thirteen areas have been selected as being worthy of special protection, and action should be implemented with much publicity and with an awareness campaign through local schools.

(2008p), Butchart & Stattersfield (2004), Chen Fuguan *et al.* (1998), Cheng Tsohsin (1976, 1987), Collar *et al.* (1994), Goodwin (1986), Grimmett (1991), Hartert (1903), Lei Jinyu & Liu Yang (2006), Ludlow & Kinnear (1933), Ma Ming (1998, 2004), Ma Ming & Kwok Hon Kai (2004), MacKinnon & Phillipps (2000), Madge & Burn (1994), Meyer de Schauensee (1984), Stattersfield & Capper (2000), Vaurie (1959), Yin Shoujing *et al.* (2005).

72. Pander's Ground-jay



Podoces panderi

French: Podoce de Pander **German**: Saxaulhäher **Spanish**: Arrendajo Terrestre del Turquestán
Other common names: Saxaul Jay, Grey/Turkestan Ground-jay, Pander's Ground-chough

Taxonomy. *Podoces Panderi* J. G. Fischer von Waldheim, 1821, Kyzyl Kum, Uzbekistan.
Forms a species pair with *P. pleskei*, both differing from other two members of genus in lacking black on crown, and in having relatively short uppertail-coverts, pale legs and a blackish breast patch. Birds from Transcaspia described as race *transcaspius* and those from E Kazakhstan (L Balkhash) as *ilensis*, but effects of bleaching and plumage wear render such forms of questionable validity. Treated as monotypic.

Distribution. N & C Uzbekistan, S Kazakhstan and N & C Turkmenistan; also isolated population in E Kazakhstan (S of L Balkhash).

Descriptive notes. 25 cm; 86–96 g. A small, striking corvid with slightly decurved, rather slim bill, relatively short, glossy black uppertail-coverts. Head, neck and upperparts are sandy grey, paling to whitish on throat, small patch of black on lores, widening in front of eye; flight-feathers almost wholly white with black bases, primaries with black tips, tertials black with white border, greater upperwing-coverts white with black bases, median coverts banded black and white, lesser coverts

sandy grey; tail glossy black; underparts rosy grey, paling to whitish on undertail-coverts, black patch at centre of breast; iris dark brown; bill black; legs pale greyish. Sexes similar. Juvenile is similar to adult, but bill pinkish-grey when recently fledged, plumage buffer, less grey, overall, with duller loral patch, lacks breast patch, and sometimes the black patterning of wings is duller and greyer. Voice. Most frequently heard is a series of far-carrying, clear ringing notes, "chweek chweek chweek chweek...", delivered from top of a bush in early mornings, less frequently in evenings. A similar but briefer call, of a different tone, seems to be given in alarm.

Habitat. Sandy desert with small dunes and extensive bushy cover; notably associated with saxaul (*Haloxylon*) bushes, but seems to avoid dense saxaul forest. Favours semi-open sand desert with mix of vegetation, including bushes and scrub of several other desert species, e.g. *Ammodendron*, *Calligonum* and *Atriplex*. Forages also around settlements and roads.

Food and Feeding. Omnivorous, but little studied. Takes variety of invertebrates and seeds of desert plants, grain and other plant materials. In winter diet almost entirely of vegetable matter; in spring and summer primarily carnivorous, taking beetles (Coleoptera), ants (Formicidae), spiders (Araneae) and scorpions (Scorpiones), also small lizards, especially Lichtenstein's toad-headed agama (*Phrynocephalus interscapularis*). Picks seeds from among animal droppings, and searches along roadsides for spilt grain. Stores food items for future use, inserting them in sand, in crevices in bark at base of bushes, or in other crevices. Normally encountered in pairs or in family parties of up to six individuals; no large gatherings reported. Gait a swaggering walk, but runs in face of danger, often balancing its run with loosely opened wings, taking to the air in low bounding short flights. Flight rather weak, but sometimes flies considerable distances, before landing and running on once more. Adaptation to desert existence so perfect that it is said to not drink, and apparently shuns shelter or shade even in heat of day; other reports, however, state that it visits cattle troughs and wells to drink, and in captivity it drinks readily.

Breeding. Season protracted, nests with eggs found from late Feb to late May, optimum period seemingly late Mar and early Apr; single-brooded, but replacement laid if clutch lost. Appears to have long-term pair-bond, partners staying together all year. Nest often has loosely constructed dome of twigs protecting the main structure, latter being a relatively wide and well-constructed bowl of twigs and rootlets, lined with animal hair, rags, feathers and soft plant material, typically well hidden up to 1 m (rarely, to 2 m) above ground in centre of bush or thicket, sometimes on ground or low down in disused building; reports of nesting in holes in ground appear to be erroneous. Clutch 4–5 eggs, rarely 6; incubation by female, commencing when third or fourth egg laid, fed at nest by male, period 16–19 days; chicks fed by both parents, nestling period at some nests 17–18 days; young able to run rapidly before able to fly properly; family-members remain close together for several weeks after fledging. Nests suffer relatively high rate of predation.

Movements. More or less sedentary, but family groups wander the desert throughout winter in search of food and shelter. Movements seem to be more dispersive following prolonged spells of winter weather; when feeding becomes difficult, leaves parts of NW range, retreating into core range or S of normal distributional area.

Status and Conservation. Not globally threatened. Locally common; rare in extreme E of range. Was described as common, in places even abundant, in Kyzul Kum and Kara Kum deserts in 1940s; sample counts included 10 birds/10–12 km travelled in C Kara Kum of Turkmenistan. Isolated population in desert S of L Balkhash, in E Kazakhstan, always considered very small and poorly known; in late 1940s, during a 1000-km journey through this desert, only five individuals "collected", all at same site. This species has evidently decreased considerably in recent decades through habitat loss incurred by construction of Karakum Canal, which took water from rivers feeding Aral Sea and irrigated large tracts of former desert, mainly for cotton production; this has created something of an environmental disaster, as Aral Sea is drying out and salt and other minerals from dessicating former seabed are wind-blown across newly cultivated regions. This corvid is known to be present in several protected areas, most notably in Repetek Biosphere Reserve, in Turkmenistan.

73. Pleske's Ground-jay

Podoces pleskei

French: Podoce de Pleske **German**: Pleskehäher **Spanish**: Arrendajo Terrestre Iraní
Other common names: Iranian/Persian Ground-jay, Pleske's Ground-chough/Groundpecker

Taxonomy. *Podoces pleskei* Zarudny, 1896, Alkhor (= Alghur?), Khorasan, Iran.
Forms a species pair with *P. panderi*, both differing from other two members of genus in lacking black on crown, and in having relatively short uppertail-coverts, pale legs and a blackish breast patch. Monotypic.

Distribution. E Iran.

Descriptive notes. 24 cm; 85–90 g. A boldly patterned small corvid with slightly decurved, rather slim bill, relatively short glossy black uppertail-coverts. Head, neck and both upperparts and underparts are warm sandy buff with pinkish hue, paling to whitish on throat and undertail-coverts; lores black, extending as narrow post-ocular streak, black patch at centre of lower throat widening over centre of upper breast; primaries white over basal two-third and with wide black tips, secondaries glossy blue-black, broadly tipped white; greater upperwing-coverts black with white tips, median coverts banded black and white, lesser coverts sandy buff; tail glossy black; iris dark brown; bill black; legs pale greyish. Sexes similar. Juvenile plumage is poorly documented; lacks black chest patch of adult, and presumably has pinkish bill. Voice. Most frequently heard is a series of far-carrying, penetrating tremulous whistles, "tseee tseee tseee tseee", reminiscent of calls given by Eastern Rock Nuthatch (*Sitta tephronota*); these whistles delivered from top of a bush in early mornings, less frequently in evenings.

Habitat. Sandy desert plains, and both *Zygophyllum* and *Artemisia* steppe, with scattered small bushes and lower-growing plants, especially *Calligonum*, *Salsola* and *Ephedra* (but not one specific shrub in particular). Recorded at 900–2000 m.
Food and Feeding. Omnivorous, diet varying with season. In spring chiefly insectivorous, feeding principally on weevils (Curculionidae) and other beetles (e.g. Tenebrionidae), as well as termites (Isoptera), also occasional small lizard; in autumn, and presumably winter, takes greater variety of plant material, including grains (chiefly barley and wheat), melon seeds and seeds of *Zygophyllum*, and some insects. Observed to hide food items for later consumption; this food-hoarding behaviour makes it an important "planter" of desert shrubs and plants. Normally encountered in pairs or in family parties of up to six individuals; no larger gatherings reported. Behaviour hardly studied, but probably differs little from that of congeners. Most active early morning and evenings, foraging along tracks and in villages and other settlements, looking for grain. Shy and wary in general, but can, exceptionally, become very confiding, even taking food from the hand. Prefers to run, rather than fly, from suspected danger, disappearing remarkably quickly between small shrubs.
Breeding. Eggs laid in first half of Mar; single-brooded. Appears to have long-term pair-bond, partners keeping together all year. Nesting little studied, based chiefly on one active nest. Nest a well-constructed bowl of twigs, lined with soft cotton-like plant materials (apparently lacks dome of *C. panderi* nest), well hidden c. 80 cm from ground in centre of a *Calligonum* bush. Clutch 4–6 eggs; no information on incubation period; chicks fed by both parents, leave nest at c. 15–18 days after hatching and still unable to fly, but run after parents for up to 500 m from nest, finally able to fly at c. 24–28 days; family-members remain close together for several weeks, but seem to disperse in autumn.
Movements. Sedentary; probably some dispersal in autumn–winter.
Status and Conservation. Not globally threatened. Widely distributed over most of interior of E half of Iran, but by no means common; can be locally quite numerous. Found chiefly in Dasht-e Lut of Khorasan and extreme E Kerman, but recorded N to Sharud (in N Semnan), W to Yazd and S to Iranian Baluchistan; one record from Namakazar Basin, on border with NW Afghanistan, and recorded as occurring right up to border with Pakistan at Nokkundi, but presence in Pakistan not yet confirmed. In Jun 1973, 13 individuals (including juveniles) counted along 16-km stretch of the Mashhad–Zahedan highway in the Salahbad area; such density unlikely to be matched other than in prime habitats which have not been grazed by domestic animals. Despite size of country, many areas of desert are quite heavily grazed. This species is known to occur in at least two protected areas, notably Touran (in Semnan province) and Bahram-e Gour (in Fars). Its ability to tolerate salt steppe is a feature very much in its favour, as such habitats not popular for grazing domestic livestock, which otherwise remain the only obvious threat to its future survival.

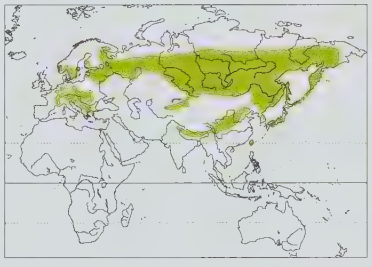
Genus *NUCIFRAGA* Brisson, 1760

74. Kashmir Nutcracker

Nucifraga multipunctata

French: Cassenoix du Cachemire **German**: Himalajahäher **Spanish**: Cascanueces del Himalaya
Other common names: Larger-spotted/Indian/Himalayan Nutcracker

Taxonomy. *Nucifraga multipunctata* Gould, 1849, north of the Pir Panjal Range, in Kashmir.
Usually treated as conspecific with *N. caryocatactes*, but has striking plumage differences from latter (of race *hemispila*), which it seems to replace abruptly in NW Himalayas beyond Pir Panjal Range; this and minor structural differences, and fact that intermediate individuals are extremely rare, suggests that treatment as separate species is appropriate. Monotypic.
Distribution. From E Afghanistan (NE Paktia and Nuristan), N & W Pakistan (Fort Sandeman N along Suleiman Range, Chitral, Gilgit, Baltistan) and Kashmir (Sind Valley, Kishtwar, Badrawar) E into NW India (E to Lahul, in Himachal Pradesh) and possibly adjacent extreme SW Xizang.



Descriptive notes. 35 cm; 155–177 g. Distinctive corvid with boldly spotted plumage, appearing largely whitish at long range; medium-short tail slightly rounded at corners, relatively slim bill conical and pointed, with straight culmen. Crown and nape are blackish-brown; side of head, neck and most of body plumage blackish grey-brown, profusely and broadly streak-spotted with white (so that dark background colour almost obliterated), rump and uppertail-coverts dark brown with distinct white spots, lower belly and undertail-coverts unmarked white; upperwing glossy black, white spot at tips of coverts and secondaries; tail glossy black, broadly tipped white on central feather pair, white becoming progressively wider towards outermost, which white over distal two-thirds; iris dark brown; bill and legs black. Distinguished from *N. caryocatactes* mainly by bold white spots on rump and uppertail-coverts, more whitish general appearance with contrasting blackish crown, wings and tail base, also slightly larger size, relatively slimmer bill and longer tail. Sexes similar. Juvenile is similar to adult, but wings and tail dull brown (not glossy), ground colour of body plumage lighter brown, wing-coverts with buffy-white tips, and overall impression of softer and looser plumage, particularly undertail-coverts. Voice. Poorly documented, and probably much as for *N. caryocatactes*. Said to have harsh grating calls, also calls like sound of squealing pigs, but latter may refer to food-begging cries from nestlings.
Habitat. Coniferous forest and mixed conifer and oak (*Quercus*) forest where conifers predominate, especially forests of blue pine (*Pinus excelsa*) and Morinda spruce (*Picea smithiana*); mainly 2000–3000 m on alpine slopes, but recorded as low as 1000 m and as high as 4000 m. Often attracted by human habitation, such as villages and encampments.
Food and Feeding. Few data. Conifer seeds taken; in Kashmir, reported as moving our of conifer forests to take walnuts (*Juglans*) and hazelnuts (*Corylus*) for winter caches. Diet and general habits seemingly very similar to those of *N. caryocatactes*.
Breeding. Poorly documented. Season often stated to be May–Jul, but likely to commence egg-laying much earlier, probably late Feb and Mar; breeding season in Afghanistan finished by end of Apr or early May, indicating that eggs must have hatched late Jan or early Feb. Solitary nester. Well-built nest of twigs, decorated with lichens, quite deep cup lined with soft roots and pine needles, placed close against trunk typically 10–30 m above ground in tall, dense conifer. Clutch 3–4 eggs. No other information.
Movements. Resident; descends to somewhat lower levels in late summer to collect nuts for winter stores.
Status and Conservation. Not assessed. Thought not to be globally threatened. Restricted-range species: present in Western Himalayas EBA. Common. Not well known, as formerly considered a race of *N. caryocatactes* and received little study, this partly because its distribution straddles an area of political instability. On slopes of Vale of Kashmir it is tolerably common and seems to adapt well to secondary cutover forest. This species' habit of associating loosely with humans, including foraging by camps and villages, should ensure its future survival.

75. Spotted Nutcracker

Nucifraga caryocatactes

French: Cassenoix moucheté **German**: Tannenhäher **Spanish**: Cascanueces Común
Other common names: Eurasian Nutcracker; Thick-billed/European Nutcracker (*caryocatactes*); Slender-billed Nutcracker (*macrorhynchos*)

Taxonomy. *Corvus Caryocatactes* Linnaeus, 1758, "Europa" = Sweden.
Usually treated as conspecific with *N. multipunctata*, but striking plumage differences and minor structural differences from latter, which seems to replace it abruptly in NW Himalayas beyond Pir Panjal Range; intermediate individuals extremely rare, suggesting that treatment as separate species is appropriate. Geographical variation rather complex, owing to extensive range and to isolation of several populations. Races fall into two groups, which have in the past been treated as separate species. S races, forming "*hemispila* group" (also with *interdicta*, *macella* and *owstoni*), very weakly spotted overall; isolated *owstoni* of Taiwan quite distinctive, but clearly resembles others of this group, and seems not to have evolved so far towards speciation as have many other Taiwan endemics. W & N races, "nominate group" (with remaining races), encompassing vast range from Norway and France E to Kamchatka and Anadyrland, more heavily marked. Nominate race intergrades with *macrorhynchos* in Urals, and *hemispila* intergrades with *macella* in Darjeeling area of N India. Proposed race *yunnanensis* (from Yunnan, in S China) considered better synonymized with *macella*. Within range of "nominate group" are several populations which have been separated racially on basis of minor differences and are best treated as synonyms: thus, in Europe, *wolfi* (from Balkans) and *relicta* (from Germany S to Serbia) are included in nominate and, in Asia, *kamchatkensis* (from Kamchatka), *altaicus* (from S Altai) and *sassii* (from L Baikal region) treated as synonyms of *macrorhynchos*. Eight subspecies currently recognized.
Subspecies and Distribution.
N. c. caryocatactes (Linnaeus, 1758) – Europe (S Fennoscandia S to SE France, N Italy, Bulgaria and N Greece, E to Ural Mts).
N. c. macrorhynchos C. L. Brehm, 1823 – from Urals E in Siberia to Anadyrland, Kamchatka and Sakhalin I, S to N Mongolia, the Altai, Korea and NE China.
N. c. japonica E. J. O. Hartert, 1897 – S & C Kurils and N Japan (Hokkaido and Honshu).
N. c. rothschildi E. J. O. Hartert, 1903 – Tien Shan from SE Kazakhstan (Dzhungarskiy Alatau) S to C Kyrgystan (Talasskiy Alatau) and extreme NW China (W Xinjiang).
N. c. hemispila Vigors, 1831 –W Himalayas from NE Pakistan (Murree) E, S of the Pir Panjal, to Nepal and N India (Darjeeling).
N. c. macella Thayer & Bangs, 1909 – E Himalayas from E Nepal and Sikkim E to NE India (Arunachal Pradesh), N Myanmar and S & C China (Qinling Mts of S Shaanxi and NW Hubei, S through Sichuan to SE Xizang and Yunnan).
N. c. interdicta O. Kleinschmidt & Weigold, 1922 – E China (SW Liaoning S to Shanxi, N Hebei and Henan).
N. c. owstoni Ingram, 1910 – Taiwan.

Descriptive notes. 32–34 cm; 124–220 g. A medium-sized, rather broad-winged and short-tailed corvid with distinctively spotted plumage (but looking dark at longer ranges). Nominate race has crown and nape very dark brown, darkest on forecrown; sides of head, neck and most of body plumage dark brown, profusely streak-spotted with white, most densely on side of head (giving whitish-cheeked appearance), spots largest but more spaced on scapulars, breast and flanks (forming confluent lines); rump and uppertail-coverts plain dark brown, lower belly and undertail-coverts white; upperwing glossy black, coverts with tiny white spot at tip; tail glossy black with white feather tips, narrow on central pair, becoming progressively wider towards outermost, which look almost all white from below; iris dark brown; bill and legs black. Sexes similar. Juvenile is similar to adult, but wings and tail dull brown (not glossy), median coverts with broad white tip (usually lacking on adult), softer and looser plumage, particularly undertail-coverts. Races form two groups, those in W & N (nominate and first three listed below) all heavily spotted with white on dark brown background and differing from each other in bill shape, those in S (last four) slightly longer-tailed, lack white tips on central rectrices but have more extensive white on outermost, all much browner and with less extensive areas of spotting: *macrorhynchos* differs from nominate in having broader white tailband, also the longest and slimmest bill of all; *japonicus* resembles previous, but has shorter and stouter bill; *rothschildi* has very dark cinnamon-brown ground colour, and stout bill with slightly arched culmen; *hemispila* has reduced spotting, scapulars and flanks virtually unmarked brown, spots most obvious on breast and mantle; *macella* is similar to previous, but individual spots smaller and less numerous; *interdicta* is ill-defined race, differing from last in having lighter brown background colour of body plumage; *owstoni* is dark, sooty brown, but still some contrast with blacker crown, has white spots much reduced, merely flecks on mantle, and tiny white spotting on breast and flanks. Voice. Generally silent outside breeding season, but quite vocal from late winter onwards (breeds early). Typical call a harsh, grating "krraaaaak", quite far-carrying, usually delivered from top of conifer; sometimes quickly repeated into discordant rattle, or abbreviated to weaker "zhreee". Utters a prolonged series of quiet musical notes, including piping, rattling, whining and mewing sounds, interspersed with some mimicry, this complex "song" audible only at close quarters.

Habitat. Coniferous forest and mixed conifer and birch (*Betula*) forest where conifers predominate; from lowlands of taiga, reaching to 4000 m in Nepal. In Continental Europe chiefly in mountain forests, especially where forests broken by clearings and alpine meadows. Prime habitat in Europe composed of Norway spruce (*Picea abies*) and Swiss pine (*Pinus cembra*); mixed forests of silver fir (*Abies alba*), Scots pine (*Pinus sylvestris*), black pine (*Pinus nigra*) and Macedonian Pine (*Pinus peuce*) also important, especially if hazel (*Corylus*) also present. Siberian populations favour cedars (*Cedrus*) and Siberian pine (*Pinus sibirica*), those in E (from Kamchatka S to Japan) linked with Japanese stone pine (*Pinus pumila*) and Sakhalin fir (*Abies sachalinensis*). In Tien Shan, preference is Tien Shan spruce (*Picea tianschanica*). Himalayan populations inhabit mixed rhododendron (*Rhododendron*) and conifer forests, with deodar cedar (*Cedrus deodara*), blue pine (*Pinus excelsa*), Pindrow fir (*Abies pindrow*) and Himalayan fir (*Abies spectabilis*), and Morinda spruce (*Picea smithiana*). Not always restricted to coniferous forests; during periodic irruptions from Siberia, can appear in extremely wide range of habitats, from suburban gardens and parks to tiny offshore islands and desert oases.

Food and Feeding. Main food throughout much of year and in much of range is pine nuts, especially those of Siberian pine; consumes also seeds of various other conifer species, as well as other nuts, especially those of hazel. During spring and early summer takes wide range of invertebrates, including earthworms (Lumbricidae), earwigs (Dermaptera), spiders (Araneae), grasshoppers (Orthoptera), bumblebees (*Bombus*) and wasps (Vespidae); small rodents and small birds also reported as rare prey items. Specialized nut-eater, prominent ridge inside base of lower mandible serving as ideal nut-cracking tool; also, holds cones and other nuts under foot and hammers at them with bill. A compulsive nut-hoarder, storing large quantities of nuts throughout winter territory, carries these in a special sublingual pouch behind the tongue, and stores them in a number of caches at base of tree, behind moss on rocks, crevices in tree bark, or simply on ground near small rock or sapling. Some conifer species lack a "winged" seed casing (which helps the seed to "flutter", thus aiding dispersal), these trees relying on nutcrackers for dispersal of seeds; clearly, this form of interdependence, or mutualism, benefits both the conifer and the bird. Employs several hunting techniques, especially when far from normal habitat during irruptions. Sits high on small tree, dropping to ground in manner of a shrike (Laniidae), or clings to tree trunk to dig into bark crevices in manner of woodpecker (Picidae); reported as following ploughing tractors, clumsily catching flying ants (Formicidae) in mid-air and hovering to get at hazelnuts; hovering over open country when searching for grasshoppers also reported. Has little fear of humans, especially during "invasions"; takes fish heads from fishermen's traps, and will even enter occupied houses, or attend picnics, accepting all manner of household scraps, from cake and pasties to peanuts. Forages among foliage of conifers, sweeping low from tree to tree, often flaring tail after landing (to display white surround); feeds also on ground at base of conifers. Hops, walks and bounds between bouts of probing or hammering into cones. Typically in pairs or in family parties; larger flocks, reaching up to 200 or more individuals, form during periodic irruptions.

Breeding. Breeding commencing even when deep snow on ground; egg-laying begins third week of Mar in Sweden, even earlier in C Europe, where two juveniles reported late Jan (must have hatched late Dec) in Switzerland; peak laying period first week of Apr in SE France, very end of Mar in Balkans; in W Himalayas late Feb seems to be main period, and in W Siberia mid-Apr reported; in Japan, most nests contain eggs in early Apr. Long-term pair-bond, partners staying together all year. Solitary nester. Nest built by both sexes, taking 5–12 days to complete, female doing most of lining of cup; typical corvid nest, a mass of twigs and branches, intertwined with bramble (*Rubus*) shoots and lichens, deep cup lined with soft plant materials, including willow (*Salix*) seeds, mosses and lichens, placed c. 6 m from ground close to main trunk of a conifer. Clutch 2–5 eggs, usually 3 or 4; incubation by both sexes, female doing most (about two-thirds), period 16–18 days; chicks fed by both parents, nestling period c. 23 days; young remain in family group for up to 3 months after fledging; in early Jul most families break up, juveniles having to establish own territory in which to hoard sufficient supplies of nuts to sustain them through forthcoming winter.

Movements. Most populations basically resident, but some, especially when hoarding hazelnuts for winter, move up to 15 km to lower elevations in search of hazel thickets. In severe winter weather Japanese populations descend to lowlands. Mainly resident in C & E Europe, Himalayas, Tien Shan, N China and Taiwan. Populations of race *macrorhynchos* inhabiting taiga zone periodically suffer shortage of pine seed (such crop failures often follow a run of good years of seed production, in which nutcracker populations have done well), forcing large numbers of Siberian breeders to disperse widely in search of food. Irruptions have occurred in Europe on c. 25 occasions in the past 250 years, since the first reference, in 1733. One of the most recent, in 1968, was also one of the most spectacular and well-documented: many thousands were reported as moving S along shores of L Baikal daily from late Jul into early Aug, flocks reaching Gobi Desert and N Kazakhstan, but bulk of the movement was seemingly towards W & SW, thousands invading Europe from E from late Jul onwards; 10,800 moved through NE Germany in early Aug, a total of 6000 was reported from Netherlands, 800 from Belgium and 300 from British Is, several individuals reaching Portugal and NW Africa (a few individuals of nominate race were also identified out of range during invasions, having no doubt been caught up with parties of migrants moving through their locations); ringing recoveries indicated that some *macrorhynchos* turned back on reaching the W, one ringed on coast of Kaliningrad (W Russia) on 1st Aug being recovered c. 2 weeks later 2500 km to E. Although only small numbers overwintered and few were noted on return spring migration, several pairs nested in Denmark, Belgium and Netherlands for several years following the 1968 invasion. Regarded as a rare vagrant in Spain, Portugal, NW Africa, Turkey, Iran and, in Japan, S Kyushu.

Status and Conservation. Not globally threatened. Locally common. Throughout its wide range a relatively conspicuous bird, but remoteness of its habitat gives false impression of relative abundance; overall, numbers fluctuate according to amount of pine seed available in late summer. Reported to be increasing in most European countries, partly owing to creation of extensive plantations of conifers since 1930s, and also to relatively small numbers that stayed behind after 1968 invasion to populate new areas (Denmark, Belgium and Netherlands). European population estimated in 1980s and 1990s at c. 300,000 pairs, of which 3000–5000 in France, 180 in Belgium, 11,000–15,000 in Germany, up to 1000 in Norway, 5000–15,000 in Sweden, 1500–2000 in Finland, 5000–10,000 in Estonia, 5000–20,000 in Latvia, 15,000 in Lithuania, 2000–5000 in Poland, 2500–5000 in Czech Republic, 3000–6000 in Slovakia, 17,000 in Austria, 20,000–30,000 in Switzerland, 10,000–30,000 in Italy, 30,000–70,000 in Romania, 10,000–50,000 in Bulgaria, up to 500 in Albania, up to 600 in Greece, 4000–6000 in Belarus, 8000–12,000 in Croatia, 2000–3000 in Slovenia, 10,000–100,000 in Russia, 200–250 in Ukraine. Bred at at least three sites in 1969–1971 in Netherlands, and up to 10 pairs during 1989–1994 in Denmark. Elsewhere over extensive range generally considered rather common in the appropriate habitat; in Japan considered uncommon and relatively poorly known except in winter, when it leaves Japanese Alps and descends a little lower.

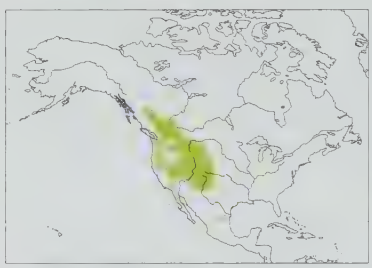
76. Clark's Nutcracker



Nucifraga columbiana

French: Cassenoix d'Amérique **German**: Kiefernhäher **Spanish**: Cascanueces Americano

Taxonomy. *Corvus columbiana* A. Wilson, 1811, two miles [3·2 km] north of Kamiah, on Clearwater River, Idaho, USA.

Probably derived from a Siberian form of *N. caryocatactes* which crossed the Bering land-bridge, perhaps as relatively recently as 1·5–2 million years ago. Monotypic.

Distribution. Rocky Mts, Cascade Mts and isolated ranges of W North America from SW Canada (E slopes of interior British Columbia, S & E through mountains of SW Alberta), S in USA to C & E Washington and Olympic Peninsula, Idaho, Montana, Wyoming, W & NE Oregon (likely across the state), N & EC California, Nevada, Utah and Colorado to S California, Arizona and New Mexico; also, in N Mexico, irregularly occurring population in Sierra San Pedro Martír (N Baja California) and isolated population at Cerro Potosí (Nuevo León).

Descriptive notes. 27–30 cm; 106–161 g. A medium-sized corvid with long wings, conspicuous white in wings and tail, and long and sharply pointed bill. Head, neck and most of body are grey (plumage soft and loose), forehead and face varyingly whiter, vent and undertail-coverts white; flight-feathers jet-black, posterior portion of secondaries contrastingly white; central pair of tail feathers black, outer feathers white; iris brown; bill and legs black. Sexes similar, male on average larger than female. Juvenile differs from adult in having mouse-grey body feathers (including face) that are looser, fluffier, and tipped buff; after first moult (completed Oct–Feb) body feathers replaced by adult-like plumage, but most of wing and tail retained so that first-year has lighter-coloured, duller and browner wings and tail, tail tips more rounded and worn, alula conspicuously brown and dull against the few coverts that are moulted; red mouth lining of nestling turns black by end of first year. Voice. Repertoire of 13 calls in three major groups, with considerable variation within and among individuals. Commonly gives sharp, rapid "kraak" or "kraa" calls as contact or flight call; these may be drawn out ("kraaaack" or "kraaaa") over 1 second and audible for more than 1 km for contact or given in rapid series (2–6 calls in 2·4 seconds) for alarm. Mated birds give musical "chirrup" calls to greet one another and other familiar birds, and perhaps to summon juveniles; both sexes beg from mate while crouching and fluttering wings. A slow frog-like rattle ("bullfrog call") given mostly Dec–Jun may facilitate pair-bonding. Mates also give variety of clicks, pops, whistles and crackles either singly (while courting and breeding) or strung together in monologues (usually while alone). Juveniles beg from food-carrying parents with repeated "aaaa" calls. Individuals in proximity to others commonly utter loud "meerk" or "mew" calls mixed with "kraaaack" calls. Lone individuals may trumpet a piercing "bray" call, possibly in defence of territory.

Habitat. Mountain coniferous forests, typically including trees that produce large, wingless seeds, e.g. pinyon pine at lower elevations and whitebark (*Pinus albicaulis*) or limber pines (*Pinus flexilis*) at higher elevations. In Canada and NW USA, nesting habitat commonly open, park-like ponderosa pine (*Pinus ponderosa*); nests also in Jeffrey pine (*Pinus jeffreyi*), grand fir (*Abies grandis*), and mixed coniferous forests including whitebark or limber pines. Tends to be found at highest elevations from mid-summer (early Jun) to autumn (Sept–Nov, depending on latitude and snowfall), in open subalpine to tree-line areas at c. 1800–3400 m, where stands of whitebark, limber, Jeffrey and pinyon pines and bristlecone pine (*Pinus longaeva*, *P. aristata*) are interspersed with shrubs, talus slopes, meadows, creeks and lakes. For late autumn–winter descends to lower-elevation conifer forests where food available. Common at human recreation sites and cabins if birdfeeders or meat scraps provided. Wanders broadly through coniferous forests and woodlands beyond normal range when preferred seed crops fail. Mostly at c. 900–3700 m; in Canada, 0–2600 m in British Columbia and c. 1000–3840 m in SW Alberta.

Food and Feeding. Specialist on conifer seeds, especially large, wingless seeds of pinyon, limber, and whitebark pines, and smaller seeds of ponderosa pine and Douglas-fir (*Pseudotsuga menziesii*). Also, opportunistically takes invertebrates, small vertebrates, and carrion; invertebrates mainly beetles (Coleoptera), bees and ants (Hymenoptera), grasshoppers and crickets (Orthoptera), moths and butterflies (Lepidoptera), flies (Diptera), stoneflies (Plecoptera), and leafhoppers (Homoptera); preys on other birds, ground-squirrels (*Spermophilus*), chipmunks (*Tamias*), voles (*Microtus*) and toads (*Bufo*). Nestling diet shelled pine seeds and some insects. Catches insects by gleaning from vegetation, soil or cones, probing and flaking bark, and flycatching from perch. Forages on green and ripened cones of pines; uses long and pointed bill to pry open green cone scales, probe into open cones, and dig in litter beneath trees to remove and assess the quality of seeds. Viable seeds are cracked in bill, pounded open while held by the feet on a branch or other substrate, or placed intact in the special sublingual pouch in floor of mouth for transportation to caching grounds. Efficiently removes seeds from tightly closed, green cones, taking 30–90 seconds per seed; rapidly removes seeds from open cones, 7–10 seconds per seed. Begins to cache food when pine seeds develop hard coat (days to weeks before cones open); each individual harvests seeds singly from cones and fills the sublingual pouch with up to 95 pinyon or 150 whitebark pine seeds, which it transports up to 8–12 km (whitebark) or 7·5–22 km (pinyon), either upslope or downslope to caching grounds; most seeds transported substantially shorter distances, e.g. average of 27 m for transportation of whitebark pine seeds in a California study. Each nutcracker caches tens of thousands of seeds (22,000–33,000 pinyon, 35,000–98,000 whitebark) each year in holes made with the bill, often at base of existing trees and rocks, on exposed rocky, south-facing slopes, or in bark, logs and stumps; up to 30 (usually 3–4) seeds placed in single cache. Caches from a single trip are often clustered 10–300 cm apart. Consistently outperforms less cache-reliant corvids (*Aphelocoma californica* and *A. ultramarina*) on tasks requiring spatial memory, and is one of few animals to have demonstrated use of basic geometric relationships in controlled laboratory conditions (found caches midway between landmarks, regardless of absolute distance between landmarks); has capacity to learn cache locations by watching others cache, though this observational spatial memory less well developed than in more social corvids (*Gymnorhinus cyanocephalus*, *A. ultramarina*); spatial memory, landmarks and geometric rules allow this species to recover caches months after they are made, even when snow covers caching grounds. Generally observed in pairs or in small groups; also in larger flocks, of 15–80 individuals in loose group, outside breeding season.

Breeding. Few nests observed, as this species often nests in remote settings during severe winter conditions. Nest-building typically begins (at 975–3658 m) in early Mar throughout range, and

laying early Mar to mid-Apr (occasionally from mid-Feb), most young fledging Apr–May; timing of breeding likely tied to previous autumn's cone crop. Pair-bond appears to be maintained throughout year. Nest constructed in 5–8 days, a coarse stick platform 21·6–33 cm in diameter and 11·4–19 cm tall, with well-insulated inner cup (10·2–11·4 cm in diameter, 6·4–8·9 cm deep; 3·8–5·1 cm thick) of soil, bark, moss and animal hair, often placed in clump of conifer trees (often in outer foliage) in protected (leeward and south-facing aspects) setting near seeds stored in previous autumn; in short nest trees e.g. Colorado pinyon (*Pinus edulis*), single-leaf pinyon (*Pinus monophylla*) or western juniper (*Juniperus occidentalis*) nests 2–5 m above ground, in taller trees e.g. Douglas-fir, lodgepole pine (*Pinus contorta*), ponderosa, whitebark and Jeffrey pines, alpine larch (*Larix lyallii*) and spruce (*Picea*) 1·8–24 m above ground; pair defends small territory (one estimated at 0·85 ha) around nest. Clutch 2–6 eggs, normally 2 or 3; incubation by both sexes, period 18 days; chicks brooded by both sexes, nearly continuously for 10–11 days after hatching, fed by both parents, nestling period 20 days; young dependent on parents until 3–4 months old (usually first half Aug), during which fed with cached and sprouting seeds, juveniles learn to find caches by spotting germinating seeds. Breeding success probably tied to previous autumn's cone crop, but this not studied in detail. First breeding begins in second winter. Maximum recorded lifespan 17 years.

Movements. Resident. Some wandering to lower elevations in winter, and periodically when cone crops fail; irregular E to Great Plains of Midwest USA, W to Pacific Coast, N to Alaska, and S throughout N Mexico. Hypothesized that emigration occurs after geographically extensive, synchronous cone-crop failure, and irruptive movements occur when local crop failure follows a year of heavy seed production. Emigration over considerable distances (up to 1800 km) after crop failure results in this species often occurring at unusually low elevations (pinyon–juniper woodland) and invading areas where rarely seen (coastal California and offshore islands, W Ontario, C Alberta, Pennsylvania, Illinois, Arkansas).

Status and Conservation. Not globally threatened. Locally common. Irruptive movements and population responses to varying cone crops make accurate estimation of trends difficult. Wide-scale surveys during 1966–1996 indicated that populations were stable to slightly increasing. Home range used by family group through spring and summer 150–200 ha; when seed crops good, estimated to remain throughout year on home range of 25–150 km². Recent habitat degradation in N Rocky Mts resulting from historical fire suppression, pine beetle (*Dendroctonus ponderosae*) outbreaks, and an epidemic of exotic white pine blister rust (*Cronartium ribicola*) that kills whitebark, limber and southwestern white pines (*Pinus strobiformis*), coupled with extensive loss of pinyon pine woodlands in SW USA to clearance, drought and disease, does not bode well for this species. The ability of pines to develop resistance to these threats and the capacity of nutcrackers to broaden the diet beyond the infected pine species will be crucial to the survival of the pine–nutcracker mutualism, and perhaps ultimately to this nutcracker species itself.

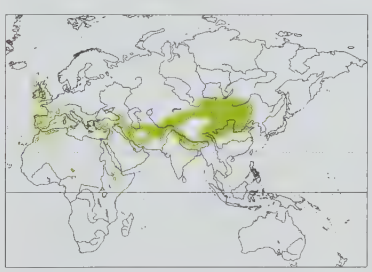
Genus *PYRRHOCORAX* Tunstall, 1771

77. Yellow-billed Chough

Pyrrhocorax graculus

French: Chocard à bec jaune **German**: Alpendohle **Spanish**: Chova Piquigualda
Other common names: Alpine Chough

Taxonomy. *Corvus Graculus* Linnaeus, 1766, Swiss Alps, Switzerland.
Hybrids with *P. pyrrhocorax* very rarely reported. Geographical variation slight; some authorities consider that *forsythi* should be absorbed within *digitatus*. Three subspecies tentatively recognized.
Subspecies and Distribution.
P. g. graculus (Linnaeus, 1766) – Morocco (Rif and Atlas ranges), Spain (Cantabrian Mts, Pyrenees and Sierra Nevada), Corsica, throughout Alps, NC Italy (Apennines), and E through former Yugoslavia, Albania, Greece (including Crete), W Bulgaria and S & E Turkey to Caucasus region and N Iran.
P. g. digitatus Ehrenberg, 1833 – SE Turkey, S to Lebanon and Mt Hermon, E across N Iraq to SW Iran (Zagros Mts).
P. g. forsythi Stoliczka, 1874 – C Asia from C & N Afghanistan NE through Pamirs and patchily on through Tien Shan and Altai to Sayan Mts and, in S, from WC & N Pakistan (including isolated population in N Baluchistan) E in Himalayas to Nepal, Bhutan and Arunachal Pradesh, and C & SW China.



Descriptive notes. 34–38 cm; male 194–277 g, female 160–254 g. Medium-sized, relatively small-headed corvid with fairly long tail, short bill slightly decurved; in flight, rather broad wings with "fingered" primaries, trailing edge of wing gently S-shaped ("pinched" wing base, shorter inner primaries), flight often gamboling in updrafts of air over sheer cliff faces and ridges, swooping and diving, soaring and sweeping down slopes. Nominate race has entire plumage black, weakly glossed bluish-green, most strongly on wings and tail; iris dark brown; bill lemon-yellow; legs bright red. Distinguished from *P. pyrrhocorax* by smaller, yellow bill, base of lower mandible less feathered (and velvety black nasal tuft inconspicuous), shorter legs, wingtips falling well short of tail tip, in flight by relatively longer tail, narrower wings less rectangular in shape and with less strongly fingered primaries. Sexes similar. Juvenile has plumage (when recently fledged) dull sooty black, bill dull horn-coloured, legs black or dark brown, legs becoming red during first winter. Races differ in size and in relative toe and tarsus lengths, nominate race smallest; *forsythi* is largest; *digitatus* is intermediate between previous and nominate.
Voice. Typical call distinctive and unlike that of other corvids, including *P. pyrrhocorax* (although not unlike call of Ethiopian race *baileyi* of latter). Most frequently heard is a sweet rippling "preeep" and a descending whistled "sweeeooo", both given with varied emphasis, the whistled note sometimes similar to a high-pitched, sweeter version of alarm call of *P. pyrrhocorax*. Also gives harsh rolling "churr". Song a subdued warbling, chittering and squeaky series of notes, often uttered by birds when feeding or when resting together.
Habitat. High-altitude mountain pastures with rocky crags above tree-line, descending into upper valleys in winter. Unlike *P. pyrrhocorax*, is very much a scavenger about human habitation, especially so about ski resorts in Europe, where breeds chiefly between 1260 m and 2880 m, but reported as low as 600 m in Balkans. In N Africa nests at 2880–3900 m, and farther E most numerous between 3500 m and 5000 m in Himalayas, where reported as following climbers as high as 8235 m in Nepal.
Food and Feeding. Primarily invertebrates in spring and summer, with more varied diet in autumn and winter. In summer grasshoppers (Orthoptera), beetles (Coleoptera) and larvae of craneflies (Tipulidae) important, but takes whole range of invertebrates, including small molluscs, dragonflies (Odonata), bugs (Hemiptera), caterpillars (Lepidoptera) and ants (Formicidae); will also take small amphibians and reptiles, nestling small birds, eggs and small rodents. In autumn and winter extensive range of seeds (including those of grasses), berries and fruits are added, notably those of rose (*Rosa*), rowan (*Sorbus*), sea-buckthorn (*Hippophae*), juniper (*Juniperus*), cherries and blackthorn (*Prunus*), barberry (*Berberis*), ivy (*Ilex*) and dogwood (*Cornus*). Wide range of discarded human food items recorded, including mashed potato and cheese, and is especially fond of sultanas. Habitually hides food, particularly food scraps, by pushing morsels into rock crevices and under stones. Flocks scavenge about mountain villages and ski resorts, in winter descending to valley bottoms and foraging around towns (but moving back into mountains to roost). Becomes remarkably confiding, following mountain walkers for scraps, even catching food items in air when thrown by humans, or taking food from the hand. Flaps clumsily in bushes when feeding on berries, but usually forages on ground, often in flocks of several hundred individuals. Flocks assemble for daytime foraging activities, later breaking up into smaller groups or pairs scattered over feeding area. On ground walks with shuffling gait or hops, with tail somewhat depressed, flicking wings and tail as it calls. Feeds by pecking at surface in manner of a starling (Sturnidae), rather than probing in manner of *P. pyrrhocorax*; will peck at animal dung after it has been turned over by latter. The two chough species often forage together, and one may temporarily join up with flocks of the other. Present species replaces *P. pyrrhocorax* at higher elevations, although considerable overlap exists and latter does not habitually forage around villages.
Breeding. Laying mainly early May to mid-Jun in Europe and Morocco, Jun and Jul in Lebanon and Kyrgyzstan, and breeds Apr–Jun in N Indian Subcontinent; single-brooded. Generally lifelong monogamous pair-bond, partners remaining together throughout year. Solitary nester, but forms loose colonies in areas of high population density; colonial breeding seems to be exceptional, e.g. up to 20 pairs in underground shaft in Bulgaria and 20–25 pairs along 7·5 km of craggy cliffs in Switzerland (closest nests 70 m apart), but inter-nest distance elsewhere in Alps varied from 600 m to nearly 5 km. Occasionally a helper (probably a youngster of previous brood) assists at nest. Nest built by both sexes, male bringing in materials and female constructing nest, a bulky structure of sticks, roots and similar, lined with grasses, feathers and moss, typically on ledge or shelf near roof of cave or rock chimney, rock crevice or cliff face, especially larger cave with small entrance; roof space of old building, mine-shaft and the like sometimes utilized, although less so than by *P. pyrrhocorax*. Clutch usually 4 eggs, rarely up to 6; incubation by female alone, fed on nest by male, period 18–21 days; chicks fed by both parents, occasionally also by a helper, nestling period 29–31 days; young remain in family group until at least Sept. First breeding at 2 or 3 years of age.
Movements. Basically sedentary; performs daily altitudinal movements from hill ridges to feeding areas lower down in valleys. Ringing studies in Europe indicate that very few move more than 50 km from natal area; maximum recorded movements 85 km and an exceptional 155 km. Vagrants reported from Poland, Czech Republic, Slovakia, Hungary, Cyprus and Balearic Is, but several of these reports probably refer to escaped captive birds.
Status and Conservation. Not globally threatened. Locally common throughout much of wide range; this most noticeable through observations of flocks of non-breeders, generally of 30–200 individuals, but as many as 1000 in winter. European population stable, with reports of increases from many countries, linked with proliferation of winter tourist resorts which has allowed *P. graculus* to scavenge and to remain at higher elevations throughout year. Total European population estimated at 48,000–96,000 pairs (of which 50% are in the Alps): 10,000 in Spain, 17,000 in France, 8000 in Switzerland, 2000–4000 in Germany, 9000 in Austria, 7000 in Italy, 6000 in Croatia, 1000 in Slovenia, 300 in Albania, 8000 in Greece and 2000 in Bulgaria. Became extinct in Poland (Tatra Mts) in middle of 19th century. Decrease reported in Greece. In Morocco uncommon to rare. Precise status in Syria unclear and requires confirmation, but recently been found breeding in mountains of adjacent C Lebanon. Estimated Turkish population at least 10,000 pairs, whereas in neighbouring Armenia only one recent report (flock of 70 in Dec 2000). Considered rare in Azerbaijan, and uncommon in Caucasus, where conspicuous only over highest ridges and passes. Similar comments apply farther E across N Iraq and N Iran, into C Asia and China, where found only around the higher passes (seemingly replaced by *P. pyrrhocorax* at more moderate elevations). Although confiding in presence of human habitation, and reported even as entering tents of climbers, this species only occasionally nests on buildings, preferring inaccessible cliff sites. Within its range and habitat, such sites appear to be secure.

78. Red-billed Chough

Pyrrhocorax pyrrhocorax

French: Crave à bec rouge **German**: Alpenkrähe **Spanish**: Chova Piquirroja
Other common names: Common Chough; Cornish Chough (England)

Taxonomy. *Upupa Pyrrhocorax* Linnaeus, 1758, England.
Hybrids with *P. graculus* reported very rarely. Isolated race *baileyi* differs vocally from others; taxonomic investigation needed. Birds in Inner Mongolia and W Heilongjiang (NE China) of uncertain racial identity, currently included in *brachypus*. Races intergrade, and size tends to increase clinally towards S. Several other races proposed, based on minor differences and/or intermediate populations: *pontifex* (Elburz Mts, in N Iran) and *subdocilis* (Khrebet Mts, on Turkmenistan–NE Iran border) synonymized with *docilis*; and *stresemanni* (Sayan Mts, in S Russia) included in *centralis*. Race *erythroramphos* often misspelt "*erythrorhamphos*". Eight subspecies currently recognized.
Subspecies and Distribution.
P. p. pyrrhocorax (Linnaeus, 1758) – N, W & S Ireland, W Scotland, I of Man, Wales and SW England (Cornwall).
P. p. erythroramphos (Vieillot, 1817) – NE Portugal, Spain, NW & S France, SW Switzerland, C Italy, and Sardinia and Sicily.
P. p. barbarus Vaurie, 1954 – mountains of NW Africa (Morocco and Algeria); also Canary Is (La Palma).
P. p. docilis (S. G. Gmelin, 1774) – S Balkans, Greece (including Crete), and Turkey E to Caucasus, Levant (Lebanon, N Israel, C Syria), N Iraq, N Iran, Turkmenistan and Afghanistan.
P. p. centralis Stresemann, 1928 – NW Himalayas NE through Altai to Mongolia and Buryatia (S Russia) and, in S, E to SW China (SW Xizang), Kashmir and Ladakh.
P. p. himalayanus (Gould, 1862) – Himalayas E to Bhutan and NE India (Arunachal Pradesh) and to C & S China (C Gansu S to Sichuan and Yunnan).
P. p. brachypus (Swinhoe, 1871) – NE & E China (Inner Mongolia and W Heilongjiang S to Ningxia, Shaanxi and Hebei).
P. p. baileyi Rand & Vaurie, 1955 – Simien (and nearby Mt Abune Yosef and Dilenta highlands) and Bale Mts, in Ethiopia.

Descriptive notes. 38–41 cm; 207–375 g. A medium-sized, relatively small-headed and short-legged corvid with comparatively long, slim and gently decurved bill with tip of upper mandible slightly overlapping lower; in flight, rather broad wings prominently "fingered", distinctly buoyant and bounding flight often interspersed with tumbling, swooping and diving, or simply soaring and gliding. Nominate race has entire body plumage glossy blue-black, glossed greenish on wings and tail; iris dark brown; bill scarlet; legs bright red. Sexes similar. Juvenile has plumage (when recently fledged) duller, less glossy, black than adult's, bill shorter and initially dull orange, becoming red by first autumn, legs dusky to pinkish, becoming

On following pages: 79. Piapiac (*Ptilostomus afer*); 80. Eurasian Jackdaw (*Corvus monedula*); 81. Daurian Jackdaw (*Corvus dauuricus*); 82. House Crow (*Corvus splendens*); 83. New Caledonian Crow (*Corvus moneduloides*); 84. Slender-billed Crow (*Corvus enca*); 85. Piping Crow (*Corvus typicus*); 86. Banggai Crow (*Corvus unicolor*); 87. Flores Crow (*Corvus florensis*); 88. Mariana Crow (*Corvus kubaryi*); 89. Long-billed Crow (*Corvus validus*); 90. White-billed Crow (*Corvus woodfordi*); 91. Bougainville Crow (*Corvus meeki*); 92. Bismarck Crow (*Corvus insularis*); 93. Brown-headed Crow (*Corvus fuscicapillus*); 94. Grey Crow (*Corvus tristis*).

red by first autumn. Races differ mainly in intensity of plumage gloss and overall size, coastal races generally smaller than mountain forms, nominate smallest: *erythroramphos* is very close to nominate, but slightly larger and with greener gloss, although birds in NW France (Brittany) somewhat intermediate; *barbarus* is largest of W races, with greenest gloss and strongest and longest bill; *baileyi* is as large as previous, but has weaker bill and almost unglossed plumage, is also relatively short-tailed (primary tips projecting beyond tail tip when on ground); *docilis* is similarly large, but has weaker, shorter bill and whole plumage washed (rather than glossed) with green; *himalayanus* is largest race, glossed blue or bluish-purple (rather than green), is also relatively longer-tailed than most of others; *centralis* has even longer tail, but is smaller, and has only weak bluish plumage gloss; *brachypus* has very weak purplish gloss and relatively the shortest bill of all races. Voice. Typical call a wheezy, hoarse "chaw" or a fading "ch'waa", delivered with explosive quality; very similar to call of juvenile *Corvus monedula* but less flat in tone. Several other calls basically variations on this theme, but alarm a more distinctive harsh, screeched scolding "ker ker ker" or single "karr". Soft, low warbling and chittering sounds reported as uttered by pair-members when relaxing together. Ethiopian race *baileyi* (at least in Bale Mts) seems to lack typical "chaw" of other races, and to be relatively more quiet; calls squeakier, and include trilled, watery "rheeep" and short, weak and rather dry "ka", thus vocally closer to *P. graculus* than to other races of present species.

Habitat. Occupies two habitat zones: coastal cliffs in W Europe, and high mountain pastures with rocky crags elsewhere. Coastal populations (Ireland, Britain, Brittany, Canaries, NW Spain) favour sea cliffs with rocky crags, interspersed with closely grazed grassland. Inland populations found in high mountain pastures above tree-line, in Europe favouring sheep-grazed slopes, farther E also associated with grazing yaks (*Bos grunniens*) and ponies. In Atlas Mts of N Africa most numerous between 2000 m and 2500; in Himalayas favours range 2400–3000 m, but ascends to 6000 m in summer and reported as high as 7950 m on Mt Everest. Less directly human-orientated than is *P. graculus*, but attends grazing stock and is sometimes attracted to human habitation for nest-sites; forages in grassy areas within towns, often nests in buildings in use (Bhutan and Tibet), even on modern buildings in heart of some cities (Ulaanbaatar, in Mongolia).

Food and Feeding. Primarily insectivorous, almost entirely so in spring and summer. Larvae of craneflies (Tipulidae) important, along with small beetles (Coleoptera), caterpillars (Lepidoptera) and ants (Formicidae); wide variety of other invertebrates identified as food items, including woodlice (Isopoda), harvestmen (Opiliones), fly larvae (Diptera), spiders (Araneae), grasshoppers (Orthoptera), bugs (Hemiptera), earthworms (Lumbricidae), and sometimes even scorpions (Scorpiones); rarely, small vertebrates such as lizards (Lacertidae), a mouse (*Mus*) and a shrew (Soricidae), and exceptionally carrion recorded. In autumn and winter, when invertebrate food more difficult to find, takes grain, seeds and small berries, including those of rowan (*Sorbus*), pear (*Pyrus*), juniper (*Juniperus*), sea-buckthorn (*Hippophae*) and olive (*Olea*). Food-hiding reported in captivity. Forages on ground in open country, typically in pairs or family parties, but large assemblies (reaching 200 or more individuals) form as groups of non-breeders merge into noisy social gatherings. On ground, hops, walks and runs between bouts of probing or vigorous digging; digging accompanied by wing-flicking and tail-flicking (a good fieldmark, even at distance). In winter especially, forages along tideline, probing seaweed piles for fly larvae and digging in sand for sandhoppers (Talitridae); may dig quite deep pits, tossing soft sand aside and over its back in the process. Reported as standing on backs of domestic animals to search for parasites. Perches on craggy outcrops, walls and buildings, but not on trees or wires. Has been reported as clumsily flapping in foliage of fruiting trees on occasions, and exceptionally as flapping about to perch on flowerheads of artichokes (*Cynara*). On La Palma (Canary Is), seen to take advantage of caterpillar swarm, flapping amid foliage of pine trees (*Pinus*) and even clinging on trunk to pick food items from bark fissures. Turns over dung and small stones in search of invertebrates; can turn relatively larger stones by reaching forwards and pulling back with stone against chest.

Breeding. Laying mainly middle to late Apr in Britain and Ireland, early May in S France, and late Apr to May in W China and Caucasus; single-brooded, exceptionally two broods in a season; some pairs "skip" a breeding season. Monogamous, generally with lifelong pair-bond, partners remaining together throughout year; first-year and second-year pairings can be short-term until preferred partner located. Solitary nester, but in areas of high population density (as in parts of W China) forms loose colonies; average inter-nest distance in Britain 1·4 km. Occasionally a helper (probably young of previous brood) assists at nest. Nest, usually instigated by male, but finished by female, a mass of sticks, thickly lined with wool, rarely all wool, built typically in roof of cave or rock chimney, or disused quarry, but equally in roof space of disused building, old mine shaft or similar site, also in roof space of inhabited house, monastery or dzong; rarely, may excavate hole or cavity up to 1 m in depth in soft sandstone cliff. Clutch usually 4 eggs, rarely up to 6; incubation by female alone, fed on nest by male, period 17–21 days; chicks fed by both parents, occasionally also by a helper, nestling period 36–41 days; young remain in family group for up to 50 days after fledging; in late autumn families gather into flocks to prepare for winter foraging, or communal roosting. Rarely, nest parasitized by Great Spotted Cuckoo (*Clamator glandarius*).

Movements. Basically sedentary. Ringing studies in Britain suggest that young disperse over short distances, rarely more than 10 km from natal site; exceptional movements recorded, the longest an individual which moved from Bardsey (off NW Wales) to Liverpool, a distance of 142 km, and another of 150 km within Wales. Unringed vagrants have turned up on Orkney, 360 km from nearest breeding sites, and E England (210 km). A succession of vagrants in Cornwall since 1986 resulted in tiny breeding toehold being established, heralding the first nesting in England for nearly 50 years. Two records of vagrants in Germany since 1977, and others reported from Slovakia, Hungary, Balearic Is and Israel. European inland populations move little, apart from leaving higher elevations after heavy snowfall; in N Spain may descend from mountains to coast during such conditions. Those in Morocco, Turkey, Iran, Afghanistan and W China likewise make altitudinal movements following adverse winter weather.

Status and Conservation. Not globally threatened. Locally common. In much of its wide range there is evidence of a decline in numbers, most evidently in Europe, where populations have become very fragmented. Changes in grazing regimes undoubtedly the most important factor in its demise. In former times grazing animals roamed freely over mountain slopes and coastal cliffs, keeping vegetation short and ideal for invertebrates (essential in diet of young). Populations have become very fragmented in the Alps, where extinct in Austria by end of 19th century, but an isolated population of c. 50 pairs near Valais, in Swiss Alps, with similar numbers in W Italian and French Alps; has disappeared from C & E Italian Alps, but a few hundred pairs breed in Apennines and Sicily, with very small population on Sardinia. In NW France, had disappeared from Normandy by 1910, but c. 30 pairs survive in Brittany (chiefly on island of Ouessant). Following a long decline, which resulted in loss of entire English and most of Scottish populations, this species now doing well in Britain and Ireland, with c. 1000 pairs, with local increases perhaps most marked on I of Man, and has started to recolonize Cornwall, where three pairs nested in 2008 (the only ones in England); part of the recovery of British choughs due to a programme of rough grazing along coastal slopes and the erection of nestboxes in suitable caves or old buildings. Spain, with 8000 or so pairs, has one of highest populations in Europe, with some local increases since 1970s; in adjacent Portugal just over 100 pairs at five sites; on La Palma (Canary Is) c. 300 pairs. In NW Africa, quite numerous in Morocco, less so in Algeria, and extinct in Tunisia (last nested in late 1800s). In E Europe, at least 3000 pairs in Croatia, an unknown small number in Albania and at least 1500 pairs in Greece, majority on Crete. Widespread in mountains of E Turkey, and probably so in adjacent N Iraq. After absence of records for several decades, has recently been rediscovered in Lebanon and C Syria (Palmyra). Numerous through Caucasus and in Elburz Mts of N Iran, as it seems to be also throughout remaining Asiatic part of range, but disappearance of an isolated population in Urals in 19th century also suggests a contraction (if the species' presence there was undoubted). Isolated populations in highlands of Ethiopia relatively few in number, at least in Bale Mts, where fires have burnt extensive tracts of the tundra-like landscape.

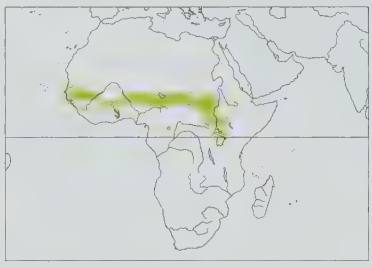
Genus *PTILOSTOMUS* Swainson, 1837

79. Piapiac



Ptilostomus afer

French: Piapiac africain **German**: Spitzschwanzelster **Spanish**: Piapiac
Other common names: Black Magpie

Taxonomy. *Corvus afer* Linnaeus, 1766, Senegal.

Long, graduated tail, sociable habits and piping calls of this peculiar corvid suggest, as with *Zavattariornis*, an affinity with the starlings (Sturnidae), but DNA-sequencing supports its inclusion in present family, with closest relatives evidently *Podoces* and *Zavattariornis*. Very unusual among passerine genera in having ten (instead of twelve) tail feathers. Monotypic.

Distribution. SW Mauritania, Senegal, Gambia and Guinea Bissau E through N Guinea, N Ivory Coast, S Mali, S Burkina Faso, N & E Ghana, N Togo, N Benin, S Niger and N Nigeria E in narrow band to SW Sudan, thence S to extreme NE DRCongo, Uganda (except SW & E), SW Ethiopia and extreme W Kenya. Also a few old reports from Sierra Leone and one recent record from Liberia, and isolated records from N PRCongo.

Descriptive notes. 35–42 cm; 121–130 g. A rather small-bodied corvid with very long, graduated tail of ten stiff feathers; stout bill with strongly arched culmen, nasal bristles soft and upcurving, overlapping along culmen ridge; feathers of forehead and lores dense and velvet-like. Head and body plumage are black with bluish or purplish sheen, rump and uppertail-coverts dull sooty black; upperwing-coverts, tertials and inner secondaries glossy black, primary coverts, primaries and outer secondaries very dark brown with blacker tips, their inner webs paler brown (light wingpanel in flight); tail dull blackish-brown, lighter on underside, becoming paler brown with wear; underwing-coverts and axillaries sooty black, contrasting with pale grey-brown undersides of flight-feathers; iris violet-blue or purple, with more red-brown outer rim; legs and feet black. Sexes alike. Juvenile has brown iris, is similar in plumage and has a pink bill, with varying amounts of black at the tip; the bill apparently not becoming wholly black until at least a year old. Voice. Party-members keep in contact with loud chattering and scolding "pee-ip, pee-ip, pee-ip" calls uttered in 2–3 seconds, similar to but shriller than calls of Long-tailed Glossy Starling (*Lamprotornis caudatus*); particularly noisy towards roosting time. Also reported is a rather clipped metallic chirrup and a short rasping "kwerr", latter given when disturbed, also a harsh, scolding chatter when alarmed.

Habitat. Savanna with scattered trees and patches of woodland, including areas heavily grazed by both domestic and wild herds; forages in dry cultivation, especially recently harvested large fields. Often around villages and edges of towns, where fond of open grassy areas with stands of *Borassus* and *Hyphaene* palms, such as golf courses and airfields. From sea-level to 1500 m.

Food and Feeding. Omnivorous. Diet includes seeds, berries and fruits, including fruits of oil palm (*Elaeis guineensis*), also spiders (Araneae), and various insects and their larvae, especially beetles (Coleoptera), termites (Isoptera) and bugs (Hemiptera). Feeds primarily on ground in parties of eight or so individuals; sometimes 20–40 or as many as 50 may gather together for a short time. Walks with confident leggy strides, tail often awkwardly askew and dragging, adept at sidestepping, hopping and even jumping into air to catch flying insects, such as emerging termites. Feeds around feet of grazing animals, chiefly domestic herds; readily alights on backs of animals, searching for ectoparasites in manner of oxpeckers (*Buphagus*). Perches on treetops and especially on palms, running and hopping along branches with agility. When flushed, may fly only a short distance, keeping low, often jerking head and scolding intruder upon alighting. If disturbed, whole group may fly up into tops of tall palms, sometimes breaking up to alight in different trees. Perches with tail hanging stiffly down. Leaves communal roost in palm crowns at dawn in order to drink and begin foraging. In heat of day flock retires to rest in shady tree.

Breeding. Poorly studied, although numerous. Season depends on local rains, laying reported Jun–Jul in Senegambia, a little later (Jul–Sept) in Mauritania, Apr–May in Ghana, and Mar–Jun in Burkina Faso, Nigeria and Sudan (also Dec); reported as "nesting" in Nov in Uganda. Solitary nester. No information on extent of pair-bond, but known to be co-operative breeder, with reports of as many as five adults and three immatures feeding nestlings. Nest a rather compact structure of twigs, grasses and strips of palm fibres, placed on earthy foundation, with well-lined cup of palm fibres, or sometimes made almost entirely from palm fibres; placed up to 11 m from ground at base of palm frond, sometimes in fork, favouring *Borassus* and *Hyphaene* palms. Clutch 3–7 eggs; no information on incubation and nestling periods.

Movements. Sedentary over most of range. Some movements suspected in parts of C Africa, where reported as visiting parts of Niger only during wet season. Occurrence of occasional individuals in Sierra Leone and the single Liberian record are difficult to explain unless some movements have

taken place. Occurrence in Kenya sporadic, based on a handful of records of wandering birds from Uganda; in Ethiopia may be only a rare seasonal visitor from Sudan.
Status and Conservation. Not globally threatened. Widespread and common over most of range. One of the most conspicuous birds of the savanna in Senegambia. Seemingly less common and more localized in Burkina Faso and Ivory Coast, and rare and little known in extreme N PRCongo, NE DRCongo, W Kenya and SW Ethiopia. This species' ability to adapt and take advantage of man's agriculture and grazing animals has no doubt benefited it; in Sudan it is perhaps even increasing and may be slowly spreading N.

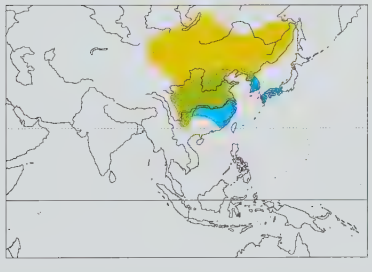
Genus *CORVUS* Linnaeus, 1758

80. Eurasian Jackdaw

Corvus monedula

French: Choucas des tours **German**: Dohle **Spanish**: Grajilla Occidental
Other common names: (Western/Common) Jackdaw

Taxonomy. *Corvus Monedula* Linnaeus, 1758, Europe = Sweden.
This species and *C. dauuricus* sometimes placed together in a separate genus, *Coloeus*. The two form a species pair and are sometimes considered conspecific, but they seem to replace each other geographically in vicinity of L Baikal and N Mongolia, meeting on very narrow front, but with very few reports of mixed pairings. Geographical variation complex, with individual and clinal variation. Other proposed races are *turrium*, *brehmi* and *hilgerti* (all described from Germany), *ibericus* (S Spain) and *nigerrimus* (Morocco), all synonymized with *spermologus*, and *tischleri* (NE Poland), *sophiae* (E Poland), *schluteri* (Belarus), *collaris* (Macedonia), *pontocaspicus* (Cyprus) and *ultracollaris* (Tien Shan), all treated as synonyms of *soemmerringii*. Four subspecies currently recognized.
Subspecies and Distribution.
C. m. monedula Linnaeus, 1758 – Scandinavia.
C. m. spermologus Vieillot, 1817 – W & C Europe from British Is, S to Morocco and NW Algeria.
C. m. cirtensis (Rothschild & E. J. O. Hartert, 1912) – NE Algeria.
C. m. soemmerringii J. G. Fischer von Waldheim, 1811 – E Europe (from S Finland, E Poland, Balkans, Greece, Turkey, Cyprus, and N Israel) E in Asia to L Baikal, W China (W Xinjiang) and Kashmir.



Descriptive notes. 34–39 cm; 136–265 g. Small, sociable crow with moderately long tail somewhat rounded at tip, small and short bill; flattish forecrown, feathers can be raised to form slight mid-crown crest; agile in flight, flocks soar and tumble, pausing to hang over cliff faces. Nominate race has forecrown blackish with slight bluish gloss, rear crown, nape and side of head contrastingly pale grey, distinct whitish collar at base of nape; remainder of plumage dark grey, upperparts with weak bluish sheen, upperwing and tail similar but darker; iris light greyish-white; bill and legs black. Sexes similar. Juvenile has dark iris and entire head and body plumage softer, tinged brownish and without gloss; by first autumn most of head and body plumage replaced and adult-like, contrasting with older (worn) wing and tail feathers; dark iris may persist until end of first winter. Races differ mainly in colour saturation and in prominence of pale collar at side and rear of nape: *spermologus* is darker than nominate, especially on nape, with blacker face, lores and throat, and lacks pale hindcollar or has only weak, diffuse greyish-white line at base of neck; *soemmerringii* is paler grey than previous, especially on nape, and has very distinct pale collar which, in S & E populations, finishes in wider whitish blotch at side of neck ("*collaris*"); *cirtensis* is uniformly slate-grey, with far less contrast on head and nape than other races. Voice. Typical call an abrupt, high-pitched "chjak", given singly, or excitedly repeated 7–8 times as birds meet and form larger groups. In late summer a *Pyrrhocorax*-like "cheeaow" given by recently fledged young, can easily confuse the unwary, but is sooner or later accompanied by "chjak".
Habitat. Inhabits great variety of open country, preferably with scattered trees. Favours mixed farmland, parks and gardens, churchyards, wooded steppe, quarries and coastal cliffs. Avoids both tracts of treeless country and extensive woodland or forests. Ascends to 2000 m in parts of Asia and Morocco; non-breeding birds reported up to 3500 m in Kashmir.
Food and Feeding. Omnivorous, but less of a carnivorous scavenger than most congeners. In one study, 84% of diet plant materials, including grain, seeds and berries, but primarily carnivorous during breeding season. Normal summer diet includes wide variety of invertebrates, e.g. grasshoppers (Orthoptera), ants (Formicidae) and great variety of flies (Diptera); moth caterpillars (especially *Tortrix viridana*) and beetles (Coleoptera) also important components. Some individuals specialize, and become adept at taking eggs of both small and large birds: on Skokholm (Wales) responsible for as much as 60% egg loss of the island's Common Murre (*Uria aalge*) population; others raided burrows of Atlantic Puffins (*Fratercula arctica*) and Manx Shearwaters (*Puffinus puffinus*); in a town in Hungary reported as feeding entirely on eggs and young of Eurasian Collared-doves (*Streptopelia decaocto*); and major egg losses at some Grey Heron (*Ardea cinerea*) colonies have been attributed to this corvid. Such incidents seem unusual, but illustrate the ingenuity of this species; even more strangely, one individuals was watched as it removed bats (Chiroptera) from a tree hole. Also, forages along tideline, primarily for sandhoppers (Talitridae). Takes household scraps of different kinds, and may become cautiously confiding about picnic sites and in city parks. Feeds chiefly on the ground, walking with bold, strutting gait, as it searches for insects; side-hops to catch prey items. Perches on cattle and sheep to feed on ectoparasites. Will fly high during ant emergences of flying ants, catching the ants on the wing. Will pursue other birds to make them drop food items. Sociable; in non-breeding season, large numbers join *C. frugilegus* and *C. corax* on short-cropped grassland and fields and in mixed corvid roosts at favoured woodland sites. Rarely stores food items, and even then seems not to bury them.
Breeding. Laying from late Apr in Britain and N Europe, mid-Apr in C Europe, and first half May in NW Russia and in C Asia and Kashmir. Long-term pair-bond. Semi-colonial, several pairs nesting in close proximity on rooftop chimneys and in quarries and caves. Both sexes take part in construction of nest, which varies in size, but can be massive as fresh nest built each year on top of older ones; foundation a mass of branches and twigs, interspersed with mud and dung, inner cup quite deep and thick, of mosses, rotten wood, feathers and fur and wool, usually in some cavity of some kind, e.g. tree hole, rock crevice in quarry, or in sea cliff alongside Razorbills (*Alca torda*) and Black-legged Kittiwakes (*Rissa tridactyla*), in rabbit (*Oryctolagus*) burrow, chimney, mine-shaft, or bridge; nestbox sometimes used and, rarely, a disused nest of *C. frugilegus* or *Pica pica* may be taken over. Clutch 3–8 eggs, average 4; incubation by female, period 17–19 days, exceptionally 23 days; chicks fed by both parents, nestling period c. 30 days; family-members soon join up with others and form quite substantial summer flocks. First breeding when c. 2 years old.
Movements. In W & S Europe resident or short-distance migrant, some reaching N Africa; native N African populations resident. In Britain leaves higher ground, dispersing SW, many reaching Ireland; occasional massive movements of seemingly displaced birds, as in late Oct 1984, when estimated 20,000 headed N over Cornwall (SW England) after 4000 had arrived on nearby Is of Scilly (where normally a vagrant) for a brief visit. N European breeders may remain throughout winter around human habitations, but others leave during Sept and Oct, dispersing towards SW, including E coast of Britain; individuals ringed in Baltic region have reached France and Italy. C European birds seem to disperse N to Netherlands and adjacent low-lying areas. Those from N of range, particularly W Siberia, move farther, although most winter in S & N Caspian region within S limits of breeding range in C Asia. Peak passage through Chokpak Pass, in W Tien Shan (Kazakhstan), in second half Oct and, in spring, first half Mar; although quite numerous in N Afghanistan in winter, few reach S, some winter in Himalayan foothills of N Pakistan and a few enter plains of NW India. Vagrancy recorded on a number of occasions, stragglers having appeared in Iceland, Faroe Is, Mauritania, Canary Is, Madeira, Azores, Balearic Is, Corsica, Tunisia, Jordan, Tibet and even Japan. Most surprising have been periodic occurrences in E North America, chiefly E Canada, including flock of 52 in Quebec in Nov 1984 (ship-assisted), coinciding with the massive movement over Cornwall (UK) in late Oct of that year.
Status and Conservation. Not globally threatened. Abundant in most of range, but apparent population decreases over recent decades in most European countries. Following estimates (territories/pairs) made for most countries within W Palearctic: Britain 390,000, Ireland 210,000, France 75,000–400,000, Belgium 21,000, Luxembourg 1200–1500, Netherlands 60,000–120,000, Germany 100,000–110,000, Denmark 25,000–140,000, Norway 1000–10,000, Sweden 150,000–500,000, Finland 40,000–60,000, Estonia 30,000–40,000, Latvia 10,000–50,000, Czech Republic 10,000–20,000, Slovakia 3000–5000, Hungary 5000–10,000, Austria 2500–4000, Switzerland 950–1000, Italy 50,000–100,000, Spain 420,000–530,000, Portugal 1000–10,000, Greece 100,000–300,000, Albania 20,000–50,000, Croatia 60,000–80,000, Slovenia 3000–5000, Bulgaria 1,000,000–5,000,000, Romania 40,000–60,000, Russia 1,000,000–10,000,000, Belarus 350,000–400,000, Ukraine 80,000–85,000, Moldova 3500–5000, Azerbaijan up to 1000, Turkey 1,000,000–10,000,000; widespread but localized in Morocco and Algeria. The opening-up of taiga forests of Siberia has permitted this species to breed farther E than previously; in early 1980s found to be not uncommon in Bratsk area and elsewhere in region N of L Baikal. Spreading N through Scottish islands, and now breeding as far N as Shetland. In Malta, where formerly common, is now extinct as a result of persecution. Distinctive race *cirtensis* thought to be extinct in Tunisia, and may be heading that way in NE Algeria (a colony near Ben Harroun was not located in 1989, perhaps displaced by dam construction; 25 had been noted in gorge at Constantine in 1982). Transatlantic vagrants have attempted to breed on more than one occasion, and a pair made unsuccessfully nesting attempt in Iceland in 1977.

81. Daurian Jackdaw

Corvus dauuricus

French: Choucas de Daourie **German**: Elsterdohle **Spanish**: Grajilla Oriental
Other common names: Asian/Pied/Black/Collared/Chinese/Eastern Jackdaw

Taxonomy. *Corvus dauuricus* Pallas, 1776, Transbaikalia, Russia.
This species and *C. monedula* sometimes placed together in a separate genus, *Coloeus*. The two form a species pair and are sometimes considered conspecific, but they seem to replace each other geographically in vicinity of L Baikal and N Mongolia, meeting on very narrow front, but with very few reports of mixed pairings. Dark immature of present species was at one time thought to be a different species ("*C. neglectus*"). Confusing variety of intermediate specimens have also been given names (e.g. *griseiventris* and *nigriventris*) Other synonyms of this species are *fuscicollis* (from Baikal) and *khamensis* (from Xinjiang, in W China). Monotypic.
Distribution. S part of E Siberia from NW L Baikal E to Amurland and Ussuriland (SE Russia), S through Mongolia to E & NE China (E from NE Xinjiang and E Qinghai, S to SE Xizang, Yunnan and Jiangsu). N breeders migrate S to as far as SE China, Korea and S Japan.

Descriptive notes. 34–36 cm; 110–275 g. Small, sociable corvid with moderately long tail somewhat rounded at tip, small and short bill; flattish forecrown, feathers can be raised to form slight mid-crown crest; agile in flight. Crown, face, throat and breast "shield" are glossy black; side of head behind eye black, usually with fine silver-white streaks (but some have only a grey wash over ear-coverts); nape, lower side of head, lower breast and flanks whitish, tinged pinkish-grey when feathers fresh, lower underparts dull grey-tinged whitish, centre of belly, feathered tibia, undertail-coverts and entire upperparts, including upperwing and tail, black; inconspicuous bluish-purple gloss on wings and tail, as well as on crown and throat; iris dark brown; bill and legs black. Sexes alike. Juvenile soon after fledging is pied like adult, but plumage soft, black areas dull sooty black, white areas washed with pale brown,

quite quickly moults into darker first-winter immature plumage; immature has white parts of plumage replaced by dull black, similar to *C. monedula* but dark-eyed, and large glossy black breast shield discernible (merely a diffusely darker throat on *C. monedula*), also rear head and ear-coverts with pale silver streaking but this temporally variable (few or no streaks in autumn and early winter, obvious streaking thereafter); fully adult pied plumage acquired towards following summer; during transitional stages a variety of patchy individuals encountered, e.g. when acquiring adult nape pattern shows whitish first on upper nape (*C. monedula* has narrow whitish collar at base of nape). Voice. Loud "chjak"; calls very like those of *C. monedula*, but perhaps a little less cackling and lower in pitch.

Habitat. Open country, preferably with scattered trees. Large clearings and edges in riverine forest, and rolling steppe with grazing animals and scattered trees (with or without human settlements); even at outskirts of cities. Up to 2000 m in Altai, where it also inhabits cliff faces.

Food and Feeding. Omnivorous; feeds chiefly on seeds and grain outside breeding season, but mostly invertebrates, chiefly insects, during breeding season. Flocks join up with those of *C. frugilegus* or *C. corone* in stubble fields in autumn and winter; large numbers of both species also join other crows in winter at mixed corvid roosts at favoured woodland sites. Also forms more discrete roosts with *Pyrrhocorax graculus* and Hill Pigeons (*Columba rupestris*). Behaviour very much as for *C. monedula*.

Breeding. Laying from mid-Feb in most of Chinese range, much later, late May, in Xizang; mid-May in Tuva (SC Russia). Semi-colonial, several pairs nesting in close proximity in stands of trees, old buildings and cliffs. Builds a stick nest similar to that of *C. monedula*, but favours hollow tree as a site, and perhaps more inclined to build open nest in tangle of branches. Clutch 4–6 eggs; no information on incubation and fledging periods. In breeding condition when c. 2 years old.

Movements. S populations basically resident. N populations migratory, although small numbers may remain about settlements as far N as Ussuriland (in Russian Far East); migrates S & SE towards milder climates, reaching Korean Peninsula and Japan (chiefly Kyushu), but largest numbers wintering along lower Yangtze valley and substantial numbers wintering farther N, in Hebei (E China); young appear to move farther than adults. Flocks of 200–300 individuals pass through Ulaanbaatar region of Mongolia from mid-Mar onwards, and several such flocks in mid-Apr 2007 contained mostly first-winter birds (only 1-2% adults); in autumn, 2876 counted as they flew through C Mongolia in a fortnight from late Sept onwards, with steady passage continuing to at least end of month, also a single flock of 1600 flying S in Ulaanbaatar on 2 Sept 2005; some birds winter in Ulaanbaatar. In Japan winter flocks of 60–90 can be found with *C. frugilegus* on Kyushu. Very rare vagrant in Taiwan and Hong Kong, also in C Ryukyu Is (Okinawa); farther W, presumed vagrants recorded in C Siberia (Krasnoyarsk), Uzbekistan and Kazakhstan, and several times in W Europe.

Status and Conservation. Not globally threatened. Quite common, but hardly abundant. Seems somewhat localized in Transbaikalia, but quite numerous in suitable habitat in Mongolia and N China. Good numbers recorded on passage in Mongolia. In Japan, where formerly a rare winter visitor, numbers have gradually increased.

Bibliography. Brazil (1991), Brouwer & Hallf (1999), Chen Fuguan *et al.* (1998), Coombs (1978), Cramp & Perrins (1994), Dementiev *et al.* (1954, 1970), Goodwin (1986), Jollie (1985), Leader (2003), Liu Yang & Lei Jinyu (2005), Madge (1994), Madge & Burn (1994), McCarthy (2006), Nechaev (1975b), Snow & Perrins (1998), Stepanyan (1990, 2003), Tomek (2002), Ushakova (2004), Vaurie (1954, 1959).

82. House Crow

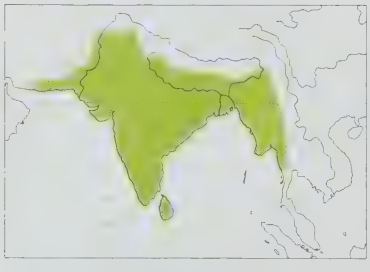
Corvus splendens

French: Corbeau familier **German**: Glanzkrähe **Spanish**: Cuervo Indio
Other common names: Indian (House) Crow, Grey-necked/Colombo Crow

Taxonomy. *Corvus splendens* Vieillot, 1817, Bengal, India.

Possibly close to, and perhaps an early offshot of, the "*C. macrorhynchos* complex", as suggested by head and bill shape; overlaps with members of that group, but somewhat ecologically separated. Races *zugmayeri* and *protegatus* intergrade with nominate in India. Birds from Maldive Is described as race *maldevicus*, but characters suggest ancestry of mixed races, and perhaps introduced on the islands long ago; considered best treated within *protegatus*. Four subspecies recognized.

Subspecies and Distribution.



C. s. zugmayeri Laubmann, 1913 – SE Iran and C & S Pakistan E to NW & NC India.

C. s. splendens Vieillot, 1817 – most of peninsular India (excluding NW part and coastal Kerala) and Nepal, Bhutan and Bangladesh.

C. s. protegatus Madarász, 1904 – SW India (S from N Kerala and W Tamil Nadu), Sri Lanka, Laccadive Is and Maldive Is.

C. s. insolens Hume, 1874 – extreme S China (S Xizang and S Yunnan) and Myanmar (including Tenasserim).

Introduced populations (most of which not racially separable, having been brought by ships from several origins) now commonplace at increasing number of towns and ports flanking shores of Indian Ocean and beyond.

Descriptive notes. 40–43 cm; 245–371 g. A relatively small (size not apparent in the field), rather slim-bodied, somewhat "leggy" crow with comparatively long, prominent, slightly arched bill enhanced by short "pinched" forecrown. Nominate race is mostly blackish-slate, blacker and more glossed on face, forecrown, chin and throat; nape to mantle, side of neck and side of breast medium-grey, shading into blackish-grey on lower underparts, and glossy blackish on back, rump and uppertail-coverts; upperwing and tail glossy black; iris dark brown; bill and legs black. Sexes similar. Juvenile is similar to adult but duller, without gloss on black parts of plumage. Races differ mainly in colour saturation (all intergrading): *zugmayeri* is palest, with nape almost whitish-grey; *protegatus* is much darker, with less contrast between nape and body; *insolens* is darkest of all, with even less contrast in plumage (could be confused with smaller races of *C. macrorhynchos*). Voice. Very vocal. Usual call a flat and toneless, dry "kaaan-kaaan", softer than that of Indian forms of *C. macrorhynchos*; also has variety of shorter, nasal calls; notes can be rather plaintive but always dry; calls of race *insolens* said to be higher in pitch than those of nominate.

Habitat. Always found in association with man, in variety of tropical and subtropical habitats. Abundant about human habitation of all types, from city-centre parks to railway stations, sprawling slums and coastal villages. Chiefly a lowland species, but has spread into several hill stations in Himalayas, mainly below 1600 m, but reported at 2100 m in Darjeeling and 2900 m in Sikkim. With increasing military activity in W Himalayas, occasional individuals have appeared around military bases to as high as 4240 m in Ladakh.

Food and Feeding. Omnivorous scavenger, feeding on all manner of crops, invertebrates, vertebrates. Main diet composed of discards and scraps foraged from rubbish dumps, abattoirs and street debris, also street markets and in fishing villages. Eats almost anything, from all kinds of places, ranging from foraging in flowering trees (for nectar) to scavenging for offal; feeds on carrion of all kinds, from dead fish to human corpses on tideline or riverside. Will take fish and insects from water, almost plunge-diving to do so, and undertakes ungainly aerial sallies to take flying ants (Formicidae). Takes eggs and nestlings of many bird species, including larger ones such as herons and egrets (Ardeidae), where it can cause havoc in nesting colonies; likewise with colonies of weavers (Ploceidae), where this crow's agility allows it to gain access to nest-chambers. Attracted to livestock, feeding among feet of cattle, where it steals food items from attendant Cattle Egrets (*Bubulcus ibis*); also rides on backs and necks of large mammals, not only taking ticks (Ixodoidea) and other parasites, but also pecking at open sores. Kills small rodents, and reports of attacks even on human babies, monkeys and cats; kills newborn domestic animals. Does great damage to crops, pulling up seedlings by roots and taking grain and rice from stores. Enters houses to scavenge food. Bold and aggressive by nature, with sociable scavenging habits, but also very wary of humans, in Egypt feeding mostly very early in mornings, spending most of the day at rest, hidden in tree or palm foliage (thus avoiding close contact with man); in most of range, however, displays little fear of man. Always alert, and constantly wary, nervously wing-flicking as it walks or hops on ground. Forms massive roosts, gathering on rooftops in noisy parties prior to flying off towards main roost, where hundreds or thousands may converge, together with large numbers of parakeets (Psittacidae) and mynas (Sturnidae) in plantations or mangroves; just before dawn, flies back to favoured foraging grounds.

Breeding. Season varies according to location, in India as a whole favoured months Apr–Jun, at start of wet season, but younger birds (15–16 months of age) often begin nesting in Oct–Nov; in S, peak in Mar–May in Kerala and May–Aug in Sri Lanka; peak months Oct–Jan on Zanzibar, Oct at Port Sudan, and Apr–May in Kuwait and S Israel; sometimes double-brooded, e.g. in Kenya. Monogamous, with long-term pair-bond, but many individuals are somewhat promiscuous. Solitary nester. Both sexes collect nest material, but normally only female builds, an untidy stick nest generally lined with soft materials gathered from rubbish tips, but stick frame often augmented with metal and wire (including e.g. spectacle frames, coat-hangers, sheet metal, bicycle pedals), and sometimes entire nest made from wire and then often unlined (and can weigh as much as 25 kg), in some cases single large wire nest used by more than one pair; generally placed high in fork of large tree, especially banyan (*Ficus*) or mango (*Mangifera*), but in desert regions often resorts to mangroves and stands of tamarisks (*Tamarix*), and nests also on ledges on buildings, electricity poles and streetlamps. Clutch on average 4 eggs; incubation probably by female alone, although some claims that male relieves female for short spells, period 16–17 days; chicks fed by both parents, nestling period 21–28 days. Nests parasitized by Common Koel (*Eudynamys scolopacea*).

Movements. Resident. Short-distance movements not uncommon.

Status and Conservation. Not globally threatened. Abundant throughout native range; perhaps even more abundant at certain sites where long introduced, either intentionally or by ship-assisted passage. One at Khost in S Afghanistan in 1964 the only record for that country. Race *insolens* formerly extended to SW Thailand, but now only a vagrant there. Introduced populations now commonplace at growing number of towns and ports flanking shores of Indian Ocean and beyond; although some were introduced (e.g. Mombasa and Zanzibar, in E Africa), most originated from ship-borne "stowaways". Once established, colonies spread through towns and into villages, in more arid regions the spread being checked only by absence of human settlements and by desert conditions. Many colonies have reached "pest" proportions, with eradication plans set in motion. In Middle East, colonies exist in SW Iran (Bushire), Kuwait, Saudi Arabia (Jedda, Yanbu), Bahrain, United Arab Emirates, Oman (Muscat), Yemen (Aden N to Hodeidah, a few sites E to Ghaydah), Jordan (Aqaba) and Israel (Eilat); in E Africa from Egypt (chiefly Suez, but also along Red Sea coast), Sudan (chiefly Port Sudan), Djibouti, Eritrea (Assab, Massawa), Somalia (Berbera, Raas Caseyr), Kenya (all along coast, some even Nairobi), Tanzania (chiefly Zanzibar, Pemba, Dar es Salaam), Mozambique (chiefly Inhaca I, also Maputo), South Africa (chiefly Durban, Cape Town); also islands in Indian Ocean, including Seychelles (controlled, but probably still on Mahe and Praslin), Mauritius, Laccadive Is (Kalpeni, Amini and Androth, with later reports from Kadmat and recently introduced Minicoy); in SE Asia on Andaman Is (Port Blair), Peninsular Malaysia (almost throughout lowland W coast, inland to Kulim) and Singapore; recently reported from Sumatra and N Borneo; in Australia has arrived several times, chiefly Perth and Victoria, but shot before becoming established, although individuals reported Melbourne for several years. Reported in ones and twos from other, more temperate, parts of world, including Hong Kong, Japan (Hokkaido), USA (New Jersey, South Carolina, Florida), Gibraltar, Morocco (Tangiers), France (Lille, Lyon), Poland, Hungary, Denmark, Netherlands (Hoek van Holland; first two in 1994, bred in most years 1997–2000, at least ten at roost in Apr 2002), Ireland (Waterford) and even Chile (Punta Arenas); in Hong Kong a substantial increase in numbers of this species has occurred, a flock of 100–200 individuals having established itself in C urban Kowloon. It is widely believed that introduced populations of this crow present considerable problems to humans and native wildlife. In addition to causing ecological damage, it has inflicted economic damage by preying on chicks and eggs of domestic poultry and eating crops such as maize (*Zea mays*) and sorghum (*Sorghum vulgare*), and can become a nuisance to people and present a threat to tourist amenities in some regions. It is known to carry a number of human pathogens, including at least eight human enteric diseases (serotypes of *Salmonella*, *Plesiomonas*, enteropathic *Escherichia coli*, *Shigella* and *Aeromonas hydrophila*), among others (e.g. possibly cholera). Lack of natural predators prevents limitation of this corvid's numbers, and its unsavoury diet and close proximity to humans suggest that human health could be at risk. Control is being attempted in various countries (Aden, Kenya, Tanzania and South Africa) by trapping, poisoning and destroying nests; Australia has a shoot-on-sight policy, which would, it is hoped, prevent the potential destruction of that country's endemic avifauna should this corvid become established there. On Socotra, this species arrived in 1996 and built up a breeding population of more than ten pairs, deemed to pose a threat to the island's native biodiversity; after numerous attempts to trap the crows failed, an imaginative scheme to control their numbers was successful, children being paid a reward for bringing a nest containing young to the Socotra Archipelago Conservation and Development Programme; the last crows were killed by a marksman in spring 2009. In complete contrast, evidence from India, within the species' natural range, suggests that the amount of insects, particularly grasshoppers and locusts (Orthoptera), that these crows consume outweighs the damage that they cause to growing crops.

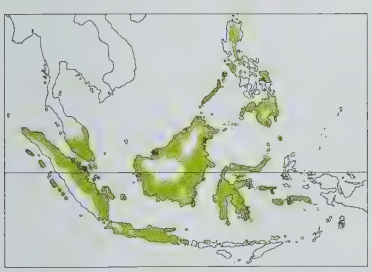
83. New Caledonian Crow

Corvus moneduloides

French: Corbeau calédonien **Spanish**: Cuervo de Nueva Caledonia
German: Geradschnabelkrähe

Taxonomy. *Corvus moneduloides* Lesson, 1831, no locality = Balab, New Caledonia. Monotypic.
Distribution. New Caledonia. Introduced on Maré, in Loyalty Is.



Descriptive notes. 40–43 cm; male 280–355 g, female 225–280 g. Medium-sized, rather long-tailed crow with throat feathers fine and hair-like, short bill is somewhat conical and chisel-tipped. Plumage is entirely glossy black; iris dark brown; bill and legs black. Sexes similar in plumage, male larger than female. Juvenile is similar to adult. Voice. Hoarse, high-pitched cawing notes, soft and drawn out or loud and staccato.
Habitat. Forest, woodland, savanna and plantations.
Food and Feeding. Omnivorous, feeding on adult and larval insects, also fruits, nuts, seeds, flowers, small birds, eggs, snails, carrion and other edible matter. Often in family groups. Foraging methods include hawking for flying insects. Has sophisticated behavioural repertoire; drops nuts on to hard surfaces to crack them, and makes spiked or hooked tools with which to impale or snag and extract prey from crevices. Locally mobile or gregarious, in groups of usually up to eight individuals, rarely up to 30.
Breeding. Season Sept–Jan. Nest a bowl of sticks lined with rootlets, diameter 19 cm, egg-cup 4·5 cm deep, placed c. 8 m above ground on small horizontal branches in outer foliage of mature tree. Clutch 2–4 eggs; no information on incubation and nestling periods.
Movements. Resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in New Caledonia EBA. Fairly common. Although it takes eggs and chicks of domestic poultry, this crow is not persecuted on New Caledonia, because it is an endemic species. Introduction on Maré has been detrimental to other birds nesting there.
Bibliography. 84. Slender-billed Crow

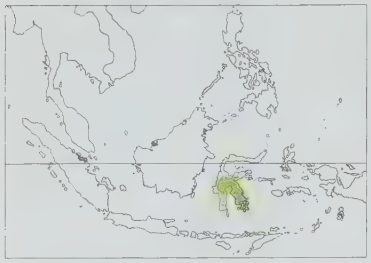
Corvus enca

French: Corneille à bec fin **German**: Sundakrähe **Spanish**: Cuervo Picofino
Other common names: Little Crow(!); Violaceous Crow (*pusillus*, *sierramadrensis*, *samarensis*, *violaceus*)

Taxonomy. *Fregilus Enca* Horsfield, 1821, Java.
Until recently *C. unicolor* treated as race of present species. Races form two groups, "nominate group" (also with *compilator*, *celebensis* and *mangoli*) and "*violaceus* group" (including also *sierramadrensis*, *pusillus* and *samarensis*); these may represent two separate species, or possible that races in latter group, which differ vocally, consist of more than one species; further study required. Birds on Mentawai Is (off Sumatra) traditionally included in nominate race, but this seems unlikely; research required. Birds from Banggai Is (off E Sulawesi) included in *celebensis* but may belong with *mangoli*; likewise, birds reported on Karakelong (in Talaud Is) and Siau placed with *celebensis*, but confirmation of race needed. Recent sight record of a family party of crows resembling present species on W coast of Sumba, in Lesser Sundas, may represent an undescribed taxon. Eight subspecies recognized.
Subspecies and Distribution.
C. e. compilator Richmond, 1903 – Peninsular Malaysia, Sumatra (including Simeulue and Nias I, off W coast) and Borneo.
C. e. enca (Horsfield, 1821) – Mentawai Is (off W Sumatra), Java and Bali.
C. e. celebensis Stresemann, 1936 – Sulawesi (and nearby small islands of Manterawu, Manadotua, Lembeh, Bangka, Talisei, Togian Is, Salayar, Basa, Buton, Bonerate and Tukangbesi Group), Banggai Is and Talaud Is.
C. e. mangoli Vaurie, 1958 – Sula Is, off E Sulawesi.
C. e. sierramadrensis Rand & Rabor, 1961 – mountains of N & C Luzon, in N Philippines.
C. e. pusillus Tweeddale, 1878 – Mindoro, Calamian Group and Palawan (and nearby Dadagican and Balabac), in W Philippines.
C. e. samarensis Steere, 1890 – Samar and Mindanao, in S Philippines.
C. e. violaceus Bonaparte, 1850 – Seram and Ambon, possibly also Buru, in S Moluccas.



Descriptive notes. 40–47 cm; 222–285 g. Medium-sized, fairly slim crow with medium-length slightly graduated tail, forecrown slightly peaked and inconspicuous throat hackles; in flight relatively broad, blunt wings and relatively short square-tipped tail. Nominate race has head, throat, upperparts, upperwing and tail entirely black, glossed purple-violet, underparts dull matt slate to black, bases of feathers of body white or whitish; iris dark brown, tiny patch of bare black skin behind and narrowly encircling eye; bill relatively long, dagger-like, straight along culmen except for gentle downward curves distally, black; legs black. Distinguished from very similar *C. macrorhynchos* by straighter culmen, slimmer build, with forecrown less peaked and throat less hackled, in flight also by relatively shorter and only slightly graduated tail, shorter hand with primaries less "fingered" (producing distinctly shallower, quicker, wingbeats). Female is like male but on average slightly smaller and weaker-billed. Juvenile has softer and less glossy plumage than adult, iris grey, inside of mandibles reddish-pink (not black). Races differ mainly in size, bill shape, and degree of gloss in plumage, members of "*violaceus* group" smaller and shorter-billed than "nominate group": race *compilator* is larger than nominate, with overall sheen to plumage, including underparts; *celebensis* is more highly glossed overall, has somewhat shorter bill than nominate; *mangoli* is smallest of group, but with relatively longest bill, plumage duller than previous; *violaceus* has culmen gently decurving throughout, plumage matt black with mauve sheen; *pusillus* is slightly larger than last, with relatively slimmer bill, plumage has greyish sheen, especially below; *samarensis* has deeper black plumage, both above and below, than previous, and has purple-blue gloss, especially on upperparts, also bill a little longer and deeper with slightly arching culmen, bases of neck feathers greyish-white; *sierramadrensis* is closest to last, but bill shorter and more slender, with less arched culmen, plumage more intensely black and bases of neck feathers darker grey. Voice. Little variation in "nominate group", a dry "akh-akh-akh" or "ka ka ka-a-a-a", in general calls higher-pitched and have a more nasal, drier quality than those of *C. macrorhynchos*; in excitement often breaks into a series of prolonged caws, interspersed with peculiar resonant, twanging notes (usually also takes to the air with vibrating wingbeats and arched neck). Members of "*violaceus* group" seem to differ from each other more obviously, but human interpretations and transcriptions of vocalizations create room for error: *violaceus* gives up to three simple nasal barks, *pusillus* gives a 3-note nasal "ack ack ack" or "wack wack wack", *sierramadrensis* a slower, lower pitched "waa waa whaaaa" (terminal note slightly inflected downwards), and *samarensis* a deeper "waaa waaa waaa".
Habitat. Lowland broadleaf evergreen forest, both primary and well-grown secondary forest, chiefly below 600 m. Favours extensive forest, and most likely to be encountered where this broken by clearings and other forms of forest edge; often by human settlements, fringes of reservoirs, riverbanks and watercourses. No longer in mangroves in Peninsular Malaysia, where *C. macrorhynchos* common (reports of present species in mangroves in recent years erroneous). In Borneo chiefly in lowland coastal and riverine forests, extending as high as 1050 m in Kelabit uplands. Reaches 1600 m on S Sulawesi, and up to 1000 m on Seram and in Philippines. Where *C. macrorhynchos* absent (Sulawesi) occupies wider range of habitats, including relatively open areas of cultivation and human habitation, with stands of trees, in coastal lowlands.
Food and Feeding. Surprisingly poorly studied. Although omnivorous, fruiting trees provide a major part of its diet; also takes variety of invertebrates, mostly insects, including large beetles (Coleoptera), also small lizards and on occasion feeds on roadkills on forest roads. In Peninsular Malaysia forages in tree canopy for ripe fruits, three species of fig (*Ficus curcubitina*, *Ficus stupenda* and *Ficus subcordata*) identified as a popular food; holds fruits under foot while pecking them open. Chiefly encountered in pairs or family parties, often feeding with other birds in fruiting trees. Also feeds on ground, usually within cover of forest. On Seram, race *violaceus* reported as flocking to feed on fields of ripening maize (*Zea mays*), but such behaviour not reported for other races. Although said to be shy of man, this more likely due to avoidance of habitation, which attracts more successful *C. macrorhynchos*.
Breeding. Not well known. For widespread race *compilator*, eggs recorded in Jun and Jul in Borneo and assumed late Feb and early Mar in Peninsular Malaysia (where nest-building reported first week of Feb, nestlings mid-Mar); eggs in Jun on Seram (race *violaceus*) and Mindoro (race *pusillus*). Generally solitary nester, but "colony" in one "enormous jungle tree" reported on one occasion in Borneo. Nest a rather bulky mass of twigs and sticks, lined with finer materials, placed high in large tree, ideally just inside upper canopy. Clutch on average 2 eggs; incubation probably entirely or mostly by female; chicks fed by both sexes, observation of five visits with food made to nest in one hour (food regurgitated for nestlings); no information on duration of incubation and nestling periods.
Movements. Generally regarded as sedentary; some wandering, as shown by sporadic observations on several Indonesian islands, and recent establishment on Peleng (in Banggai Is) aided by forest clearance and absence of *C. macrorhynchos*. Record of a small family party on W side of Sumba (Lesser Sundas) quite extraordinary and difficult to explain.
Status and Conservation. Not globally threatened. Everywhere rather uncommon; often elusive, favouring confines of quite dense forest, this eases competition from *C. macrorhynchos*, which favours forest edge and patchy cultivation; these habitats used by present species where *C. macrorhynchos* absent (Moluccas). In Peninsular Malaysia considered "Vulnerable, bordering on Endangered"; inhabits forested plains but forest destruction over most of its haunts has caused great fragmentation of its range. In Philippines, Luzon race *sierramadrensis* always considered rare and difficult to find, but recent observations indicate that it is more widespread across hills of N Luzon than was previously thought. Most members of "*violaceus* group" seem to be relatively numerous. Main problem for all races is forest destruction, and in some areas mining. Such activities have opened up large tracts of forest, enabling the larger, less specialized and more successful *C. macrorhynchos* to become established.

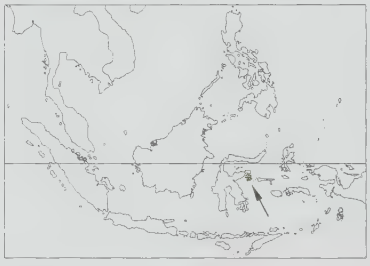
Bishop (1992a), Chasen (1939), Coates & Bishop (1997), Dickinson, Eck & Martens (2004), Dickinson, Kennedy & Parkes (1991), Goodwin (1986), Kennedy *et al.* (2000), Londei (2002), MacKinnon & Phillipps (1993), Madge & Burn (1994), Meinertzhagen (1926), Nuytemans (1998), Oortwijn (1987), Rand & Rabor (1961), Robson (2000), Sheldon *et al.* (2001), Smythies & Cranbrook (1981), Vaurie (1958a), Wells (2007), White & Bruce (1986).

85. Piping Crow

Corvus typicus

French: Corneille des Célèbes **German**: Celebeskrähe **Spanish**: Cuervo de Célebes
Other common names: Celebes (Pied) Crow

Taxonomy. *Gazzola typica* Bonaparte, 1853, "Nouvelle Calédonie"; error = Buton Island, Sulawesi. Sometimes placed in separate genus, *Nesocorax*. Forms a species pair with *C. unicolor*, which it resembles closely in structure; until recently, both were thought to belong with the "*C. enca* complex", but differ from that in their behaviour and vocalizations. Monotypic.
Distribution. C & S Sulawesi and smaller islands of Muna and Buton.
Descriptive notes. 35–40 cm; c. 175 g. Unmistakable small pied crow with short tail almost square at tip, medium-length bill with gently curved culmen, nasal bristles conspicuous but culmen ridge bare to base, throat feathers almost hair-like in texture. Head and upper nape are black, glossed bluish-purple, throat dull brownish-black; lower nape, side of neck, upper mantle and underparts to belly white, bases of neck feathers dark grey; lower mantle greyish-black to brownish-black, rest of upperparts, including upperwing and tail, black with blue and purple gloss, lower belly and tibia feathering dull greyish-black or brownish-black; iris dull reddish-brown, tiny patch of bare skin behind eye; bill and legs black. Sexes similar, but female has more diffuse line of demarcation between blackish throat and white breast. Juvenile has white of collar and underparts sullied with greyish-brown. Voice. Very noisy. Variety of rising nasal screams and upslurred piping whistles, often in twos and threes or mixed as a series of 3–5 notes; loud "wheep" seems to be a flight contact call. Also delivers prolonged fine, clear medium-pitched whistle of c. 2 seconds in duration, ini-



tially dropping in pitch before slowly rising (this note apparently given by two birds simultaneously).
Habitat. Tall secondary and primary tropical forests, both in lowlands and in hills, ascending to 1600 m in NC Sulawesi and 2150 m in S Sulawesi. Forages at forest edge and clearings and locally amid stands of riverine rainbow eucalyptus (*Eucalyptus deglupta*).
Food and Feeding. Various small invertebrates and their larvae; also small fruits, such as figs (*Ficus*). Sociable; typically forages in noisy parties of 4–10 individuals, working through lower to middle levels of forest canopy. Extremely active, dropping and fluttering among foliage, even hanging upside-down. Noisily chases away or mobs birds of prey and other intruders. Flies rapidly and quite directly with shallow whistling beats.
Breeding. No information.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Despite relatively small range, this peculiar crow is patchily distributed, but locally quite common. Reaches its N limit c. 20 km N of Palu (thus absent from almost entire Minahassa Peninsula). Occurs in a number of protected areas, including forest reserves and national parks.
Bibliography. Coates & Bishop (1997), Collar *et al.* (2001), Goodwin (1986), Jepson (1997), Madge & Burn (1994), Meinertzhagen (1926), Riley (1921), Vaurie (1958a), Wardill *et al.* (1999), Watling (1983), White & Bruce (1986).

86. Banggai Crow

Corvus unicolor

French: Corneille des Banggai **German**: Banggaikrähe **Spanish**: Cuervo de las Banggai

Taxonomy. *Gazzola unicolor* Rothschild and E. J. O. Hartert, 1900, Banggai Islands, Sulawesi.
Forms a species pair with *C. typicus*, which it resembles closely in structure; until recently, both were thought to belong with the "*C. enca* complex", but differ from that in their behaviour and vocalizations. Monotypic.
Distribution. Banggai Is, off E Sulawesi.

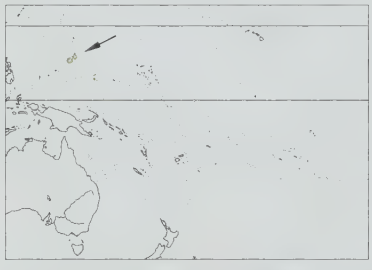
Descriptive notes. 40 cm; c. 175 g. A small, short-tailed crow with relatively small bill. Plumage is wholly black, weakly glossed with bluish or greenish, bases of hindneck feathers grey; iris dark, tiny patch of bare skin behind eye (probably invisible in the field); bill and legs black. Sexes similar. Juvenile undescribed. Voice. No information.
Habitat. Remnant hill forest, to 900 m on W side of Peleng; most other islands in archipelago quite low-lying.
Food and Feeding. No published information.
Breeding. No published information.
Movements. Sedentary.
Status and Conservation. CRITICALLY ENDANGERED. Restricted-range species: present in Banggai and Sula Islands EBA. Very rare; very poorly known. Following its initial discovery, in 1880s, remained undetected for more than a century until, in 1991, an individual was found on mountain slopes of Peleng, largest island of the archipelago, suggesting that this species survived on W side of this island. Subsequent searches in 2004, 2006 and 2007 confirmed that this species survived, but only in forest on mountain slopes of W Peleng and, in small numbers, at lower levels in centre of the island. Very rough estimates suggest global population of between 30 and 200 individuals. Since these observations were made, local conservationists have worked in conjunction with local communities to devise ways in which the crow and its forest habitat can be protected. Help is being provided to enable communities to practise more sustainable agriculture; development of ecotourism may also help in increasing local awareness of the archipelago's important biodiversity. Establishment of forest reserves on these islands is a matter that requires urgent attention.
Bibliography. Anon. (2008p), Bishop (1992a), Butchart & Stattersfield (2004), Coates & Bishop (1997), Collar *et al.* (2001), Goodwin (1986), Indrawan & Masala (2007), Indrawan *et al.* (1997), Madge & Burn (1994), Masala *et al.* (2008), Meinertzhagen (1926), Riley (1921), Stattersfield & Capper (2000), Vaurie (1958a), White & Bruce (1986).

87. Flores Crow

Corvus florensis

French: Corneille de Florès **German**: Floreskrähe **Spanish**: Cuervo de Flores

Taxonomy. *Corvus florensis* Büttikofer, 1894, Maumere, Flores, Lesser Sundas.
Sometimes placed in a separate genus, *Nesocorax*. Relationships uncertain; perhaps an ancient derivative of the "*C. enca* complex", but differs fundamentally in bill structure and plumage texture. Possibly nearest to *C. typicus* and *C. unicolor*. Monotypic.
Distribution. Flores, in Lesser Sundas.
Descriptive notes. 40 cm; c. 175 g. Small crow with relatively short bill with gently curving culmen, nostrils very long but concealed by dense nasal tuft (which extends half-way along side of upper mandible and overlaps base of culmen), relatively long tail and broad, rounded wings; plumage soft in texture. Plumage is purplish-black, not highly glossed, bases of neck feathers smoky grey; iris dark brown, tiny patch of bare skin behind eye; bill and legs black. Sexes similar. Juvenile apparently similar to adult, but information inadequate. Voice. Usual call a high-pitched, but downwardly inflected rasping "cwaaa" or "waaaak", repeated up to three times, delivered with downward tail-pumping or with head thrown back with each call. Sometimes gives elaborate resonant pumping and gurgling, which becomes progressively louder with repetition. Hoarse wheezing contact call also reported, as well as a drawn-out call likened to that of a wailing human baby.
Habitat. Tall secondary and primary moist, semi-deciduous monsoon forest along watercourses; chiefly in lowlands, but occasionally in hills, to 950 m. Has been found in relict patches of tall



forest in areas of short secondary growth, but such fragmentation probably unsuitable for long-term survival. Possibly also in forest habitats remaining in E Flores, which markedly drier.
Food and Feeding. No specific information on diet; most likely to consist of small invertebrates and small fruits. Forages in ones and twos, parties of up to five being family groups. Larger gatherings very rare, but 15 reported together in 1988. Feeds in tree canopy, both in crown and in subcanopy. Like *C. typicus*, its flight is rapid and direct with shallow whistling wingbeats.
Breeding. Season Sept–Jan. Nest constructed of sticks, built c. 12 m above ground; one documented nest was in isolated tree amid wooded cultivation but close to edge of forest. Clutch 2–3 eggs, usually 3. Nest sometimes parasitized by Channel-billed Cuckoo (*Scythrops novaehollandiae*) and possibly by Common Koel (*Eudynamys scolopacea*). No other information.
Movements. Sedentary.
Status and Conservation. ENDANGERED. Restricted-range species: present in Northern Nusa Tenggara EBA. Rare. Formerly found throughout Flores, but now virtually restricted to rainforests at extreme W end of the island, where occurs in four prime areas: Wolo Tadho Nature Reserve, Mbeliling, Sano Nggoang and Nggorang Bowosie (at E limit of regular recent sightings on N coast, with Kisol at E limit on S coast). Has been reported also from Wae Wuul Nature Reserve, near Mbura. It is important that further forest reserves are allocated or extended, and protection implemented. Until at least 1998 was present much farther E on N coast, at Mausambi, and could well exist as small pockets elsewhere in E and in interior and C parts of the island. A forest inhabitant, and has always had reputation for being rare and poorly known. Seems to be intolerant of forest clearance, and at most of its "regular" sites the impression is that it is definitely decreasing, presumably through forest fragmentation. Forest clearance has also allowed considerable range expansion of larger *C. macrorhynchos* on Flores, which could result in potential nest predation by latter. Present species reported as having reputation in some villages for stealing chicken eggs, and some villagers regard it as a pest and put out eggs laced with DDT to poison the crows. Rate of forest destruction on Flores is alarming; clearly, the only way to save this corvid is by creating large forest reserves and strictly enforcing logging controls, as well as through programmes aimed at increasing public awareness of the island's unique wildlife.
Bibliography. Anon. (2008p), Butchart & Stattersfield (2004), Butchart *et al.* (1994, 1996), Coates & Bishop (1997), Collar *et al.* (2001), Drijvers *et al.* (2000), Gibbs (1990), Goodwin (1986), Jepson (1997), Madge & Burn (1994), Meinertzhagen (1926), Pilgrim *et al.* (1997), Rensch (1931), Smith (1983), Stattersfield & Capper (2000), Vaurie (1958a), Verhoeye & Holmes (1999), White & Bruce (1986).

88. Mariana Crow

Corvus kubaryi

French: Corneille de Guam **German**: Guamkrähe **Spanish**: Cuervo de las Marianas
Other common names: Guam/Kubary's Crow

Taxonomy. *Corvus Kubaryi* Reichenow, 1885, Palau; error = Guam.
Relationships uncertain; appears to be derived from *C. splendens* of S Asia. Monotypic.
Distribution. Rota and Guam, in S Northern Marianas.

Descriptive notes. 38 cm; male 231–270 g, female 205–260 g. A small crow with lax plumage. Plumage is coal-black, with greenish-black gloss on head and back, bluish-black tail, and dull underparts; base of feathers grey, grading to white around neck (giving ragged appearance); iris brown; bill and legs black. Sexes similar, male slightly larger than female. Immature resemble adult, except for having less gloss and browner wings and tail. Voice. Poorly known. Adult gives high-pitched "caw" or "hi", often in series, as contact or locational call; sometimes more nasal and drawn out, as "caaaw" or "aaa". Juvenile location call similar, but shorter than those given by adults. Alarm call sharp series of rapid "caws". Adults and young give soft, rambling monologues when together at a nest, alone, or near other birds. Juvenile beg with squalling "aaa", rising in inflection.
Habitat. Most commonly in mature native limestone forest characterized by fig (*Ficus*) and yoga (*Elaeocarpus*) trees. Also habitats other than mature native forest, including secondary limestone forest, coastline forest, ravine forests, agricultural forests, and coconut (*Cocos nucifera*) plantations. Possible that immatures prefer secondary limestone forests for foraging. Croplands, savannas, grasslands and urban areas rarely used today; in the past, when the species was abundant, frequently foraged on croplands and was viewed by some as an agricultural pest.
Food and Feeding. Omnivorous, eating a varied mix of invertebrates, small vertebrates and plant matter. Invertebrates include Lepidopteran larvae, grasshoppers and mole-crickets (Orthoptera), praying mantis (Mantidae), earwigs (Dermaptera), hermit crabs (Paguroidea); small vertebrates skinks (Scincidae), geckos (Gekkonidae), immature rats (*Rattus*), bird eggs; vegetable matter includes foliage, fruits, seeds and buds of 26 species of native and introduced plant species on Rota, 18 species on Guam. Forages throughout all layers of forest, from canopy to ground. In detailed studies on Rota, most foraging at 4·9 m above ground (canopy 7·5 m tall). Usually found in pairs or extended family groups of 3–5 individuals, occasionally in flocks of up to 15; in recent past on Guam, communal roosts of 25–66 birds.
Breeding. Primarily during dry season, Aug–Feb, but may breed throughout year, nest-building from as early as end Jul and fledging as late as May on Rota; in recent times, season on Guam shortened, Oct to mid-Apr, perhaps in response to nest predation by snakes; renest within 2 weeks of failure, most pairs nesting two or more times per year (up to seven repeat attempts documented) because of initial failures. Territorial throughout year; on Rota, each pair defends 12–37 ha of forest. Nest built by both sexes, working together for c. 7 days, a bulky structure 24–53 cm in diameter, 15 cm thick, consisting of banago (*Jasminum marianum*) twig platform, intermediate cup of interwoven *Ficus* twigs, rootlets, vines and coconut palm fibres, and finely lined inner cup (often of *Flagellaria* tree fibres on Guam), placed in variety of native trees, often at 4–10 m, on Guam usually in outer portion of canopy of emergent tree, on Rota in inner portion of canopy of

non-emergent tree; difference in nest placement may reflect attempts to avoid snakes on Guam and drongos (*Dicrurus*) on Rota. Clutch 1–4 eggs (average 2·3); incubation, typically by female, period 21–23 days; chicks fed by both parents, nestling period 36–39 days; fledglings are poor fliers, tended by parents for 99–537 days, stay with parents in natal territory until following breeding season (prolonged parental care means that some paired adult crows may not breed every year). Examined nests usually only contain a single young bird; only about 50% of these reach fledging. Regular nest failure, historically caused by severe typhoons, appears to have selected for rapid and repeated nesting attempts.
Movements. Resident.
Status and Conservation. CRITICALLY ENDANGERED. Restricted-range species: present in Mariana Islands EBA. Rare and declining. Global population in 2009 estimated at fewer than 250 individuals, with just 4 on Guam (reintroduced from Rota); this is only 50% of estimate made in 2006. Best estimates of population trend on Rota suggest decline of 69–94% from 1982 to 2004. Has never been abundant nor widely distributed, but recent extirpation from Guam and reduction in population size on Rota make its current status extremely tenuous. Extinction on Guam directly attributable to arrival of exotic species, most importantly brown tree-snake (*Boiga irregularis*); during 1940s crows abundant throughout forests of Guam, but numbers dropped precipitously after brown tree-snakes were accidentally introduced to the island at end of world war; by 1978 crows restricted to the northern third of the island; last native crow on Guam died in 2003; 10 birds translocated from Rota to Guam by 2006, but by 2009 only 4 remained. Listed on US Endangered Species Act as "endangered" since 1984, and protected by Guam law since 1981. Important habitat for the crow on Guam is protected by a National Wildlife Refuge and designation of critical habitat (as allowed by Endangered Species Act); critical habitat designated also on Rota. A US recovery plan and federally appointed recovery team work with local and national landowners, managers and residents to guide the recovery of the species. Intensive management, including snake removal, protection of nest trees from predators, captive-breeding and propagation of young, reintroduction and translocation of eggs, young and adults between islands are currently being used to maintain the species on Guam. Predation by accidentally introduced brown tree-snakes clearly the most important limiting factor on Guam; reasons for declines on Rota are poorly understood, but limiting factors may include human persecution, predation by rats, monitor lizards (*Varanus*) and cats, loss and degradation of limestone-forest habitat by human activity and invasion of exotic plants and animals, harassment by and competition with introduced Black Drongos (*Dicrurus macrocercus*), lingering effects of previously widely used pesticides, disruption of social behaviour owing to small population size, and reduced nesting success from increasingly common and violent typhoons. Crows on Rota are significantly less genetically diverse than those on Guam and contain no novel genetic sequences; this suggests those on Rota were derived from those on Guam, and that either a recent and small founding population colonized Rota or the original Rota population was greatly reduced in size in recent past; either event could have occurred as recently as late 1940s, when Rota was denuded by battles of world war. As with most long-lived birds, high adult survival (for this species in excess of 90%) is a key to population viability. It is estimated that recovery to a level where three self-sustaining populations each of at least 75 territorial pairs exist on Rota, N Guam and S Guam would cost in excess of US$600 million and take at least 50 years. To meet this recovery goal and prevent extinction of this corvid, federal, state and private stakeholders are attempting to reduce the population of brown tree-snakes on Guam, reduce threat of the snake colonizing Rota, protect and restore limestone forest on Guam and Rota, and determine what is currently limiting the crow on Rota. The trust and co-operation of the people of Rota and Guam is essential to these efforts.
Bibliography. Anon. (1997, 2006, 2008p), Baker (1951), Butchart & Stattersfield (2004), Duckworth *et al.* (1997), Engbring & Pratt (1985), Fancy *et al.* (1999), Jenkins (1983), Lusk & Taisacan (1996), Meinertzhagen (1926), Morton *et al.* (1999), Plentovich *et al.* (2005), Savidge (1987), Stattersfield & Capper (2000), Steadman (1999), Steinheimer (2009), Tarr & Fleischer (1999), Tomback (1986), Wiles (1998), Wiles *et al.* (2003).

89. Long-billed Crow

Corvus validus

French: Corneille des Moluques **German**: Molukkenkrähe **Spanish**: Cuervo Moluqueño
Other common names: Moluccan Crow

Taxonomy. *Corvus validus* Bonaparte, 1850, Halmahera.
Affinities uncertain; has been considered to be part of the "*C. enca* complex", but its pale eyes suggest an affinity with Australian group of crows. Monotypic.
Distribution. Morotai, Halmahera, Kayoa, Kasiruta, Bacan and Obi, in N Moluccas.

Descriptive notes. 46–53 cm; c. 300 g. Large crow with top-heavy appearance created by very long bill and relatively short tail; bill gradually tapering from relatively deep base, culmen gently curving over distal third, prominent nasal tuft but (because of bill length) bristles hardly conceal base of culmen; tail relatively short and almost square at tip. Plumage is black, with purple gloss on upperparts, including wing, head glossed steel-blue, becoming green on throat; bases of neck feathers pure white; underparts dull black, very fine grey fringes on feathers of lower underparts; iris bluish-white; bill and legs black. Sexes similar. Juvenile has dark iris and duller, unglossed plumage. VOICE. Call an abrupt, dry, croak, "cruk…cruk…cruk", has been likened to bark of a puppy.
Habitat. Favours primary forest, in both lowlands and hills, and found more locally also in secondary or partially logged forest. Frequently recorded in farmland, including coconut (*Cocos nucifera*) plantations, and *Imperata* grassland with stands of trees. Sea-level to 380 m on Halmahera, and to 1150 m on Bacan.
Food and Feeding. No information on diet; from amount of time spent in tree canopy, likely to include various fruits and berries. Keeps within tree canopy for as long as possible; spends little time on ground or anywhere in open. Often perches on top of tall forest tree and calls for several minutes. Generally encountered singly or in pairs; also in small parties, presumed to be family groups.
Breeding. No information.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in Northern Maluku EBA. Poorly documented; seems to be reasonably numerous. Perhaps lives at low density over the most heavily forested parts of the island.

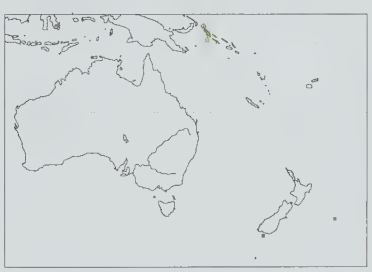
Bibliography. Bishop (1992a), Butchart *et al.* (1994), Coates & Bishop (1997), Collar *et al.* (2001), Gibbs (1990), Goodwin (1986), Jepson (1997), Madge & Burn (1994), Riley (1921), Smith (1983), Vaurie (1958a), Watling (1983), White & Bruce (1986).

90. White-billed Crow

Corvus woodfordi

French: Corneille à bec blanc **German**: Buntschnabelkrähe **Spanish**: Cuervo Piquiblanco
Other common names: Solomon(s) Crow

Taxonomy. *Macrocorax woodfordi* Ogilvie-Grant, 1887, Aola, Guadalcanal, Solomon Islands.
Probably closest to *C. meeki*, *C. fuscicapillus* and *C. tristis*, all apparently forming part of an "old endemic" Melanesian group. May form a superspecies with *C. meeki*; sometimes treated as conspecific, but differs in bill and eye colours, nature of nasal bristles, and plumage gloss. Proposed race *vegetus* (described from S Santa Isabel) considered inadequately differentiated from those in rest of species' range. Monotypic.
Distribution. Choiseul, Santa Isabel and Guadalcanal Is, in Solomon Is.



Descriptive notes. 40–41 cm; male 615 g, female 555–568 g, unsexed 375–568 g. Medium-sized, short-tailed crow with massive dark-tipped pale bill, culmen strongly arched; nasal bristles parted at forehead; feathers of head and neck fine and silky. Plumage is entirely black, somewhat glossed green (those on Choiseul slightly glossier); iris brown or grey to dull bluish-white; bill ivory-coloured with black tip (often appears pale pink in life); bare purplish-red inter-ramal skin on side of chin; legs black, soles orange. Sexes similar, male larger than female (especially on Choiseul and Santa Isabel). Juvenile undescribed. VOICE. Series of staccato cawing notes, higher-pitched and more rapid than those of *C. orru*.
Habitat. Lowland and montane rainforest to 1000 m, rarely to 1250 m; more common in hills. Frequents forest interior and forest edge, and may forage in nearby coconut (*Cocos nucifera*) plantations.
Food and Feeding. Omnivorous. Food insects, mainly beetles (Coleoptera), also fruits. Forages singly, in pairs and in small groups in forest canopy. Gleans unobtrusively in foliage.
Breeding. Three of four adult females were approaching breeding condition in Jun–Jul, suggesting laying in austral spring. No further information available.
Movements. Resident, with no records outside normal distribution. Flocks are apparently mobile locally.
Status and Conservation. Not globally threatened. Restricted-range species: present in Solomon Group EBA. Locally common within small global distribution, where seen in small flocks. Biology very poorly known.
Bibliography. Doughty *et al.* (1999), Dutson (2009), Goodwin (1986), Kratter, Steadman, Smith & Filardi (2001), Kratter, Steadman, Smith, Filardi & Webb (2001), Madge & Burn (1994), Mayr (1945b), Meinertzhagen (1926), Webb (1992).

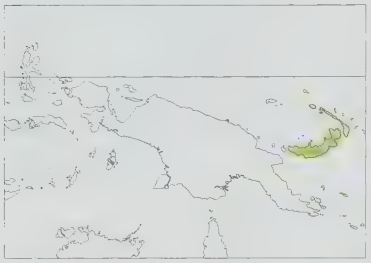
91. Bougainville Crow

Corvus meeki

French: Corneille de Meek **German**: Bougainvillekrähe **Spanish**: Cuervo de la Bougainville
Other common names: Short-tailed/Solomon (Islands) Crow

Taxonomy. *Corvus meeki* Rothschild, 1904, Bougainville Island, Solomon Islands.
Probably closest to *C. woodfordi*, *C. fuscicapillus* and *C. tristis*, all apparently forming part of an "old endemic" Melanesian group. May form a superspecies with *C. woodfordi*; sometimes treated as conspecific, but differs in bill and eye colours, nature of nasal bristles, and plumage gloss. Sometimes treated as conspecific with *C. insularis*, but differs notably in iris colour of adult, vocalizations, preferred habitat, lack of flocking behaviour, and flight action (shallow wingbeats, as opposed to deep wingbeats interspersed with glides). Monotypic.
Distribution. Buka I, Bougainville I and Shortland Is, in extreme N Solomons.

Descriptive notes. 40–41 cm. Medium-sized, glossy crow with massive bill with strongly arched culmen, and short narrow tail; nasal bristles forming tuft at base of culmen (not parted at forehead). Plumage is entirely black, with strong bluish-green gloss on head and underbody and strong purple gloss on upperparts; iris mid-brown to dark brown; bill black; bare purplish-red inter-ramal skin on side of chin; legs black, soles orange. Sexes similar. Juvenile is similar to adult; young have pale blue-grey to mid-brown eyes, the former perhaps juveniles, the latter probably subadults. VOICE. Series of raucous or staccato cawing notes, similar to calls of *C. woodfordi*; higher-pitched and more rapid than those of *C. orru*, but slower and more rolling than call of *C. insularis*.
Habitat. Principally rainforest; also occurs at forest edge, and in open country, village gardens, and occasionally coconut (*Cocos nucifera*) plantations; lowlands to at least 1600 m.
Food and Feeding. Eats insects, berries and fruits, including papaya (*Carica papaya*) in gardens. Forages in small groups, sometimes noisily, in forest canopy. Gleans in foliage.
Breeding. Female specimen from N Solomon Is in breeding condition in Sept, suggesting laying in austral spring. One nest in Mar contained four partly feathered nestlings, and another had a sitting adult. No further information available.
Movements. Resident, with no records outside normal distribution. Flocks are apparently mobile locally.
Status and Conservation. Not globally threatened. Restricted-range species: present in Solomon Group EBA. Fairly common to common within very small global range, where often seen in small flocks. Has been listed as Near-threatened, but recent observations suggest that such treatment is unwarranted. Biology very poorly known.



Bibliography. Coates (1990), Coates & Peckover (2001), Doughty *et al.* (1999), Dutson (2009), Dutson *et al.* (2009), Goodwin (1986), Hadden (1981, 2004), Jones & Lambley (1987), Madge & Burn (1994), Mayr & Diamond (2001), Meinertzhagen (1926), Schodde (1977).

92. Bismarck Crow

Corvus insularis

French: Corneille des Bismarck **German**: Heinrothkrähe **Spanish**: Cuervo de las Bismarck
Other common names: Island Crow

Taxonomy. *Corvus insularis* Heinroth, 1903, Gazelle Peninsula, New Britain, Bismarck Archipelago.
Formerly treated as a race of *C. orru*, more recently as a race of *C. meeki*; resembles each in different aspects, but appears sufficiently distinct not to be considered conspecific with either, and probably best treated as a separate species; differs from *C. orru* mainly in overall morphology (structure, bill size, tail length), iris colour of juvenile, and vocalizations; differs from *C. meeki* less markedly in overall morphology, but significantly in iris colour of adult, vocalizations, preferred habitat, flocking behaviour, and flight action (deep wingbeats interspersed with glides, as opposed to shallow wingbeats). Monotypic.
Distribution. Bismarck Archipelago, on New Britain, New Ireland, New Hanover and satellite islands.

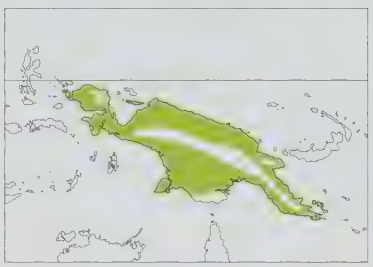
Descriptive notes. 40–41 cm. Medium-sized crow with a massive black bill and a rather short tail. Entire plumage is glossy black; iris pale blue; bill black, sometimes with pale tip; legs black. Sexes similar. Differs from *C. meeki* in slightly smaller bill, and slightly longer tail, but most importantly in iris colour. Juvenile is like adult, including pale blue eyes. Voice. Series of short nasal staccato cawing notes, shorter and more rapid than those of *C. orru*, and shorter and less rolling than those of *C. meeki*; caws can end with drawn-out terminal note. Also a long rattling caw and deep knocking sounds.
Habitat. Forest edge, partly cleared areas, gardens, and plantations of coconut (*Cocos nucifera*) and oil palm (*Elaeis guineensis*); lowlands to 1500 m. Sometimes seen in towns; only rarely in closed-canopy forest, the preferred habitat of *C. meeki*.
Food and Feeding. Probably omnivorous; insects, berries and fruits, including wood-boring grubs in coconut plantations. A tame bird was seen to cache surplus food. Forages in small groups both in canopy and on ground; also in gardens.
Breeding. Eggs reported in Feb–Mar and nestling(s) in Mar. One nest was 50 cm wide and 15 cm deep, lined with coconut palm sheath fibres and aerial roots, and built high in fork of tree. No further information available.
Movements. Apparently resident. Flocks appear to be locally mobile; often seen flying at great height, suggesting extensive local movement.
Status and Conservation. Not assessed. Probably not globally threatened. Restricted-range species: present in New Britain and New Ireland EBA. Common in disturbed areas; one of the very few bird species to inhabit oil palm plantations in Bismarcks. Biology very poorly known.
Bibliography. Coates & Peckover (2001), Dutson (2009), Dutson *et al.* (2009), Finch & McKean (1987), Goodwin (1986), Madge & Burn (1994), Mayr & Diamond (2001), Meinertzhagen (1926), Smith (1991), Storer & Eastwood (1991).

93. Brown-headed Crow

Corvus fuscicapillus

French: Corneille à tête brune **German**: Braunkopfkrähe **Spanish**: Cuervo Cabecipardo
Other common names: Brown-capped Crow

Taxonomy. *Corvus fuscicapillus* G. R. Gray, 1859, Dorey, New Guinea; error = Aru Islands, New Guinea.
Probably closest to *C. woodfordi*, *C. meeki* and *C. tristis*, all apparently forming part of an "old endemic" Melanesian group. Races based on small sample sizes, and validity doubtful; racial affinity of birds on New Guinea mainland not certain. Two subspecies tentatively recognized.
Subspecies and Distribution.
C. f. megarhynchus Bernstein, 1864 – W Papuan Is (Gemien and Waigeo).
C. f. fuscicapillus G. R. Gray, 1859 – Aru Is.
Also, of uncertain race, in coastal NW New Guinea.
Descriptive notes. 45 cm. Medium-sized crow with massive, strongly arched bill, and short tail squared at end; nasal bristles parted at forehead; throat feathers bristly, and breast feathers hair-like, loose and scruffy. Male has glossy black plumage, except for dark brown head and neck, and abdomen with distinct brown tones; iris blue; bill and legs black. Female is like male, but has black-tipped yellow bill, sometimes some black also at bill base (uncertain whether bill colour of female related to age or breeding status). Juvenile is scruffier and browner than adult, with yellow bill. Races differ slightly in size, although few specimens: *megarhynchus* is apparently larger, and larger-billed, than nominate. Voice. Deep, harsh cawing notes, either staccato and disyllabic (or perhaps antiphonal) or drawn out; deeper than those of *C. orru*.



Habitat. Lowlands and foothills, in rainforest and mangroves. Usually deep in primary forest, occasionally in secondary growth; rarely in open areas, and avoids shoreline and outlying islands.
Food and Feeding. Feeds on fruits. Forages singly, in pairs and occasionally in small flocks in forest canopy. Gleans in foliage.
Breeding. No information.
Movements. No information, but probably sedentary.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Aru Islands EBA, Northern Papuan lowlands EBA and West Papuan lowlands EBA. Generally rare, and biology very poorly known. Most numerous in wetter parts of range. Locally well distributed in Aru Is in low numbers, and locally common in parts of NW New Guinea mainland. Has fragmented and restricted distribution, where usually seen singly or in pairs, although occasionally in small flocks. Some areas of habitat threatened by logging, by mining and by damming of rivers, although large areas of intact forest, including protected areas, remain.
Bibliography. Anon. (2008p), Beehler *et al.* (1986), Butchart & Stattersfield (2004), Coates (1990), Coates & Peckover (2001), Diamond & Bishop (1994), Eastwood (1996), Goodwin (1986), Iredale (1956), Madge & Burn (1994), Meinertzhagen (1926), Rand & Gilliard (1967), Stattersfield & Capper (2000).

94. Grey Crow

Corvus tristis

French: Corneille grise **German**: Greisenkrähe **Spanish**: Cuervo Gris
Other common names: Bare-eyed/Bare-faced Crow

Taxonomy. *Corvus tristis* Lesson and Garnot, 1827, Dorey Harbour, New Guinea.
Probably closest to *C. woodfordi*, *C. meeki* and *C. fuscicapillus*, all apparently forming part of an "old endemic" Melanesian group. Monotypic.
Distribution. New Guinea, except lowlands of Trans-Fly; also West Papuan Is (Salawati, Batanta), Yapen I (in Geelvink Bay) and D'Entrecasteaux Archipelago.

Descriptive notes. 51–56 cm; one bird 635 g. Medium-sized, long-tailed, scruffy crow with stout bill and bare pink facial skin; sparse nasal and rictal bristles. Plumage is variable, blackish to dark brown or grey, with slightly glossy wings and tail; iris light blue; bill grey; legs pink to grey. Sexes similar. Juvenile much paler than adult, pale grey-brown above, whitish on head and below, appearing rather bleached, with brown eyes and white bill; immature is only marginally less pale, with pink bill and feet (birds with mottled grey-brown eyes are probably immature); takes three years to acquire darker adult plumage. Voice. Series of plaintive, startled, rising caws, resembling yelping when several birds in chorus. Also utters hoarse, weak caw, whining caw, and bursts of excited hoarse caws.
Habitat. Primary rainforest, forest edge, secondary growth, gardens, swamp-forest; lowlands to 1500 m. Sometimes visits open areas and riverbanks or sandbars.
Food and Feeding. Feeds mainly on fruits in forest canopy; also takes insects, especially when raising young, and sometimes scavenges. Forages often in noisy groups. Gleans in foliage and also on ground.
Breeding. Poorly known. Apparently breeds through dry season (austral autumn–spring); two nests found in Mar, nestlings in Oct to early Dec, and fledglings in Oct–Nov (including group of five fledglings and five adults in Oct). One nest was a bowl of sticks in outer fork near top of emergent deciduous tree over rainforest, contained four fully grown nestlings, attended apparently by only two adults; one nests in top of tree in primary forest and another high in large forest-edge tree. No information on clutch size; one alleged clutch of 2 eggs not attributable to this species. No other information.
Movements. Resident; flocks apparently locally mobile.
Status and Conservation. Not globally threatened. Locally fairly common to common, and widespread. Often observed in flocks of up to ten individuals, rarely up to 50.
Bibliography. Beehler *et al.* (1986), Coates (1990), Coates & Peckover (2001), Diamond (1972), Glynn (1995), Goodwin (1986), Jollie (1978b), Madge & Burn (1994), Meinertzhagen (1926), Peckover & Filewood (1976), Rand & Gilliard (1967), Schodde & Hitchcock (1968), Walters (2005).

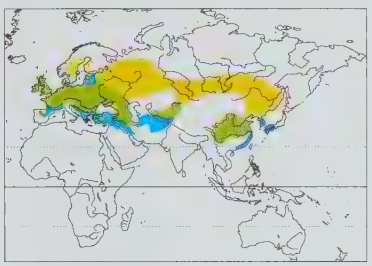
95. Cape Crow

Corvus capensis

French: Corneille du Cap **German**: Kapkrähe **Spanish**: Cuervo de El Cabo
Other common names: Cape/African Rook, Black/African Crow

Taxonomy. *Corvus capensis* M. H. C. Lichtenstein, 1823, Cape of Good Hope, South Africa.
Has been suggested that this species could form a superspecies with *C. frugilegus*, but there are major differences between the two, not least in nesting habits, the most apparent similarity between them being the pointed bill. Races, although geographically disjunct, are not well marked. Two subspecies recognized.
Subspecies and Distribution.
C. c. kordofanensis Laubmann, 1919 – SE Sudan, N Eritrea, most of Ethiopian Highlands, N & SE Somalia, SE Uganda, W & C Kenya and extreme N Tanzania.
C. c. capensis M. H. C. Lichtenstein, 1823 – from C Angola, W Zambia and Zimbabwe S to South Africa, Swaziland and Lesotho; possibly also SW Mozambique.



Descriptive notes. 48–50 cm; 410–697 g. Large crow with distinctive head-and-bill shape (rather flat forecrown, slim pointed bill with gently decurved culmen, and prominent throat hackles); moderate-length tail with only slightly rounded tip. Plumage is entirely black, glossed with violet and green on upperparts, upperwing and tail, less intensely glossed with bronze on head and neck, with dull black underparts and underwing; with wear, plumage becomes less glossy, at times even quite brownish; iris dark brown; bill and legs black. Sexes alike. Juvenile is similar to adult, but plumage softer and dull sooty brown, although in fresh plumage some gloss on secondaries and tail feathers. Distinguished easily from *C. edithae* by slender bill and rather flat crown, as well as more squared tail tip. Races differ in size: *kordofanensis* is smaller than nominate, mean male wing length 321 mm (nominate mean 347 mm). Voice. Harsh cawing "kraa-kraa-kraa" uttered at variety of pitches and speeds, from short, rising, rasped "kraa" to longer rising "krooaah", a series of calls perhaps terminating with downslurred "krooaaauw". Often calls from roadside pole, bowing with erected throat hackles, giving gurgling "gwurrr" followed by sharp "tik". Also produces a variety of gurgling and bubbling sounds both in display flight and when perched, these rendered variously as "kwollop, kwollop..." or "glogloglog...".
Habitat. Occurs in open country with scattered trees, from moorland and alpine meadows, through farmland and acacia (*Acacia*) savanna to stands of riverine trees in semi-desert conditions; prime habitat seems to be upland farmland with scattered trees; in W Kenya mostly between 1200 m and 2500 m, and above 1800 in Ethiopia, whereas in coastal Somalia has been found almost at sea-level. S populations can be found locally at sea-level (in SW & NE South Africa), but tend to occur mostly farther inland. In Zimbabwe, species restricted to C plateau above 900 m, occurring up to 2200 m.
Food and Feeding. Omnivorous. Various roots, seeds and grain, including maize and peanuts, small bulbs (e.g. *Cyperus*), fruits and berries (*Scutia*, *Royena* and *Opuntia*). Major component of diet invertebrates, particularly insects such as beetles (Coleoptera), grasshoppers and locusts (Orthoptera) and termites (Isoptera), including their larvae and pupae; also centipedes (Chilopoda), millipedes (Diplopoda) and worms (Annelida). Also small vertebrates, i.e. frogs, lizards, rodents and bird eggs and nestlings. Said rarely to kill newborn lambs or sickly sheep, and may sometimes feed on carrion, including dried flesh from dead fur seals (*Arctocephalus*). Forages on ground, alone or in pairs, walking with long strides, sometimes hopping; parties and small flocks develop, occasionally containing as many as 200 or even 1000 individuals, these likely unmated non-breeding birds. Digs vigorously in soil with bold backward-stabbing action or gentler probing; turns over animal droppings, and sometimes alights on back of grazing animal to search for ectoparasites. Also reported instance of an individual hovering over clutch of Ostrich (*Struthio camelus*) eggs and dropping stones to break them. Food-hoarding observed; buries food scraps in sand, returning later to retrieve them. Despite its varied diet, and unlike many other crows, seems to shun rubbish dumps and towns, although readily follows ploughing tractors. Flies with deep, measured beats, appearing less agile than *C. albus*, and rarely soars. Non-breeders form roosts of 30–50 birds, exceptionally as many as 600.
Breeding. Laying season varies with onset of local rains, breeding reported Dec–Feb in Sudan, Feb–May in Eritrea and Ethiopia, Mar–Apr and Dec in Kenya, and Mar–Dec in Somalia; in S of range laying chiefly Aug–Dec, a little later (Sept–Jan) in Botswana; sometimes double-brooded. Monogamous, probably with lifelong pair-bond. Solitary nester. Nest probably wholly built by female, an untidy mass of sticks, cup lined with wool, feathers, fur and dried dung, placed 2–24 m above ground in tree fork, in tall thicket, on telegraph pole, in artesian windmill and similar, rarely on cliff ledge; nest repaired each year for reuse; territory c. 60 ha. Clutch 1–6 eggs, mostly 4; incubation by both sexes, period 18–19 days; chicks fed by both parents, nestling period 36–39 days; young remain with parents for first 6 months. Nests occasionally parasitized by Great Spotted Cuckoo (*Clamator glandarius*).
Movements. Sedentary. A few records outside normal range (N Angola, S DRCongo and S Zambia) indicate propensity to wander; in South Africa, stragglers reported in C & W Free State well away from breeding areas in E.
Status and Conservation. Not globally threatened. Common and widespread, but somewhat localized, over extensive range. No population estimates made, but density in optimum habitat 1 pair/5 km². Accused of killing newborn lambs in parts of South Africa, where consequently deemed a local nuisance, especially in Great Karoo, where c. 50% of farmers "control" this corvid's numbers by shooting, poisoning and nest destruction.
Bibliography. Allan (1981), Ash & Atkins (2009), Britton (1980), Cyrus & Robson (1980), Fry *et al.* (2000), Goodwin (1986), Hall & Moreau (1970), Harrison *et al.* (1997), Hockey *et al.* (2005), Irwin (1981), Mackworth-Praed & Grant (1960), Maclean (1993), Madge & Burn (1994), Meinertzhagen (1926), Morgan-Davies (1967), Newman (1990), Skead (1952), Steyn (1965), Urban & Brown (1971), Wilson (1990, 1993), Winterbottom (1975), Zimmerman *et al.* (1996, 1999).

96. Rook

Corvus frugilegus

French: Corbeau freux **German**: Saatkrähe **Spanish**: Graja
Other common names: Eurasian Rook; Eastern Rook (*pastinator*)

Taxonomy. *Corvus frugilegus* Linnaeus, 1758, Europe = Sweden.
Has been suggested that this species could form a superspecies with *C. capensis*, but there are major differences between the two, not least in nesting habits, the most apparent similarity between them being the pointed bill. Races possibly merit treatment as separate species; although breeding ranges not known to meet (200 km apart at nearest points), intermediates are said to occur in foothills of Altai and Sayan Mts; further research required. Proposed races *tschuii* (described from Gilgit, in N Pakistan) and *ultimus* (from Russian Altai) are on average smaller and finer-billed than other taxa, but differences considered trivial and both are synonymized with nominate; populations of E Siberia, Mongolia and NE China described as race *centralis*, tending to be slightly larger and with a more purplish sheen than *pastinator*, but differences considered clinal and insufficient to warrant naming of additional race. Two subspecies currently recognized.
Subspecies and Distribution.
C. f. frugilegus Linnaeus, 1758 – breeds from S Sweden, S Norway and W Finland, British Is, France and N Spain (isolated population in Leon) E across Europe (N of Alps) and W Siberia (N to 60° N) to R Yenisei and NW foothills of Altai and, in S, to Asia Minor, Armenia, Azerbaijan and NW Iran, patchily N through Caucasus region (avoiding mountains) to S Russia, and from S Kazakhstan, Uzbekistan and N Turkmenistan E to foothills of Tien Shan in Kyrgyzstan and extreme NW China (NW Xinjiang). N populations migrate S to Mediterranean Basin and Middle East E across Iran to Afghanistan, NW China and NW Indian Subcontinent.
C. f. pastinator Gould, 1845 – breeds from C Siberia and N Mongolia (from upper R Yenisei) E to SE Russia (Amur basin S from Yakutsk) and in C & NE China (E from E Qinghai and E Gansu, S to N Zhejiang). N populations migrate to E China, Korea and Japan.
Introduced (nominate race) in New Zealand, chiefly in S part of North I and Canterbury area of South I.

Descriptive notes. 44–46 cm; 325–571 g. Relatively small-headed, short-legged crow with low-slung belly, loose tibia feathering ("baggy shorts") and tapered pointed bill. Nominate race is wholly black, highly glossed with bluish and purplish (blue gloss tinged violet in S range), gloss most evident on wing; plumage of head and neck particularly dense and silky; distinctive bare whitish area on chin and lores extending to bill base (bare face empasizes peaked crown); iris dark brown; bill dusky towards tip, becoming whiter towards base (making nostrils apparent, enhanced by absence of nasal bristles); legs dark slate-grey. Sexes similar. Juvenile is less highly glossed than adult, with nape and mantle browner, and bill base and face fully feathered (complete with nasal tuft), extremely similar to *C. corone* (best separated by more pointed bill with less curved culmen, shorter and thinner legs, more peaked crown, and more strongly "fingered" primaries with P9 longer than P5, which is not emarginated); bare face and absence of nasal tuft may not be apparent until 10–15 months of age. Race *pastinator* has feathered face and chin, with just bill base bare and whitish, gloss of head and neck is dull reddish-purple (rather than shiny bluish), N populations have bluer gloss on head and neck are on average a little smaller. Voice. Typical call a hoarse, rasping, slightly rising "gaarrkh", uttered at varying pitches, and repeated excitedly at colonies (rookeries); song a mixture of caws interspersed with variety of chuckles, gurgles and clicks, accompanied by head-bowing. Vocabulary varied, but many calls quite inconspicuous and juveniles generally silent.
Habitat. Mixed farmland in fairly flat open country, typically in lowland riverine plains, with stands of tall trees or patches of woodland for nesting and roosting. Needs extensive areas of grassland or arable farmland for foraging. Found also in large city parks; tall trees at edges of towns and villages are ideal for rookeries, which often in churchyards. In Europe mostly below 400 m, but reaches 700 m in Carpathians; in foothills of Altai, in C Asia, breeds at 2000 m, possibly even a little higher.
Food and Feeding. Omnivorous, but less of a carrion-feeder than are many other crows. Main food items include earthworms (Lumbricidae) and grain; wide range of other small invertebrates taken, notably beetles (Coleoptera) and cranefly larvae (Tipulidae), also such vertebrates as small lizards, frogs and small mammals, and eggs and nestlings of small birds. Grain and seeds taken mostly in autumn and winter, when can account for up to 90% of diet. Grain may be salvaged from stubble fields or dug up from freshly sprouting crop, causing crop damage. Highly gregarious, foraging in flocks in open country; freely mixes with *C. monedula*, *C. dauuricus*, *C. corone* and *C. cornix* and starlings (Sturnidae). Feeds by probing and digging, walking and hopping between bouts of digging. Will also feed along lakeshores and seashores; one reported as dropping mussels (*Mytilus*) on to hard surface to break shells. Scavenges about picnic sites, even entering litter bins, but rarely searches for ectoparasites on necks and heads of large mammals. In suburban gardens many now visit birdtables and feeders, where they show great ingenuity by hanging on suspended bones or fat, or pulling string up with bill and clamping it underfoot to get at food. Also chases other birds to force them to drop food item. In autumn stores food items for the winter, placing acorns, walnuts and pine cones in hole and covering it over with grasses; reported also as storing earthworms, but this possibly only for short period. Roosts in stands of large trees, often flying quite high for considerable distances to reach roost, which usually also attended by large numbers of jackdaws; some winter gatherings reach immense size.
Breeding. Egg-laying begins early to mid-Mar in Britain, early Apr in C Europe but not until mid-Apr in Moscow region, and early May in Omsk region (Russia) and Kazakhstan; introduced birds in New Zealand breed during austral spring, laying late Aug to mid-Nov; single-brooded. Despite highly gregarious nature, has long-term, possibly lifelong pair-bond; promiscuity, however, commonplace. Strongly colonial, forming rookeries of a few pairs up to thousands of pairs (up to 2000 in C Europe, up to 50,000 in Kazakhstan) in stands of tall mature trees, up to 60 nests in crown of single very large tree; in open steppe rookeries may be in bushy thickets as low as 4 m from

White-necked Crow (*Corvus leucognaphalus*); 106. Carrion Crow (*Corvus corone*); 107. Hooded Crow (*Corvus cornix*); 108. Large-billed Crow (*Corvus macrorhynchos*).

ground; cases of nests constructed on electricity pylons, and even in reedbeds as in Azerbaijan, where rookery of 250 nests constructed from bent-over reed stems and dry leaves seems to thrive; in Volga Delta also in mixed colonies with cormorants (Phalacrocoracidae), herons (Ardeidae) and Glossy Ibises (*Plegadis falcinellus*). Nest built by both sexes, male bringing in material and female undertaking most of construction work, both sexes constructing and shaping the cup, work can take 1–4 weeks (depending on how much material stolen by occupants of neighbouring nests); a bulky structure of twigs and sticks, cup lined with roots, dry grasses and dead leaves; nest may be repaired and reused for many years. Clutch 2–7 eggs, usually 4; incubation by female alone, although male briefly covers eggs while female leaves nest, period 16–18 days; chicks tended and fed by both sexes, male alone feeding for first 10 days, nestling period 30–36 days; young fly strongly at 42–45 days, remain with parents and fed by them for 6 weeks from fledging; most then join non-breeding roving flocks, some of which composed entirely of juveniles. Age of maturity or first breeding 2 years, but sometimes attained at one year. Rookeries provide ideal nest-sites for many other birds in regions where trees sparse; disused nests often taken over by falcons, particularly Red-footed (*Falco vespertinus*) and Amur Falcons (*Falco amurensis*), which may form small colonies scattered within rookery, and both Common Kestrel (*Falco tinunculus*) and Lesser Kestrel (*Falco naumanni*) will use old nests, and Long-eared Owls (*Asio otus*) habitually do so.

Movements. Resident over W & S parts of range; migratory in N & E. Ringing recoveries indicate intricate pattern of wintering areas for migratory populations, most of which forsake breeding grounds during Oct. Many Baltic and Dutch breeders winter in E England, those from E Europe (including Poland and Russia) winter in C Europe, those from W & C Ukraine move to plains from Hungary to N Italy, and S Ukrainian birds winter in Bulgaria, whereas those from SC Ukraine move to W Caspian region; a couple of ringing recoveries indicate that N Caspian breeders winter in Iraq; birds from NW Kazakhstan move to lowlands of SW Caspian, and many other Kazakh birds winter from N Iran to Uzbekistan, being joined by others from Altai region to winter from E Uzbekistan to Tajikistan and W Pakistan (chiefly North West Frontier), a few entering Ladakh and NW India (exceptionally to Haryana). Vagrants reported Iceland, Svalbard, Bear I, Balearic Is, Malta, Lebanon, Jordan, Kuwait, Tunisia, Algeria, and Azores and Madeira. N populations of E Asian race (*pastinator*) winter over E China S to Guangdong, with vagrants recorded Hainan I and Taiwan; also winter visitor to Japan, chiefly to Kyushu and Tsushima, with vagrants recorded on Hokkaido and S to Okinawa, and recently reported on Sakhalin I and extreme S Kuril Is (Kunashir), where flocks of up to 100 reported in winter; in S Korea, thought now to be uncommon winter visitor. In New Zealand, where introduced, disperses widely, with vagrants reported Northland, Wellington, Stewart I and even Chatham Is.

Status and Conservation. Not globally threatened. Nominate race abundant, and also well studied. Colonial nesting makes it an easy bird to census, the most recent figures for Europe (excluding Russia) indicating population of between 5,000,000 and 7,500,000 pairs. Numbers of nesting pairs in each country based on surveys undertaken chiefly in 1980s and 1990s: Ukraine 390,000–500,000, Moldova 60,000–70,000, Romania 150,000–200,000, Bulgaria 10,000–100,000, Hungary 118,000, Slovenia 30–50, Croatia 3500, Czech Republic 3000–4000, Slovakia 10,000–17,000, Belarus 700,000–1,200,000, Poland 300,000–900,000, Lithuania 100,000, Latvia 7000–9000, Estonia 5000–10,000, Finland 1100–1200, Sweden 23,000–25,000, Norway 500–700, Denmark 12,000–140,000, Germany 68,000–70,000, Netherlands 28,000, Luxembourg 1700, Belgium 7000–10,000, Britain 853,000–857,000, Ireland 520,000, France 100,000–300,000, Switzerland 300–500, Austria 450, Spain 1000–1500. Outside Europe figures are sparse, but estimates of 4000–5000 pairs in Azerbaijan and 10,000–50,000 pairs in Turkey. Some winter gatherings reach immense size, e.g. roosts of up to 500,000 individuals recorded in several urban centres in Poland. Although flocks widely regarded as destructive to crops (either by perching on and flattening growing corn or by digging up sprouting cereals and root crops), it can be argued that any harm done by this species is balanced by its usefulness in consuming large quantities of insect pests. Nevertheless, is still persecuted in many countries, by means of shooting and also indirectly through use of pesticides. Throughout the 20th century populations of this corvid have risen and fallen according to changes in farming practices, notably the loss of extensive pasture, and also the application of pesticides and seed-dressings. In Netherlands, for example, population was estimated at 40,000 pairs in 1944, had dropped by 97% to 1100 pairs by early 1970s (this blamed principally on pesticides), but by 1985 had risen again to 28,000 pairs. In Latvia, the 16,000 pairs of early 1970s had dropped to 7000–9000 ten years later through persecution. Farther E, has expanded range and increased numbers enormously in S Russia and parts of Kazakhstan, due to afforestation since 1960s with wind breaks in agricultural parts of steppe zone; preys significantly on eggs and chicks of Critically Endangered Sociable Lapwing (*Vanellus gregarius*). Elsewhere in C Asia, has become much more localized in the steppe regions and foothills of Altai. Race *pastinator* appears to have declined considerably over much of its wide range, probably through use of pesticides. At Beidaihe, in NE China, where very large numbers were noted on migration in 1940s ("cloud-like flocks of 10,000" in Nov 1945) and where it was described as a common breeding species, there was no evidence of breeding and only relatively small numbers passing (peak day count of 392) during observations in 1985–1990, despite popularity of the area as a birdwatching holiday destination. Status in Korea unclear, has declined considerably, thought now to be uncommon winter visitor; in Feb 1998, flock of 16,000 observed while foraging on tidal mudflats in Mangyong-gang Estuary. Nominate race introduced into New Zealand during 1862–1874; c. 30,000 birds present in 1978, of which 25,000 in Hawkes Bay area and 2500 about Canterbury, despite attempts to control numbers (at least 35,000 were poisoned or shot during 1971–1976); well established over SE part of North I and Canterbury area of E coast of South I.

97. Northwestern Crow

Corvus caurinus

French: Corneille d'Alaska **German**: Sundkrähe **Spanish**: Cuervo de Alaska

Taxonomy. *Corvus caurinus* S. F. Baird, 1858, Fort Steilacoom, Washington, USA.

May form a superspecies with *C. brachyrhynchos*, with which it appears to interbreed in S of range. Genetic swamping of unique features of present species may be accelerated by increasing expansion of *C. brachyrhynchos* facilitated by urbanization and agricultural development of formerly densely forested NW Pacific coast. Monotypic.

Distribution. S Alaska (E from Kodiak I) and coast and islands of SW Canada S in USA to NW Washington.

Descriptive notes. 42–45 cm; male 378–458 g, female 340–392 g. A small crow with medium-length tail and smallish bill. Plumage is entirely black, with purple sheen on head, neck, wing, tail and back; iris dark fuscous brown; bill glossy black; legs black. Differs from *C. brachyrhynchos* in generally smaller size, with hoarser voice and faster wingbeats, but generally indistinguishable in the field. Sexes similar, male on average larger than female. Juvenile (up to 3 months after fledging) is dull black, fluffy, and has blue iris; immatures like adult but less iridescent, often with brownish wings, tail and back. Voice. Likely as complex as that of *C. brachyrhynchos*, but not so well studied. Coarse, deep-pitched "craah" given in series to advertise territory. During mobbing, "kaar" at stationary predators and "kirrr" at end of dive at flying or perched predators. More drawn-out "craar" used as defensive call by both sexes; "aaag" as begging call by female, similar to typical begging call of nestlings and fledglings; small nestlings give "shreeh" while being fed, and older ones "creeach" gutturally with open beak to threaten. Copulation call loud, repeated, drawn-out "arghargh". Rattle like the pulling of a cork from a bottle, "errrrrr". High, falsetto "cowp" given in flocks. Nasal "neh" while perched and being mobbed by small birds.

Habitat. Restricted to beaches, rocky shores, tidelands, and river courses of coast and nearby islands. Historical restriction to coasts and islands lessened today as contiguous temperate rainforests have been cleared in many parts of species' range, thereby facilitating spread inland (typically to E) and colonization of towns, recreation areas and agricultural lands simultaneously with spread of *C. brachyrhynchos* NW into anthropogenic habitats. Degree to which crows in such anthropogenic landscapes are of present species and not *C. brachyrhynchos* (which has simultaneously spread N & E to overlap greatly in range, including at Hyder, in Alaska) is presently unknown.

Food and Feeding. Omnivorous, but specializing on marine and terrestrial invertebrates, especially crabs (Decapoda), clams, mussels, and carrion. Inland, flakes bark and moss in search of insects, scavenges human foods from recreation areas and refuse containers, and forages on the ground in gardens and along roadways. Preys on small vertebrates and eggs and nestlings of other birds. Eats native and planted fruits and nuts. Common at road-killed carrion. Large flocks may congregate along rivers to forage on emerging insects (hawked from air) and spawned-out salmon (*Oncorhynchus*). Routinely caches surplus food, especially the bounty from low tides, which it caches above high-tide line. Conspicuous in dropping nuts and especially bivalves on hard surfaces (roads and rocky coasts) in order to crack them; height from which items dropped is closely gauged to reduce loss and increase cracking. During autumn and winter, gathers at food bonanzas (towns, villages, salmon runs, dead marine mammals, agricultural fields, productive shores, and refuse dumps).

Breeding. Egg-laying Apr–Jun. Monogamous; occasionally (c. 20% of nests) with a single helper (offspring from previous year); loosely colonial. Bulky nest built by both members of pair, 35 cm in diameter × 23 cm tall, a coarse outer collection of sticks 15–30 cm long, finely woven inner cup (16 cm across × 9 cm deep) of grass, moss, soil and leaf litter, cup lined with moss, animal hair, feathers, cedar bark and human litter, placed usually in branch fork of tree or shrub at varying height (up to at least 50 m in old temperate rainforest), on some islands built on ground under tree or shrub (and then includes sparse outer stick structure); defended territory small, 0·12–0·94 ha. Clutch 3–6 eggs (average 4); incubation by female only, beginning when clutch complete, fed on and off the nest by the male, period 17–20 days; chicks fed by both sexes, and by helper if present, nestling period 32 days; all also feed young for up to a month post-fledging; young often mix with those from neighbouring nests at intertidal foraging locations within a few weeks of fledging. First breeding apparently at 2 years. Maximum observed lifespan 16 years 9 months; annual survivorship of breeders in areas with reliable food supply exceeds 95%.

Movements. Resident. Moves considerably outside breeding season to utilize locally abundant foods.

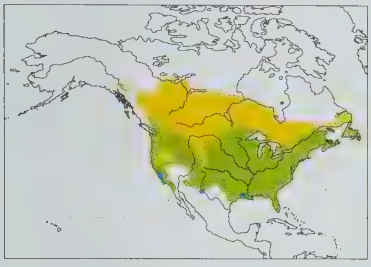
Status and Conservation. Not globally threatened. Populations of crows within the range of this species increased substantially in 1960s and 1970s. More recently, urban populations have increased, often exponentially, and most population assessments indicate general increases, with some local decreases. Local variation in degree of population increase may indicate movements, especially into growing human settlements, rather than population trends. Status of this corvid, however, remains unclear, as uncertain whether increases apply to present species or to *C. brachyrhynchos*; if they are a result of latter's NW range extensions, then the status of present species is bleak. Depending on extent of interbreeding between the two, it may may already be extinct as a distinct species; at best, "pure" individuals of present species likely exist today only on sparsely inhabited islands and coasts in N parts of its historical range. In order to resolve this matter, genetic investigation throughout the geographical range and across the time range during which specimens have been collected is needed.

Bayer (1989), Brooks (1942), Butler (1974), Butler *et al.* (1984), Emslie (1998, 2004), James & Verbeek (1983), Johnston (1961), Marzluff & Angell (2005), Marzluff & Neatherlin (2006), McCarthy (2006), Meinertzhagen (1926), Neatherlin & Marzluff (2004), Richardson & Verbeek (1986), Richardson *et al.* (1985), Robinette & Ha (2000, 2001, 2003), Verbeek (1982, 1995, 1998), Verbeek & Butler (1981, 1999), Zach (1978, 1979), Zwickel & Verbeek (1997).

98. American Crow

Corvus brachyrhynchos

French: Corneille d'Amérique **German**: Amerikanerkrähe **Spanish**: Cuervo Americano
Other common names: Common Crow



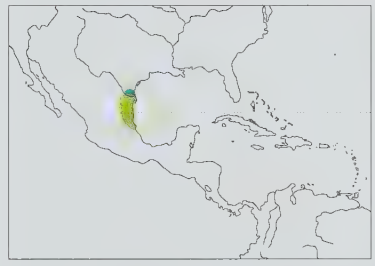
Taxonomy. *Corvus brachyrhynchos* C. L. Brehm, 1822, North America = vicinity of Boston, Massachusetts, USA.

Recent molecular-genetic studies suggest that this species might be most closely related to *C. corone* and that the two form a sister-taxon to the Caribbean *C. jamaicensis*, *C. nasicus* and *C. leucognaphalus*. Genetic similarity to *C. caurinus* unknown, but the two may well be a single species at present owing to present species' genetic swamping of former, probably accelerated by its NW range expansion (now extending N to Hyder, in Alaska), facilitated by urbanization and agricultural development of formerly densely forested NW Pacific coast. There appears to be no distinct boundary between nominate race and *hesperis*, and individuals of this species found N into SE Alaska and E to C Alberta, C Saskatchewan, Nevada, Arizona and New Mexico may include *hesperis*. Geographical variation largely clinal: in S USA, proposed races *paulus* (described from Alabama) and *hargravei* (Great Basin) synonymized with nominate. Known to hybridize in wild with *C. corax*. Three subspecies recognized.

Subspecies and Distribution.

C. b. brachyrhynchos C. L. Brehm, 1822 – S Canada from SW Northwest Territories E to Atlantic coast of Newfoundland, and S throughout Midwest and E USA to at least NW Florida and Gulf of Mexico; expanding W through Montana, Idaho, Wyoming, Utah, Colorado, Nevada and C Arizona.

C. b. hesperis Ridgway, 1887 – SW Canada (interior British Columbia) S in W USA to Washington, N Idaho, Oregon and California, and extreme NW Mexico (extreme NW Baja California).
C. b. pascuus Coues, 1899 – peninsular Florida.



Descriptive notes. 43–53 cm; 250–575 g. A moderately sized crow rarely found far from humans. Plumage is all black with iridescent purple sheen, especially on back and wings; iris dark brown; bill and legs black. Distinguished from *C. ossifragus* by slightly larger size, less iridescent plumage, also by voice, habitat and timing of breeding. Sexes similar, male larger than female. Juvenile (up to 3 months after fledging) is duller black to grey-black, fluffier in appearance, with grey-blue iris; immature mostly black, with brown eyes, feathers of wing and tail often fading and wearing to brown, and contrasting with body plumage, outer rectrices narrower and more pointed than adults. Races differ only in size, nominate largest: *hesperis* is small, with especially small, straight bill; *pascuus* is intermediate in general size, with relatively large feet, long legs, and long bill. Voice. Large repertoire of more than 30 vocalizations (variously patterned, modulated and graded caws, soft calls, song, and mimicked sounds). Alarm calls, and likely all calls, have individually distinct elements; songs are socially learnt and may be culturally inherited as local dialects. Eight functional groups: (1) harsh, easily located assembly caws given to form a mob around dangerous, usually stationary, predators; (2) harmonic "koaw" calls disperse crows from danger; (3) tonal "ko" or warning caw, difficult to locate, alerts crows to presence of danger; (4) distress squalls and death cries given by captured individuals in grave danger mark especially deadly situations and locations; (5) wavering begging calls by juveniles or breeding females to stimulate feeding; (6) variety of cooing, snapping and groaning noises given at short distance among mates; (7) courtship or group songs that combine "cou" calls, rattles, growls, groans, other soft and unique noises, and posturing; and (8) mimicked natural and anthropogenic sounds, including of human voices.
Habitat. Common in human-dominated landscapes from core of large cities (where may nest on buildings) to parks, suburbs, golf courses, woodlands, some forests (especially deciduous and riverine ones, but also forest edges and open or fragmented coniferous forests), farms, orchards, ranches, and wildland recreation areas. Frequently found at refuse dumps, agricultural fields (especially maize), lawns, streets, shorelines, and along rivers. Historically, was found in deciduous forest landscapes, especially where forest openings, edges and small woodlots allowed diverse array of land covers to occur in proximity to one another; in response to human activities that have fragmented dense forest, planted trees in grasslands, watered arid lands, and otherwise increased the juxtaposition between rich food sources (notably open areas, agricultural fields, urban areas) and suitable nest-sites, this crow has greatly expanded its habitat use in the last 200 years.
Food and Feeding. Omnivorous, typically foraging on ground for invertebrates, notably earthworms (Lumbricidae), grasshoppers (Orthoptera), moth and butterfly larvae (Lepidoptera), and beetles (Coleoptera), also fruits, seeds, grains, carrion, and human food scraps. Preys on small birds, nestlings, eggs, small mammals (mice, voles, shrews), reptiles (snakes, lizards), amphibians (adult and larval toads and frogs), fish; also crabs and gastropods. Uses stout bill to dig, pry, flip, peel, scrape, grab, probe, pick and hammer to obtain food. Flycatches emerging insects. Chases flying insects and small birds, catching them in flight. Where conditioned with frequent rewards, may harass or beg from people for food. Occasionally uses artefacts, notably hard surfaces (and perhaps attendant automobiles), to crack thick-shelled nuts and invertebrates. Caches surplus food in subterranean, subnivian or arboreal locations, short-term memory of food locations well developed; long-term memory of danger, including aversive conditioning to food, feeding locations and individual people, well developed. Highly social, occurring in pairs or small family groups; in loose flocks of up to several thousand individuals when not breeding, and in even larger aggregations (hundreds to over a million birds) at communal roosts and along routes to and from such roosts.
Breeding. Nest-building from Feb to early Jun (1–2 months earlier than *C. ossifragus* where sympatric), progressively later from S to N, but accelerated by c. 1 month in warmer urban areas, most building by late May being renesting after initial failure; eggs laid late Mar to mid-Apr in most parts of range, May in N, peak hatching late Mar to Apr, peak fledging May–Jul in most locations. Socially monogamous, with long-lasting pair-bond; extra-pair copulations appear to be rare. Co-operative breeding (by 30–95% of pairs per year) reported throughout range except in migratory N populations (study needed), pair accompanied by up to ten helpers (mostly yearlings, but 6-year-olds known to help) which participate in territory defence, vigilance, and feeding of nestlings and fledglings. Nest defence tempered where persecuted but exaggerated in urban and suburban areas with no hunting; smallest territories (2-50 ha) in dense urban and suburban populations, where anthropogenic foods abundant, largest territories (200-400 ha) in rural areas; shown to recognize faces of individual human persecutors, with social and individual learning rapid, memory long-term (over 3 years). Nest variable in size, 17–76 cm wide × 10–38 cm high, made externally from sticks 6–35 mm in diameter, filled to some extent with dirt (mud early in season) and plant matter (stems, grass, maize stalks), rubbish and cow dung, lined with soft, shredded bark, grass, rootlets, moss, fibre, hair, leaves, pine needles or rubbish, inner bowl 16–36 cm in diameter and 10–20 cm deep; well concealed in wide variety of deciduous and coniferous trees (more often in conifer than expected from availability), usually near top (10–20 m in most of range) and above 30 m in tall conifer, less often in shrub, on building (including above 100 m on top of stadium), trestle or bridge support, and occasionally on ground; nest rarely reused, perhaps only in areas where sites especially limited (e.g. urban Seattle). Clutch 2–7 eggs (average 4·7), clutches of 2–3 eggs typical in some dense urban populations (e.g. Seattle) and remote wildland populations (e.g. Olympic Peninsula, in Washington); incubation by female alone, period 16–18 days; chicks fed by both parents and all helpers present, nestling period 33–43 days; parental care extends for several weeks to more than 4 months after fledging; juvenile dispersal varies greatly, some (typically males) remain for 1–5 years or more as helpers on natal territory, others travel at least 60 km (typically less than 20 km) to flock with others at reliable food sources (e.g. urban areas in Seattle); some birds that disperse from natal territory in autumn return before spring to help parents. Recorded longevity up to 14 years 7 months in wild and to 59 years in captivity; annual survivorship of adults in most areas very high (c. 95%), but can be significantly reduced in areas remote from most human activity; survival during first year of life varies from 35% (rural New York) to 45% (rural Illinois and Seattle) and to 55–63% (suburban New York and Los Angeles, respectively).
Movements. Migrates from N parts range, upper elevations, and drier, seasonal agricultural sites (e.g. E Oregon) after breeding (but increasing numbers remaining all year in N interior, e.g. Athabasca, in Alberta, and coastal towns e.g. Hyder, in Alaska). Flocks of 30–200 (occasionally 500–1000, rarely more than 2000) migrate S during autumn to SC USA (ringed indivivuals captured in Texas and Oklahoma); those from NE Canada and upper Midwest USA (Michigan, Wisconsin, Illinois) migrate to SE (ringed birds captured in Arkansas, Tennessee, North Carolina); W populations less migratory, appearing to stay throughout year in coastal areas and moving S & E from more seasonal areas (ringed birds tracked from British Columbia and Colorado S to Oklahoma and Arkansas, respectively). Longest movement by a ringed individual 2804 km, from Oklahoma to British Columbia. Spring migration (Feb–Apr) is conspicuous and rapid compared with that in autumn (Aug–Dec).
Status and Conservation. Not globally threatened. Common. Density variable; non-migratory crows occupy areas of up to 1000 ha or more throughout year, some defending exclusive breeding territories ranging from less than 1 ha to more than 100 ha; in areas where food widely scattered or less predictable crows wander over large, overlapping home ranges, e.g. home ranges of 300 ha to more than 10,000 ha on Olympic Peninsula overlap neighbouring ones by up to 48%. While Canadian population was stable, US population increased in accelerating manner from 1966 to 1997 (annual increases 0·8% during 1966–1971 and 1·5% during 1980–1997); exponential increases occurred in many W and urban areas during these decades (e.g. 30-fold increase in Seattle). Expanding and increasing populations led to increased predation on gamebird nests, damage to agriculture, possible spread of disease, and other nuisances to people. Systematic reduction of human subsides (food, water, nest-sites) would seem more effective at solving conflicts. With introduction of West Nile Virus to E USA in 1999 and its subsequent rapid spread across USA and S Canada, this species' populations have been dramatically reduced in parts of range; local populations declined steeply as 30–70% of all crows in marked populations died during epizootics, and regional populations declined by up to 45% across their range. Passive immunity, behavioural differences among the crows, and the patchy occurrence of West Nile Virus spared large numbers of this corvid in spite of high susceptibility to the disease. Vulnerability of highly social corvids, even widespread and increasingly abundant ones, to new challenges, especially exotic diseases, is illustrated by this species' response to West Nile Virus.

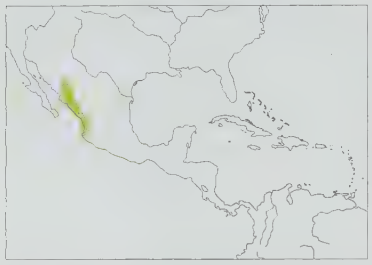
99. Tamaulipas Crow

Corvus imparatus

French: Corneille du Mexique **German**: Mexikanerkrähe **Spanish**: Cuervo Tamaulipeco
Other common names: Mexican Crow (when treated as conspecific with *C. sinaloae*)

Taxonomy. *Corvus imparatus* J. L. Peters, 1929, Río La Cruz, Tamaulipas, Mexico.
Forms a superspecies with *C. sinaloae* and possibly conspecific; preliminary genetic analysis suggests that the two may be sister-taxa (2% divergent) within a clade of Asian/Pacific taxa that includes *C. ossifragus*. Monotypic.
Distribution. NE Mexico (E from E Nuevo León) to N border of Veracruz; regularly occurs in extreme S USA (to immediately N of lower Rio Grande, in S Texas), but breeding unconfirmed.



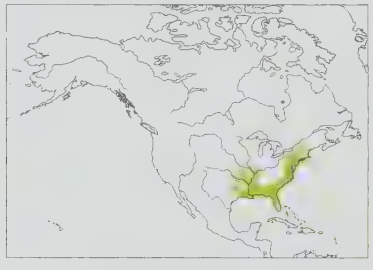
Descriptive notes. 34–40 cm; 192–237 g. A small, slender crow with comparatively small bill and highly glossed plumage. Has entire plumage black with rich purple, blue and green gloss; iris dark brown; bill and legs black. Differs from almost identical *C. sinaloae* in having slightly shorter tail. Sexes similar, male larger than female. Juvenile is dull black, with limited sheen, has dark dull grey bill and legs. Voice. Calls low-pitched, reedy, nasal, frog-like "nark", "gar" or "nar-ur", distinct from those of *C. sinaloae* (higher-pitched); calling often accompanied by puffing-out of throat feathers and lifting of tips of wings from back. Known calls burry, low-pitched, soft, and without clear harmonics, six described; croaking "gar-lic" or simply "gar" most common, used in variety of situations, including mobbing; "kawoo" and a quiet mutter given when calm; "rattling" and "begging" calls similar to those produced by most other corvids.
Habitat. Lowland, scrubby farmland, open woodland, towns and villages. Not strongly associated with beaches, but found along coast, especially in Tampico (S Tamaulipas), where it frequents coconut palms (*Cocos nucifera*). Sea-level to 300 m, occasionally to 800 m.
Food and Feeding. Omnivorous. Small groups seen foraging in semi-arid brushland. Regularly feeds in agricultural fields and refuse dumps around settlements. Co-operation in obtaining food seen in captivity, when flock-members passed food out of cage to escaped bird. Pairs to large flocks observed. Roosts communally.
Breeding. Poorly known in wild. Egg-laying in early Apr and fledglings in May. Apparently nests in loose colony. Coarse nest of sticks with rootlet lining, built by male and female. Clutch 4–5 eggs; incubation by female, period 17–18 days; no information on nestling period; dependence on parents extends throughout autumn and early winter, as begging calls heard into Nov.
Movements. Resident. Non-breeding birds wandering regularly to Brownsville (Texas) and N throughout lower Rio Grande Valley in winter.
Status and Conservation. Not globally threatened. Restricted-range species: present in Northeast Mexican Gulf Slope EBA. Locally abundant; has small range of c. 150 × 400 km. Observed in both summer and winter in Texas (at Brownsville refuse dump), breeding unconfirmed in USA. Tolerant of human activity, despite small range; utilizes human refuse and associated closely with pastures, farms, ranches, villages, and towns.
Bibliography. Arvin *et al.* (1975), Davis (1958), Goodwin (1986), Hardy (1990), Howell & Webb (1995), Johnston (1961), Lasley & Sexton (1989), Madge & Burn (1994), Peters (1929), Webber & Hardy (1985).

100. Sinaloa Crow

Corvus sinaloae

French: Corneille du Sinaloa **German**: Sinaloakrähe **Spanish**: Cuervo Sinaloense
Other common names: Mexican Crow (when treated as conspecific with *C. imparatus*)

Taxonomy. *Corvus sinaloae* L. I. Davis, 1958, Escuinapa, Sinaloa, Mexico.
Forms a superspecies with *C. imparatus* and possibly conspecific; preliminary genetic analysis suggests that the two may be sister-taxa (2% divergent) within a clade of Asian/Pacific taxa that includes *C. ossifragus*. Monotypic.
Distribution. NW Mexico on Pacific slope from S Sonora S to SW Nayarit.



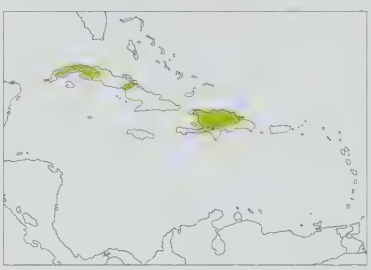
Descriptive notes. 34–38 cm; two birds 229 g and 258 g. A small, slender, glossy crow with relatively small bill. Entire plumage is black with rich purple, blue and green gloss; iris dark brown; bill and legs black. Differs from almost identical *C. imparatus* in having somewhat longer tail. Sexes similar, male larger than female. Juvenile is duller than adult, with limited sheen, has dark dull grey bill and legs. Voice. Little known. A clear, gentle, harmonically structured "ceow", most similar to that of *C. brachyrhynchos*, distinct from lower-pitched croaking call of *C. imparatus*; high hollow "caow" or "kwaa" also reported.
Habitat. Coastal lowlands, open and semi-open woodlands, thorn-forest, shrublands with saguaro-like *Pachycereus pecten-aboriginum* cacti, intertidal beaches, river courses, pastures, farms, ranches, towns and villages. Sea-level to 400 m, occasionally to 1000 m.
Food and Feeding. Omnivorous. Feeds in intertidal zone on marine invertebrates, including crabs (Decapoda) and shellfish. Elsewhere feeds on ground and in trees on insects, fruits and nuts. In Sonora, forages at rubbish dumps and preys on nestlings of other birds, including *Calocitta colliei*. Habitually turns over small stones, vegetation and detritus in search of food. Likely to use marine resources in same manner as does better-studied *C. caurinus*. Pairs to large flocks observed, but may be less gregarious than *C. imparatus*.
Breeding. Poorly known. In Sonora, nest-building from late May to early Jun, nestlings usually present in early Jul (after start of mid-Jun summer rains) and fledging from early Aug to early Sept. Loose colonies observed in Sonora. Nest made from coarse outer vegetation and fine inner material, placed in thorny, scrubby *Mimosa* tree, in tall coconut palm (*Cocos nucifera*), or above 3 m in crotch formed by vertical arm of *Pachycereus pecten-aboriginum* cactus. Clutch 4–5 eggs; no information on incubation and nestling periods.
Movements. Resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in Northwest Mexican Gulf Slope EBA. Locally abundant; has small range of c. 80 × 800 km, diverging from coast in N, where environment extremely arid. Tolerant of human activity, despite small range; utilizes human refuse and associated closely with pastures, farms, ranches, villages and towns.
Bibliography. Davis (1958), Goodwin (1986), Hardy (1990), Howell & Webb (1995), Johnston (1961), Madge & Burn (1994).

101. **Fish Crow**

Corvus ossifragus

French: Corneille de rivage **German**: Fischkrähe **Spanish**: Cuervo Pescador

Taxonomy. *Corvus ossifragus* A. Wilson, 1812, Great Egg Harbor [= Beasley's Point, New Jersey], USA.
Preliminary genetic analysis suggests that this species may be part of a clade of Asian/Pacific taxa that includes also *C. imparatus* and *C. sinaloae*. Monotypic.
Distribution. E & SE coastal reaches of USA from coastal Maine S throughout Florida, W across Louisiana border into E Texas, in W extending N along major rivers into Oklahoma, Kansas, Missouri, Illinois and Indiana.



Descriptive notes. 36–41 cm; male 260–332 g, female 195–304 g. A small crow with proportionately rather long tail. Plumage is all black with bluish-violet and green gloss on head, upperparts and underparts; iris dark brown; bill and legs black. Distinguished from similar *C. brachyrhynchos* by substantially smaller size, relatively longer legs, and voice. Sexes similar. Juvenile (up to 3 months after fledging) is duller black than adult, fluffier in appearance, with grey-blue iris; immature mostly black, with brown eyes, often feathers of wing and tail brown and contrasting with body plumage. Voice. Relatively little known; repertoire of nine calls is limited compared with *C. brachyrhynchos*, from which best separated by more nasal voice, especially "uh-uh" call (similar to begging calls of latter). Short, nasal "awwr" indicates aggression, used to defend territory; shorter and higher-pitched "ewh" appears to be contact call, frequently given among flock-members; distinctive disyllabic nasal "uh-uh" may also be used for contact; predators mobbed with drawn-out "awwpp"; when delivering food to nest, parents give soft "feeding call" that alerts nestlings. Nestlings, fledglings and perhaps females beg from mates and parents with higher-pitched and drawn-out calls similar to "awwr"; disturbed young give similar call that sounds like "arrgh". "Aggressive rattle" given in flight or from perch at close distance to predators, aggressive conspecifics, or mobbing passerines. "Meow" heard once from male sitting near nesting female.
Habitat. Usually found close to water in coastal or riverine settings; exploits human settlements and, to lesser extent, agriculture. Abundant at refuse dumps in winter.
Food and Feeding. Eats variety of natural and anthropogenic foods, including carrion, crabs (Decapoda) and marine invertebrates, earthworms (Lumbricidae), grains and fruits, also household scraps. Preys on small vertebrates and eggs and nestlings of other birds, especially colonial waterbirds, e.g. herons (Ardeidae). Forages in trees, on ground, and in variety of human settings, including rubbish-containers in urban areas. Routinely caches excess food. Flocks of breeders and non-breeders roam in winter, congregating at locally abundant and dependable foods; often associated with humans (urban settings and landfills).
Breeding. Nest-building from late Mar to early Jun throughout range (1–2 months later than *C. brachyrhynchos* where sympatric) and egg-laying Mar–Jun. Pair-bond apparently monogamous and long-lasting. Adult helpers at nest not uncommon. Nests sometimes aggregated, with several in single tree or clump in areas of limited nest-site availability, but not truly colonial. Nest of modest size, 35–50 cm wide and 20–35 cm high, made externally with sticks 4–8 mm in diameter, filled to some extent with dirt and plant matter, lined with soft, shredded bark, moss, fibre, hair or pine needles (*Pinus*), inner bowl 13–19 cm in diameter and 13–15 cm deep, placed in tree; new nest built for each attempt; defends area around nest as small as 50 m in radius. Clutch 2–6 eggs (average 4·5); incubation by female alone, period 18–19 days; chicks fed by both parents, long nestling period 32–40 days; parental care extends for several weeks to more than a month after fledging. Oldest known individual lived for 14·5 years.
Movements. Extent of migratory behaviour poorly studied. Some may migrate from C or N portions of range to S coasts, but confusion with *C. brachyrhynchos* during winter makes evidence equivocal. Seasonal movements from breeding range to rich feeding locations common.
Status and Conservation. Not globally threatened. Common; most abundant in Florida; currently expanding N & W. Exploits human settlements and to lesser extent agriculture. Range-wide significant increase in population size of 1·6% per year (1966–1998); increase greatest during 1966–1979 (6% per year); apparently stable at present (0·8% per year). Less susceptible to West Nile Virus than are other corvids, and has not experienced significant local or range-wide declines since this disease emerged in USA. Hunted, but protected from indiscriminate shooting since 1972 (US Migratory Bird Treaty Act); availability of human provisions and protection within cities likely important factors in population growth and range expansion.
Bibliography. Fink (1975), Goodwin (1986), Hardy (1990), Johnston (1961), LaDeau *et al.* (2007), Madge & Burn (1994), Marzluff & Angell (2005), McGowan (2001b), McNair (1985), Meinertzhagen (1926), Sauer *et al.* (1997c).

102. **Palm Crow**

Corvus palmarum

French: Corneille palmiste **German**: Palmenkrähe **Spanish**: Cuervo Palmero
Other common names: Cuban Palm Crow (*minutus*); Hispaniolan Palm Crow (*palmarum*)

Taxonomy. *Corvus palmarum* Paul von Württemberg, 1835, vicinity of Cibao Mountains, Dominican Republic.
Appears to be more closely related to ravens than it is to other Caribbean crows; preliminary comparison of DNA sequences suggests 6% divergence from ravens, but 8–10% divergent from *C. leucognaphalus* and *C. nasicus*. Races have been treated as two distinct species, but differences minimal; indeed, even as races they are weakly differentiated. Two subspecies recognized.
Subspecies and Distribution.
C. p. minutus Gundlach, 1852 – Cuba.
C. p. palmarum Paul von Württemberg, 1835 – Hispaniola.

Descriptive notes. 34–38 cm; one male 315 g, one female 263 g. Small, rather tame crow with short, stout, sharp-pointed bill and well-developed nasal bristles covering nostrils. Nominate race has coarse black plumage with considerable purple-blue iridescence; iris brown; bill and legs black. Sexes similar, male slightly larger than female. Juvenile somewhat duller than adult. Race *minutus* slightly smaller and duller than nominate, and male tends to have larger tarsi and smaller bill. Voice. Calls poorly known, but those known are similar to "caw" of *C. brachyrhynchos* and to sequences of sharp, high-pitched "craa" of *C. ossifragus*. Also gives deep, harsh, burring sounds like a frog, which help to distinguish it from *C. nasicus* and *C. leucognaphalus*.
Habitat. Pine (*Pinus*) forests, arid brush, and hill country in Hispaniola, often at higher elevations (1300–1900 m) where pine trees intermingle with sparse woods and extensive corn agriculture on steep slopes; also in lowland forests, swampy forests, dry plains and wooded ravines. In Cuba, occurs in lowland cultivation with scattered palms.
Food and Feeding. Omnivorous. Feeds on invertebrates, including beetles (Coleoptera), caterpillars, cicadas (Cicadidae), snails (Gastropoda), small vertebrates (lizards), and fruits; not known to eat carrion, but diet studies lacking. Forages in trees and on ground in pairs or small groups of up to 20 individuals.
Breeding. Poorly known. Season Mar–Jul in Cuba; eggs laid in Apr. Presumed solitary nester on exclusive territory. Small groups (3–6) commonly seen, especially when mobbing potential predators. Builds typical crow nest with coarse stick platform lined with dry grasses and other soft materials, placed among tree branches or at base of palm frond; one was 10 m above ground in pine tree. Clutch 4 eggs; no information on incubation and nestling periods.
Movements. No information.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Cuba EBA and Hispaniola EBA. Not uncommon in Hispaniola, but mainly in lowland and hill forests; formerly abundant, but distribution has narrowed and populations have declined in response to extensive forest clearance, especially in Haiti. Rare in Cuba, where likely now confined to Camaguey province. Was killed for food in 19th century, its flesh apparently being considered delicious.
Bibliography. Anon. (2008p), Bond (1936), Butchart & Stattersfield (2004), Danforth (1929), Garrido & Kirkconnell (2000), Garrido *et al.* (1997), Goodwin (1986), Holyoak (1983), Johnston (1961), Keith *et al.* (2003), Madge & Burn (1994), Meinertzhagen (1926), Stattersfield & Capper (2000), Wetmore & Swales (1931).

103. **Jamaican Crow**

Corvus jamaicensis

French: Corneille de Jamaïque **German**: Jamaikakrähe **Spanish**: Cuervo Jamaicano
Other common names: Chattering/Jabbering Crow

Taxonomy. *Corvus jamaicensis* J. F. Gmelin, 1788, Jamaica.
May form a superspecies with *C. nasicus* and *C. leucognaphalus*. Monotypic.
Distribution. Jamaica.
Descriptive notes. 35–38 cm; two birds 336 g and 339 g. Smallest and dullest Caribbean crow; body plumage loose and soft, nostrils of some individuals fully exposed. Has head, face and throat black, base of neck feathers grey, rest of plumage mostly dark, dull grey or sooty black, back greyish-black with hint of brown; some violet iridescence in wings, tail and neck; iris grey-brown or reddish-brown (possibly indicating age or sex), bare suborbital patch evident on most individuals; bill slate-grey; legs black. Sexes similar, male slightly larger than female. Juvenile undescribed. Voice. Remarkably variable, especially jabbering outbursts, which are frequent in social gatherings and include mix of chuckling, chattering and gobbling, strung together in a garbled melody, once described as "like a half dozen Welshmen quarrelling"; known to croak like raven and to give harsh "craa craa" sound like *C. frugilegus*.

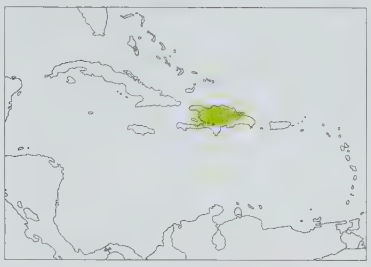
Habitat. Wet limestone forests, mountain pastures, wooded hills and open parkland, including landscapes with settlement and agriculture. Early explorers emphasized association with wild, high-elevation (above 600 m) forests. Recent observations suggest a wider distribution and use of low elevations during dry season.
Food and Feeding. Omnivorous. Consumes variety of fruits, e.g. bitterwood (*Picrasmas excelsia*), pimento (*Pimenta pimenta*), soursop (*Annona muricata*), banana (*Musa sapientum*), plantain (*Musa paradisiaca*), wild fig (*Ficus trigonata*), wattle-wood (*Laetia thamnia*) and burnnose (*Daphnosis tinifolia*), also arthropods, primarily from forest canopy. Also probes bromeliads, pries bark, and digs into rotting wood in search of invertebrates. Preys on eggs and nestlings of other birds, especially wild pigeons (Columbidae). Steals snared small birds. In Worthy Park, observed to carry an orange and a frog. In pairs and small groups.
Breeding. Poorly known. Presumed solitary nester in exclusive territory. Nest high in tree or possibly in natural cavity. No information on season, clutch size, and incubation and nestling periods.
Movements. No information. Appears sedentary and territorial during breeding season, but may wander in small groups during non-breeding season.
Status and Conservation. Not globally threatened. Restricted-range species: present in Jamaica EBA. Locally common and perhaps expanding range in Westmoreland and Manchester; common in Cockpit Country, Moneague, Good Hope, Worthy Park, and John Crow Mts. Rare or absent in Blue Mts. Despite use of some open habitats, possibly at some risk due to extensive forest clearance.
Bibliography. Bond (1936), Cruz (1972, 1974), Fletcher (2006), Goodwin (1986), Gosse (1847), Johnston (1961), Lack (1976), Madge & Burn (1994), Meinertzhagen (1926).

104. Cuban Crow

Corvus nasicus

French: Corneille de Cuba **German**: Kubakrähe **Spanish**: Cuervo Cubano

Taxonomy. *Corvus nasicus* Temminck, 1826, Cuba.
May form a superspecies with *C. jamaicensis* and *C. leucognaphalus*. Monotypic.
Distribution. Cuba, I of Pines, and S Bahama Is (Providenciales, North Caicos, Grand Caicos).



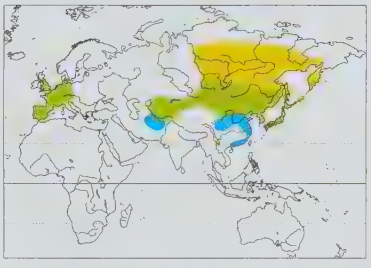
Descriptive notes. 40–42 cm; 330–510 g. A moderate-sized crow with upturned nasal bristles that do not cover nostrils; relatively long bill. Plumage is deep black with slight blue-purple gloss, body feathers with grey bases; iris brown, patch of bare skin behind eye and at base of bill; bill and legs black. Distinguished from *C. palmarum* by longer and less stout bill, and by longer wings and slower, heavier wingbeats in flight. Sexes similar, male slightly larger than female. Juvenile is slightly duller than adult. Voice. Vocalizations quite musical, and less nasal and abrupt than those of *C. palmarum*. Ringing, high-pitched "aaaaauh" rising in inflection, liquid bubbling, trilling and chattering similar to sounds made by *C. jamaicensis*. Raven-like croaks and guttural chatter of great variety.
Habitat. Forests and woodlands, including villages and towns with substantial tree cover. Uses edges and semi-cleared forest, wooded cultivation and agricultural areas, including those with grains and fruits.
Food and Feeding. Omnivorous. Feeds in trees and on ground on invertebrates, fruits and berries. Formal dietary studies lacking. Often observed in small, noisy groups. Readily flocks with *C. palmarum*. Singly and in pairs, sometimes in larger groups.
Breeding. Season Mar–Jul. Nest a coarse stick platform lined with dry grasses, feathers and other soft materials, placed in palm, among tree branches or on large bromeliad in tree. Clutch 3–4 eggs; no information on incubation and nestling periods.
Movements. No information.
Status and Conservation. Not globally threatened. Common to locally abundant. Often persecuted by man, and may have been reduced in numbers as extensive forests have been cleared. Use of partially cleared forest, edges, agricultural areas and settlements reveals adaptation to human activities.
Bibliography. Bond (1936), Buden (1992), Garrido & Kirkconnell (2000), Garrido *et al.* (1997), Goodwin (1986), Johnston (1961), Madge & Burn (1994), Meinertzhagen (1926), Olson & Hilgartner (1982).

105. White-necked Crow

Corvus leucognaphalus

French: Corneille d'Hispaniola **German**: Antillenkrähe **Spanish**: Cuervo de la Española

Taxonomy. *Corvus leucognaphalus* Daudin, 1800, Puerto Rico.
May form a superspecies with *C. jamaicensis* and *C. nasicus*. Monotypic.
Distribution. Hispaniola.
Descriptive notes. 42–46 cm. The largest Caribbean crow; long (35–49 mm) and tapered bill, nasal bristles upturned and sweeping over culmen ridge, intense plush-like black feathers at base of culmen between bill and eye. Plumage is black with purple or blue gloss, body feathers with white bases (concealed white bases give rise to name); iris red-brown (yellow iris also reported, possibly age-specific), bare skin about bill base and below eye; bill and legs black. Sexes similar, male slightly larger than female. Juvenile is slightly duller than adult. Voice. Raven-like, including guttural "culik-calow-calow", deep "wallough", and variety of high-pitched musical notes, e.g. "klook"; does not "caw" like a typical crow.
Habitat. Most closely associated with old, mature forests in mountainous and hilly, inaccessible country; also coastal mangrove swamps and cactus forests.
Food and Feeding. Omnivorous. Formal dietary studies lacking. Feeds in large flocks on seasonally abundant fruits, primarily in forest canopy. Known to eat drupes of *Dacryodes excelsa*; also tree-toads and passerine nestlings. Formerly seen in large foraging flocks, commuting between



mountain roosts and lowland feeding areas; strong, graceful flier, travelling long distances high in air.
Breeding. Poorly known. Season Feb–Jun; eggs and well-grown young observed in Mar in Puerto Rico (now extinct) and nests in early May in Haiti. Builds a typical crow nest, a coarse stick platform lined with dry grasses and other soft materials, placed among tree branches, one was high in a palm, another high in a pine tree (*Pinus*). Clutch 3–4 eggs; no information on incubation and nestling periods.
Movements. No formal study. Casual visitor to islands of Gonâve and Saona.
Status and Conservation. VULNERABLE. Restricted-range species: present in Hispaniola EBA and (formerly) Puerto Rico and the Virgin Islands EBA. Rarest crow in Caribbean. Now exists only on Hispaniola; last recorded Puerto Rico in 1963 and considered extinct there (more recent possible sightings around El Yunque may be escaped pets). Severe population declines of this once widespread species were noted in early 20th century, and continue to this day. Was valued as a gamebird, with delicious flesh, and was hunted extensively; moreover, its habitat has been largely destroyed by forest clearance.
Bibliography. Anon. (2007b, 2008p), Bond (1936), Butchart & Stattersfield (2004), Garrido *et al.* (1997), Goodwin (1986), Johnston (1961), Keith *et al.* (2003), Madge & Burn (1994), Meinertzhagen (1926), Stattersfield & Capper (2000), Wetmore (1927), Wetmore & Swales (1931), Wiley (2006).

106. Carrion Crow

Corvus corone

French: Corneille noire **German**: Rabenkrähe **Spanish**: Corneja Negra
Other common names: Common/Eurasian Crow (with *C. cornix*); Eastern Carrion Crow, Oriental Crow (*orientalis*)

Taxonomy. *Corvus Corone* Linnaeus, 1758, England.
Thought to form a superspecies with *C. cornix*, possibly also including *C. pectoralis*; was for long treated as conspecific with former. Situation complex, as narrow bands of hybridization between present species and *C. cornix* exist across Scotland, through C Europe, in C Siberia and in C Asia, but striking plumage differences, subtle differences in vocalizations, and both narrowness and plasticity of hybrid zones all suggest that speciation has been at least partially achieved. Presence of "black crows" over both W & E regions of Eurasian landmass, separated by *C. cornix*, is noteworthy; preliminary research indicates that these black populations may merit treatment as two separate species, but more extensive investigation required. Within extensive range of E populations (*orientalis*) there is a cline of increasing bill size from W to E, which has prompted the describing of a further three races: *interpositus* (described from Japan), *saghalensis* (from Sakhalin I) and *yunnanensis* (from S Yunnan, in China) are all regarded as synonyms of *orientalis*. Two subspecies currently recognized.
Subspecies and Distribution.
C. c. corone Linnaeus, 1758 – Britain (except N Scotland), France, Spain and Portugal E to Denmark, W Germany, Czech Republic, Slovakia, Austria, N Italy and Switzerland; many C European birds disperse S & W in winter, reaching Corsica, Sardinia and SE Europe.
C. c. orientalis Eversmann, 1841 – breeds from C Siberia (Russia) and N Mongolia from R Yenisei E (N to N limit of taiga) to Kamchatka, Kuril Is and Sakhalin I, and from C Kazakhstan, E Turkmenistan, NE Afghanistan and extreme NW Indian Subcontinent E through Tien Shan and across N China (S to N Qinghai, N Sichuan and Hebei, with isolated population S Yunnan) E to Japan (S to Kyushu); N populations migrate S to E & SE China, also S to NE Iran, Baluchistan and N Pakistan (NorthWest Frontier Province) in winter.

Descriptive notes. 48–53 cm; 396–602 g. A rather compact archetypal crow with relatively flat crown running onto slightly arched culmen. Plumage is wholly black, greenish hue on head and wings becoming more purplish-red on rest of upperparts, the lower underparts dull black; in worn plumage, becomes very dull, unglossed black overall; iris dark brown; bill and legs black. Differs from *C. frugilegus* in head shape, less glossy plumage, less prominent feathering on thighs, in flight by having tail more gently rounded at tip, wings appearing rather broader and less fingered (impression created by slightly shorter "hand"). Sexes similar. Juvenile has plumage duller and rather looser, more sooty black, than adult, also greyer iris and pinkish-red interior of mandibles (grey in adults), and may show pale or fleshy gape-flanges into first autumn; birds with whitish patches on wings (on some forming a band along whole length of wing, at bases of primaries and secondaries) are not unusual, and seem invariably to be first-years. Races differ only in size: *orientalis* is on average larger than nominate, and has larger, stouter bill (largest in E of range). Hybrids between present species and *C. cornix* vary from being almost wholly black with scattered grey feathers on mantle and breast to being *cornix*-like with blackish markings. Voice. Typical call a flat, dry "aaaah" or "kraaah", repeated on same pitch c. 3–6 times, varying somewhat in strength of delivery. Also sometimes gives an almost raven-like "konk-konk", but this usually accompanied by more typical call notes. Song rarely noticed, a bubbling mixture of call notes interspersed with some mimicry.
Habitat. Inhabits a huge variety of open country, preferably with at least scattered trees. Favours mixed farmland, parks and gardens, also by forest clearings, and equally at home on moorland and on inshore islands, coastal cliffs and estuarine flats. Nominate race ascends to 2000 m in Swiss Alps; *orientalis* reaches 3600 m in parts of C Asia.
Food and Feeding. Omnivorous, but chiefly a carnivorous scavenger. Diet varies according to local habitats, but consists basically of invertebrates, especially earthworms (Lumbricidae), small mammals, frogs, bird eggs and nestlings, as well as carrion; in addition, small amounts of grain and weed seeds taken. Feeds almost entirely on ground, turning over seaweed, dung or stones to get at insects and other invertebrates. Although not known for its agility in the air, will pursue other birds to make them drop or regurgitate food items. Surprising number of reports of attempting to catch birds in flight: Common Starling (*Sturnus vulgaris*) was successfully captured in full flight, Common Woodpigeon (*Columba palumbus*) taken, and Northern Lapwing (*Vanellus vanellus*) forced to

the ground by three crows was killed by one of them; attempt to capture Barn Swallows (*Hirundo rustica*) on the wing seems not to have been successful. Opens shellfish by flying high before pausing and dropping them on to a hard surface, repeating the performance several times if necessary. Pairs patrol roadsides in early mornings for roadkill carrion, or forage along lakeshores, across intertidal mudflats and along seashores, searching for both dead and live food items. Exceptionally, recorded as picking dead and live fish from surface of lake, even hovering briefly while doing so, sometimes using feet, as well as by picking from surface with bill. Although forages among taller grass than do other corvids, prefers newly mown hayfields and fresh stubble following harvest, where considerable numbers may assemble. Several observations of food-hoarding, but this habit seems to be less widespread than it is among several other corvids. Often encountered in pairs or family parties, and assemblages of 50–100 can gather at favoured feeding sites such as rubbish dumps and tidal mudflats. Larger numbers, up to 5000, may roost in mixed flocks in stands of large trees. Often indulges in apparent "play" activities, including repeatedly sliding down sloping roof, or hanging upside-down and swinging by feet from washing line or telephone wires.

Breeding. Season commences late Mar in Britain, peak egg-laying mid-Apr, and dates similar in W Europe overall; E race *orientalis* more varied over more extensive range, generally early Apr in Ussuriland (SE Russia), late Apr in C Asia but not until late May or early Jun on Kamchatka in far N; single-brooded. Monogamous long-term pair-bond, pair-members keeping together throughout year (even when flocking); pair has home range of c. 14–49 ha, which contracts during breeding season, when adults defend nest against potential predators, chiefly other crows. Solitary nester, but rarely two and exceptionally three active nests in one tree. Nest built by both sexes, female doing bulk of the work, work normally taking 20 days (but nest can be built in 6–7 days if a replacement after failed first attempt); a rather large structuire based on sticks and twigs, often mixed with rabbit (*Oryctolagus*) bones or wire and heather (Ericaceae) twigs, mud pushed into base to give a solid foundation, deep cup thickly lined with soft materials such as wool, animal fur, soft grasses, feathers and paper; built mainly in crown of tall tree, normally a fresh nest built each year, although in some cases (where availability of nest-sites limited) an old nest repaired and reused; in more open habitats electricity pylons provide nest-sites, whilst on exposed coasts cliff ledge or stunted shrub may be used; some nests built on old buildings, in reedbeds, or even on ground, sheltered by heather, stone wall or rocks. Clutch almost invariably 4 eggs; incubation almost entirely by female, fed on or near nest by male for first 9–10 days, male sometimes taking over for short stints, period 17–22 days; chicks fed by both parents, leave nest after 30–34 days; young dependent on adults for several further weeks; in autumn many young join up with flocks of non-breeders at key sites, whereas others remain with parents for the first winter. Nest occasionally parasitized by Great Spotted Cuckoo (*Clamator glandarius*) in Spain. Able to breed when 15–17 months old. As with other large corvids, old nests used by a number of other birds, including Long-eared Owls (*Asio otus*), sparrowhawks (*Accipiter*) and various falcons (*Falco*).

Movements. Nominate race basically resident, although birds from interior of Continental Europe show tendency to disperse SE, S & SW in winter, some reaching E Hungary, W Ukraine, S Spain, Gibraltar and rarely even N coastal Morocco; vagrants reported also from various parts of Balkans, S Italy, Sicily, Corsica and, exceptionally, Atlantic islands (Madeira, Azores) and Kola Peninsula (NW Russia). In spring, presumed overshooting returning migrants annual in S Sweden and W Norway. E race *orientalis* also a partial migrant, N birds moving S, many reaching coastal lowlands of Hong Kong, South China Sea and inland to S China (but wintering also in W Mongolia); has occurred as vagrant in N Vietnam. Migration numbers and routes unclear (owing to potential confusion with E race of *C. frugilegus*), but first arrivals appear in Yakutia (Arctic Circle) around mid-Mar, joining few which sometimes have overwintered there; large flocks form in Sept, prior to moving S, these moving out in latter half Oct; on Sea of Okhotsk coast first arrivals on Shantar Is on 10th Apr, with last passing up to very end of Nov. Winter dispersal takes birds across Pakistan, vagrant having reached Karachi, but not found S of Kashmir (although breeding in Ladakh); farther W in C Asia flocks form in wintering areas, notably in W Turkmenistan, some penetrate into NE Iran. This dispersal may account for occasional vagrant occurrence in E Turkey and Lebanon (i.e. it is possible that these are *orientalis* rather than wanderers from W Europe). Vagrant S to Ryukyu Is and Izu Is, and even Bonin Is (where formerly nested).

Status and Conservation. Not globally threatened. European nominate race abundant, with population of 2,000,000–3,000,000 pairs: Britain 790,000 (spreading N, now in C Scotland), France 200,000–1,000,000 (increasing), Belgium 16,000, Netherlands 50,000–80,000, Luxembourg 8000–10,000, Germany 320,000–400,000, Spain 320,000–530,000, Portugal 1000–10,000, Switzerland 80,000–150,000, and Denmark 300–4000. Although having for long been persecuted as "vermin" by gamekeepers and farmers because of its egg-stealing and nest-robbing habits, over much of its European range this corvid is now increasing, Reduction in keepering intensity since 1920s has allowed a steady increase, which accelerated in 1950s as creation of larger suburban gardens and city and town parks provided habitats safer from human persecution. E race *orientalis* also common over most of its huge range, although seems to be scarce at S limits of in NE Afghanistan, Kashmir and Yunnan. In Japan, it is common on N islands S to Kyushu.

Bibliography. Ali & Ripley (1972, 1987b), Beaman & Madge (1998), Blinov & Kryukov (1992), Blinov *et al.* (1993), Brazil (1991), Chen Fuguan *et al.* (1998), Cook (1975), Coombs (1978), Cramp & Perrins (1994), Dementiev *et al.* (1954, 1970), Goodwin (1986), Grimmett *et al.* (1998), Haffer (1993h), Hagemeijer & Blair (1997), Higuchi (1979), Holloway (1996), Kryukov & Blinov (1994), Madge (2000), Madge & Burn (1994), McCarthy (2006), Meise (1928), Melde (2004), Prior (2007), Rasmussen & Anderton (2005b), Roselaar (1995), Saino & Scatizzi (1991), Sangster *et al.* (1997), Stepanyan (1990, 2003), Vaurie (1954, 1959), Williams *et al.* (1992).

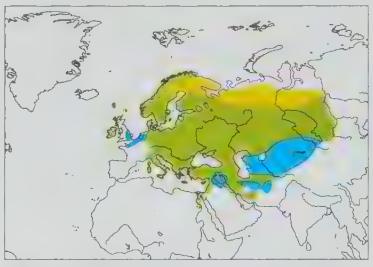
107. Hooded Crow

Corvus cornix

French: Corneille mantelée **German**: Nebelkrähe **Spanish**: Corneja Cenicienta
Other common names: Common/Eurasian Crow (with *C. corone*); Mesopotamian Crow (*capellanus*)

Taxonomy. *Corvus Cornix* Linnaeus, 1758, Sweden.

Thought to form a superspecies with *C. corone*, possibly also including *C. pectoralis*; was for long treated as conspecific with former. Situation complex, as narrow bands of hybridization between present species and *C. corone* exist across Scotland, through C Europe, in C Siberia and in C Asia, but striking plumage differences, subtle differences in vocalizations, and both narrowness and plasticity of hybrid zones all suggest that speciation has been at least partially achieved. British Is present a most interesting distributional jigsaw, with present species throughout Ireland, I of Man, N Scotland and Scottish isles, being replaced by *C. corone* over England, Wales and S Scotland; this suggests that present species had colonized from E, probably being the original British crow, but N-spreading *C. corone* from France or Spain colonized S England; meanwhile, Ireland and I of Man had separated from mainland Britain before England became separated from continental Europe. The spread continues today, with Scottish band of hybrids creeping N as black-plumage genes obliterate grey genes. Nominate race intergrades with *sharpii* in region of Urals. In E Europe and W Asia there is a cline of increasing paleness and smaller size from N to S, but complicated by bleaching, and several other described races are best treated as synonyms: thus, *khozaricus* (described from S Russia) is synonymized with nominate, and *kaukasicus* (Caucasus region), *sardonius* (Sardinia), *italicus* (Italy) and *minos* (Crete) are treated as synonyms of *sharpii*. Extreme S race, *pallescens*, is at palest end of cline, is relatively small and rather weak-billed, and contrasts markedly with the almost black-and-white, large-billed *capellanus* of Iraq and extreme SW Iran, suggesting that latter may well have evolved to full species level. Four subspecies recognized.



Subspecies and Distribution.

C. c. cornix Linnaeus, 1758 – Faroe Is, N Scotland, Ireland and I of Man E throughout Fennoscandia and W Russia to Urals, S in Europe to Hungary and NW Romania, N Balkans, N Italy and Corsica; some N birds move S or SW in winter, reaching as far as W France.

C. c. sharpii Oates, 1889 – Urals E in Siberia to R Yenisei, C Asia, Iran, Turkey (except S), from Caucasus W through S Ukraine to S Balkans, Crete and S Italy (including Sardinia and Sicily); N populations migrate S to as far as Afghanistan.

C. c. pallescens (Madarász, 1904) – Cyprus, S Turkey E to N Iraq, S to Egypt, Israel and Jordan.

C. c. capellanus P. L. Sclater, 1877 – Euphrates Valley of lowland Iraq (reaching N to Kirkuk) and E into SW Iran (as far as Bushire).

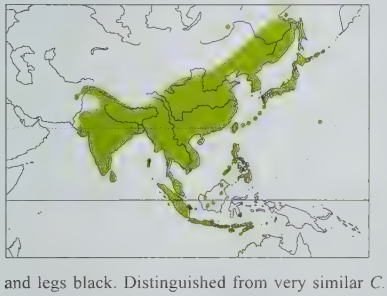
Descriptive notes. 48–54 cm; 396–602 g. Size, structure and habits are basically as for *C. corone*. Nominate race has black hood formed by glossy black crown, upper nape, side of head, throat and "breastplate" (lower border of breastplate somewhat irregular); tibia and both wing surfaces and tail also black, and uppertail-coverts variably blotched blackish and grey; rest of plumage, including nape, side of neck, mantle, scapulars, rump and some uppertail-coverts, remaining underparts and axillaries ashy grey with fine dark shaft streaks; through wear, black areas of plumage become dull and unglossed; iris dark brown; bill black; legs dark grey. Sexes similar. Juvenile has duller and rather looser, softer, more brown-toned grey plumage than adult, lacking dark shaft streaks on body feathering, also has greyer iris and pinkish-red interior of mandibles (dark grey in adult), and may show pale or fleshy gape-flanges into first autumn. Races differ mainly in size and plumage tone, variation chiefly clinal: *sharpii* is paler grey than nominate, W birds tending to be larger than those in E; *pallescens* is smaller and even paler grey than previous; *capellanus* is distinctive, large and stout-billed, with extremely pale grey body plumage, appearing almost black and white in the field (especially when plumage worn). Hybrids with *C. corone* variable, some being like present species but with blackish markings on mantle or lower underparts, others almost wholly black with scattered grey feathers on mantle and breast. Voice. Much as for *C. corone*, but a certain amount of regional variation of a fairly varied vocabulary complicates interpretation of differences. Most frequently heard call a slightly softer, more rolling "aaarrr", less hoarse than that of *C. corone*; some evidence to suggest that some basic vocalizations may have different meanings for the respective species. Race *capellanus* said to have a deeper and gruffer voice than others.

Habitat. Open country with at least scattered trees. Favours mixed farmland, parks and gardens, from city centres to forest clearings, and equally at home on moorland as it is on inshore islands, coastal cliffs and estuarine flats. Tolerates humans more so than does *C. corone*, being far more approachable and quite numerous in the streets of many cities. With encroachment of cultivation into the desert (e.g. in Israel), it has now come into contact with *C. ruficollis*, but it keeps very much to lusher areas of cultivation and does not tolerate true arid conditions. Breeds at up to 1350 m in the Tatra Mts (Poland–Slovakia); recorded to 1000 m in the Carpathians and the Urals, 1125 m in the Altai and 2050 m in the Saraibulag Range of Armenia. In hybrid/overlap zone in E Alps, there is a tendency for *C. corone* to occupy higher elevations than the lowland-haunting present species.

Food and Feeding. Omnivorous, but chiefly a carnivorous scavenger. Diet varies according to local situations and season, but basically invertebrates, especially earthworms (Lumbricidae) and insects, also small mammals, frogs, bird eggs and nestlings, and carrion; also takes small amounts of grain and weed seeds. Fledglings fed almost entirely on insects through early summer, switching to higher levels of grain and weed seeds in autumn and winter. Forages almost entirely on ground, turning over seaweed, dung or stones to get at insects and other invertebrates; chases other birds to make them drop or regurgitate food items. Pairs patrol roads and tidal shorelines for carrion, or forage along lakeshores, across mudflats and along seashores, searching for dead or live food items. Sociable, in pairs and small groups; sometimes larger flocks. Roosts singly, in pairs or in small to large gatherings (up to several thousand, especially in winter), usually in trees or on cliff faces, but in open areas among heather on open moorland.

Breeding. Season commences late Mar in Britain, peak egg-laying mid-Apr; at S limit of range, eggs from end of Jan in Egypt, Feb in Israel and Persian Gulf, mid-Mar in Iraq (*capellanus*) and Georgia; oddly, laying said to be in May in Greece; farther N, laying begins in mid-Apr in N Caspian region and N Caucasus foothills, about third week in Apr in Moscow region, and May in Finnish Lapland; single-brooded. Monogamous long-term pair-bond, partners keeping together through most of year, but bond less strong when flocking. Solitary breeder, although generally more sociable than *C. corone* even in breeding season, when can form loose colonies; inter-nest distance 20 m in parts of Moscow. Nest built by both sexes, often female doing construction whilst male collects materials, fresh nest can be built in 7–8 days; rather bulky, based on sticks and twigs, often mixed with animal bones, sheep wool and heather, mud pushed into base to give it a solid foundation, deep cup thickly lined with soft materials such as wool, fur, soft grasses and the like, usually placed in crown of tall tree; normally fresh nest built each year, but in some places where availability of sites is limited an old nest may be repaired and reused; in more open habitats electricity pylons provide nest-sites, and on exposed coasts a cliff ledge or stunted shrub may be used; some nests built on old buildings or even on the ground, sheltered by heather, a stone wall or rocks. Clutch usually 4–5 eggs; incubation by female, period 17–20 days; chicks fed by both parents, nestling period 3–5 weeks; young somewhat dependent on parents for a further 2–3 weeks and often throughout first winter; in late summer family unit normally breaks up as juveniles join foraging flocks, either with or without adults. Nest occasionally parasitized by Great Spotted Cuckoo (*Clamator glandarius*) in E Mediterranean region. Capable of breeding at 2 or 3 years of age.

Movements. Resident in W & S; N and interior birds move S in autumn (Sept–Nov) to varying degrees, many remaining about towns and settlements even in far N in milder winters. Birds from Scandinavia and E to C Finland winter in countries bordering S coast of North Sea, those of E Finland wintering chiefly NE Germany and N Poland. Formerly substantial numbers wintered across W Europe to N France and E England, but far fewer have done so in recent decades (presumably because birds remain in towns and villages in breeding areas). Breeders from W Russia E to the Urals move S to Volga Delta and nearby steppes; those from farther E migrate to Kazakhstan, Turkmenistan and Afghanistan, a few reaching Pakistan, W China (Xinjiang) and extreme NW India. Vagrants reported from Greenland, Jan Mayen, Bear I, Iceland, Svalbard, Novaya Zemlya,



Malta, Tunisia and Libya, most of which referable to overshooting on spring migration (Mar–May). At migration times, can assemble in thousands at key points.
Status and Conservation. Not globally threatened. Abundant, with apparent population increases over recent decades in most European countries, most notable being its spread into cities from the countryside. Densities vary with location; in Moscow city area as high as 32–36 pairs/km², whereas in agricultural land nearby only c. 2–3 pairs/km². Reports from Egypt indicate a dramatic decline in populations of Nile Delta, which could be linked to pesticides. Following estimates (pairs/territories) have been made for most countries within W Palearctic: Faeroe Is 500–1000, Scotland & I of Man 160,000 (plus 20,000 hybrids), Ireland 290,000, Germany 63,000–84,000, Denmark 21,000–220,000, Norway 200,000–600,000, Sweden 250,000–500,000, Finland 200,000–300,000, Estonia 50,000–100,000, Latvia 20,000–60,000, Lithuania up to 70,000, Poland 50,000–100,000, Slovakia 15,000–30,000, Hungary 70,000–80,000, Italy 110,000–520,000, Greece 150,000–200,000, Albania 10,000–30,000, Croatia 110,000–150,000, Slovenia 8,000–12,000, Bulgaria 500,00–1,000,000, Romania 30,000–50,000, Russia 1,000,000–10,000,000, Belarus 280,000–320,000, Ukraine 450,000–500,000, Moldova 7000–10,000, Azerbaijan 8000–10,000, Turkey 100,000–1,000,000, Israel c. 20,000, Egypt 10,000–100,000. Has long been persecuted by gamekeepers and farmers owing to its egg-stealing and nest-robbing habits; over much of its European range, however, it is now increasing, finding that city and town parks as well as rubbish dumps provide not only easy scavenging, but also habitats safer from human persecution.
Bibliography. Ali & Ripley (1972, 1987b), Beaman & Madge (1998), Blinov & Kryukov (1992), Blinov *et al.* (1993), Cook (1975), Coombs (1978), Cramp & Perrins (1994), Dementiev *et al.* (1954, 1970), Goodman & Meininger (1989), Goodwin (1986), Grimmett *et al.* (1998), Haffer (1993h), Hagemeijer & Blair (1997), Kryukov & Blinov (1994), Madge (2000), Madge & Burn (1994), Meise (1928), Melde (2004), Nakamura & Murayama (2004), Rasmussen & Anderton (2005b), Roselaar (1995), Saino & Scatizzi (1991), Sangster *et al.* (1997), Shirihai (1996), Stepanyan (1990, 2003), Vaurie (1954, 1959).

108. Large-billed Crow

Corvus macrorhynchos

French: Corbeau à gros bec **German**: Dschungelkrähe **Spanish**: Cuervo Picudo
Other common names: Jungle/Thick-billed/Black Crow; Japanese Crow (*japonensis*, *connectens*, *osai*); Eastern Jungle Crow (*levaillantii*); Indian Jungle Crow (*culminatus*)

Taxonomy. *Corvus Macrorhynchos* Wagler, 1827, Java.
Taxonomy confusing owing to large number of races covering wide geographical area. Formerly included in *C. coronoides*, and listed as *C. levaillantii* in some older literature. Races probably represent several different species. In Indian Subcontinent, small race *culminatus* meets larger Himalayan *intermedius*; the two differ both vocally and in some behavioural aspects, but it is uncertain where the species limits are in relation to the lowland Bengal race *levaillantii*. In a recent study, four species tentatively proposed: "*C. japonensis*" (with races *mandshuricus*, *connectens*, *osai*, *tibetosinensis* and *intermedius*), "*C. levaillantii*" (with *culminatus* and *colonorum*), "*C. macrorhynchos*" and "*C. philippinus*". Subsequent study, however, has indicated that *osai* and *connectens* are not closely related to N Japanese forms, and, indeed, *japonensis* and *mandshuricus* behave as two species on the island of Sakhalin, with no mixed pairs found in overlap zone (C Sakhalin). These factors suggest that as many as seven species may be a reasonable assessment of the complex, but more research is required, not only through genetic and vocal comparisons, but also involving investigation of their parasitic lice (Mallophaga) and whether differences between races is gradual or abrupt. Race *intermedius* intergrades with *tibetosinensis*. Other proposed races are *hondoensis* and *borealis* (subsumed in *japonensis*), *andamanensis* (in *levaillantii*), *anthracinus* (in *culminatus*), *hassi*, *mengtszensis* and *hainanus* (in *colonorum*) and *timoriensis* (in nominate). With such a complicated species, however, one or two of these, especially *anthracinus* of Sri Lanka and *andamanensis* of the Andamans, could well be resurrected following a comprehensive review. Eleven subspecies currently recognized.
Subspecies and Distribution.
C. m. intermedius Adams, 1859 – E Afghanistan and W & N Pakistan E along Himalayas to S Xizang and N Nepal.
C. m. culminatus Sykes, 1832 – peninsular India, SW Nepal and Sri Lanka.
C. m. levaillantii Lesson, 1831 – SE Nepal, Bangladesh, NE India, Andaman Is, Myanmar and Thailand E to C & S Indochina and S to N Malay Peninsula.
C. m. macrorhynchos Wagler, 1827 – C & S Malay Peninsula and Sundas E to Wetar and Timor.
C. m. philippinus (Bonaparte, 1853) – Philippine Is.
C. m. tibetosinensis O. Kleinschmidt & Weigold, 1922 – E & SE Tibetan Plateau and E Himalayas (E from Bhutan) E to N & NE Myanmar and extreme S China (S Qinghai S to Yunnan).
C. m. mandshuricus Buturlin, 1913 – N & C Sakhalin I, Russian Far East, Korea and NE China; breeding also recorded in Transbaikalia.
C. m. japonensis Bonaparte, 1850 – S Sakhalin I, Kuril Is and Japan (S to Kyushu and Osumi Is).
C. m. connectens Stresemann, 1916 – Amami Oshima and Ryukyu Is (Japan).
C. m. osai Ogawa, 1905 – S Ryukyu Is.
C. m. colonorum Swinhoe, 1864 – C & S China, Taiwan, Hainan I and N Indochina.

Descriptive notes. 46–59 cm; 450–1000 g. A medium-sized to large crow, varying much in size, with relatively long, dagger-like bill with somewhat arching culmen (most marked in males of the N races), base of culmen concealed by overlapping bristles. Nominate race has distinctly peaked forehead, plumage entirely black, head, neck and upperparts, including wing and tail, strongly glossed, upper surface of wing and central tail feathers shot with purple; underparts black with strong sheen; bases of neck feathers pale grey, throat feathers with notched hackles (giving somewhat jowled appearance); iris dark brown; bill (60–69 mm) and legs black. Distinguished from very similar *C. enca* by concealed culmen base, in flight by relatively longer tail with more graduated tip, wing with longer hand and more obviously fingered primaries. Sexes similar, female on average smaller than male, with less arched culmen and less strongly graduated tail. Juvenile has softer and less glossy plumage than adult, with matt black underparts, lacks throat hackles, has inside of mandibles reddish-pink (black in adult), iris smoky blue. Races differ in bill size, also in overall size and degree of gloss in plumage: *japonensis* is largest, has largest bill (70–80 mm) with almost ridged arch on culmen, dusky-grey bases of neck feathers and highly glossed plumage; *connectens* is similar to last but smaller (bill 62–69 mm); *osai* also is similar but bill smaller (55–59 mm); *mandshuricus* is only a little smaller than *japonensis*, has duller plumage, bill shorter (60–68 mm) but deeper and more highly ridged; *colonorum* is similar to *japonensis* but smaller (bill 57–61 mm), with duller neck and underparts, less purple in gloss of wings and tail; *tibetosinensis* is large (bill 60–73 mm), very black and glossy, and has variable whitish to dark grey bases of neck feathers; *intermedius* is large (bill 54–73 mm), dull greyish-black in colour, with bill somewhat slimmer, and has whitish bases of neck feathers; *philippinus* is close to nominate race in plumage, but has whiter bases of neck feathers and relatively longer tail; *levaillantii* is wholly glossy black, with bases of neck feathers dusky grey, bill 61–69 mm, rather deeper than the next; *culminatus* is small and rather glossy black, with slimmer bill than other races (bill 52–67 mm). Voice. In need of comparative analysis. Complex, with degree of variation within vocabulary of each taxon. All have reasonably similar cawing note which varies in hoarseness, *intermedius* has loud, dry "kaaa-kaaa", stronger and lower in pitch than that of *culminatus*, some calls of *intermedius* are quite musical and include single weak croak which lacks deep croaking resonance of the "prruuk-prruuk" of *C. corax*. Tibetan race *tibetosinensis* has low-pitched and rather hoarse "keearrh-keearr". Philippine *philippensis* gives loud, guttural "weerrk-weerrk-weerrk", the notes deeper and more spaced in delivery than those of *C. enca*. Race *levaillantii* said to give distinctive nasal yapping, with duck-like quality, each note rising and falling suddenly, "nYArk, nYArk", while those on Andamans are said to utter calls which are more plaintive and less harsh than those of *culminatus*. Nominate race has relatively low-pitched and gruff caws, and also gives deep gargling rattle in flight. Race *japonensis* patrolling territory utters "kroo-kroo" or "krau-krau". As is evident, it is difficult to decide on precise vocal differences between taxa on basis of transcriptions alone, especially when range of calls of each taxon not well known (e.g. the well-studied Indian *culminatus* is known to have at least ten distinct calls).
Habitat. Forests and woodland of all types across its wide range. In far N (in Amurland and on Sakhalin) chiefly by rivers and their floodplains in forests of the taiga, gathering by villages and settlements, particularly in winter. Reaches 2000 m in Sri Lanka, 2300 m in Nilgiris of S India and 4500 m in Sikkim. In Himalayas ranges to upper limits of tree-line and beyond, following yak (*Bos grunniens*) and pony caravans high into mountains; has reached 5000 m on Tibetan Plateau and been recorded following mountaineers on Everest as high as 6400 m. N populations forsake frozen interior in winter and congregate by river mouths and seashores. Farther S in Asia can often be found alongside the more numerous *C. splendens* in towns and cities; far less closely associated with man than is latter, but each little village with a large tree usually has a nesting pair of present species. Parties converge and flock to large trees, particularly those close to slaughterhouses, rubbish dumps and small fishing ports. In tropical Asia its habitats are similar to those in the far N, but may often be found in more or less semi-open agricultural land, with scattered trees. Favours forest edge and clearings, paddyfields and coconut (*Cocos nucifera*) plantations, especially by rivers and in coastal lowlands, including mangroves and wooded inshore islands. Where range overlaps with that of *C. enca*, latter seems unable to compete successfully with present species and becomes an inconspicuous crow of dense lowland forests.
Food and Feeding. Omnivorous scavenger. Takes carrion of all kinds, by foraging along shorelines and roadsides, stealing food items from vulture nests (food brought in by parent vultures to feed their young). Robs bird nests of both eggs and fledglings, feeds with vultures on animal carcasses, kills rodents and palm-squirrels (*Funambulus*), lizards (*Colotes*), frogs, large invertebrates including crabs, centipedes (Chilopoda), grasshoppers and locusts (Orthoptera), moths and caterpillars (Lepidoptera), beetles (Coleoptera), ants (Formicidae) and termites (Isoptera); clumsily hawks for winged termites and even small bats in flight. Also takes variety of fruit, both wild and cultivated, including berries and cherries; variety of cereals (e.g. *Sorghum*, *Oryza*, *Pennisetum*, *Triticum*, *Zea*), seen to wrench off whole maize cobs and digs up groundnuts (*Arachis*). Clumsily feeds among foliage of a variety of flowering trees (e.g. *Bombax*, *Erythrina*, *Butea*, *Grevillea*, *Spathodea*), taking both nectar and petals. In Japan, a bird feeding young was seen to hide food items during early-morning foraging, returning later to feed both young and sitting partner on nest. In N India one was watched as it hammered a concealed object, possibly a nut or a pine cone, with a stone. Usually encountered in pairs or family parties, often feeding with other birds in fruiting trees; larger congregations at good food sources. In Himalayas, follows herds of goats and sheep high into their summer pastures.
Breeding. Egg-laying begins at almost any time of year over such an extensive range. Eggs recorded late Apr in Amurland (*mandshuricus*), early May on Kuril Is and from late Apr on Hokkaido (*japonensis*), early Mar on Okinawa (*connectens*), Mar–Jun on Negros and Aug on Luzon (*philippinus*), Dec to early May in Peninsular Malaysia and Jan–Jun in Indochina (nominate), late Apr and May in Kashmir and Nepal (*intermedius*), Nov–Apr but chiefly Jan–Mar in Assam and Bangladesh (*levaillantii*), Mar–Apr in N India, and Apr–Sept but chiefly May–Jul in Sri Lanka (*culminatus*). Has long-term pair-bond. Solitary breeder. Nest built by both sexes, a platform of twigs and sticks, with deep cup lined with soft materials such as wool and hair, placed c. 7–10 m above ground in prominent tree fork, sometimes in crown of palm. Clutch 3–6 eggs (mean 4); incubation almost entirely by female, period 17–19 days (mean 18 days); chicks fed by both parents, leave nest at 3 or 4 weeks; family-members roost close to nest for c. 19 days after fledging, do not return to site once they have joined communal roost, but continue to keep together for up to 94 days after fledging. Nests parasitised by Common Koel (*Eudynamys scolopacea*).
Movements. Generally regarded as sedentary, but presumably wanders to a degree; sporadic observations on several islands of Japan, Indonesia and Philippines. In far N, Amurland, Kurils, Sakhalin and Hokkaido, many move out of the hostile interior in winter to coastal waters, particularly ice-free river mouths.
Status and Conservation. Not globally threatened. Widespread and quite numerous over most of its range. Few reports from Borneo, where rare; several specimens collected there in the past. Statements concerning its presence in NE Iran and extreme S Turkmenistan, and in Tajikistan and adjacent parts of N Afghanistan, almost certainly erroneous, as habitats there unsuitable (likely that such references are due to confusion with *C. corone* and/or *C. ruficollis* and *C. corax*). In Afghanistan it is confined to extreme E, where common in forest to N & E of Jalalabad. Over remainder of range it is a common and widespread species, which has benefited from man's forestry policies, opening up swathes and large clearings, providing open areas for foraging. In Malay Peninsula it has spread across the country with the opening-up of forests, having reached the hill stations of Cameron Highlands and Fraser's Hill in late 1940s and early 1950s, respectively; has also colonized Singapore over recent decades. As with *C. splendens*, evidence from India suggests that the amount of insects, particularly grasshoppers and locusts, that this corvid consumes outweighs the damage that it causes in fields of growing crops.

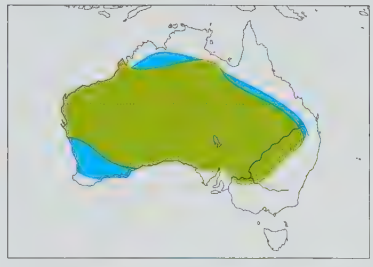
109. Torresian Crow

Corvus orru

French: Corbeau de Torres **German**: Salvadorikrähe **Spanish**: Cuervo de Torres
Other common names: New Guinea/Papuan Crow (*orru*); Tanimbar Crow (*latirostris*); Australian Crow (*cecilae*)

Taxonomy. *Corvus orru* Bonaparte, 1850, Lobo, Triton Bay, New Guinea.
Until recently considered conspecific with *C. insularis*. Australian race *cecilae* formerly regarded as a separate species. Has been suggested that *latirostris* might not belong with present species. Other proposed races in Australia are *hartogi* (described from Dirk Hartog I, off Western Australia) and *probleema* (from Derby, in N Western Australia), both considered synonyms of *ceciliae*, and *queenslandicus* (from Dawson R, in Queensland), which possibly valid but further study required; described race *marngli* (from W Kimberley, in N Western Australia) based on misidentified *C. bennetti*. Three subspecies currently recognized.
Subspecies and Distribution.
C. o. orru Bonaparte, 1850 – Moluccas E to New Guinea, including D'Entrecasteaux Is and Louisiade Archipelago.
C. o. latirostris A. B. Meyer, 1884 – Babar and Tanimbar Is (E of Lesser Sundas).
C. o. cecilae Mathews, 1912 – W, C & N Australia, including major offshore islands.



Descriptive notes. 48–53 cm; male 430–700 g, female 430–650 g. Medium-sized crow with rather stout bill, short throat hackles; compact, blunt-winged and short-tailed in flight. Nominate race is entirely glossy black, with white feather bases on head and neck; iris white, sometimes pale blue (in West Papuan Is and locally in N New Guinea); bill and legs black. Sexes similar. Juvenile is duller than adult, with pink gape, eyes blue-grey (fledgling) to brown; immature has eyes brown, becoming hazel. Race *latirostris* is similar to nominate, but slightly stouter bill, and eyes bluish-white (Tanimbar Is) or white (Babar); *cecilae* is like nominate, but slightly longer-winged and longer-tailed. Voice. Series of high-pitched (tenor), nasal, usually rapid and staccato caws, although utters some longer and harsher notes; typically 3–8 notes, sometimes with final 1–3 lower and slower, terminal note occasionally drawn out and descending, more honking than calls of *C. bennetti*. Also high-pitched yodelling caw, softer bubbling, croaking and long creaking calls, and single guttural notes.
Habitat. All terrestrial habitat types within range, from montane rainforest (1500 m) to littoral. Common in lightly wooded and open habitats, farmland, urban areas and other modified habitats. In Australian arid zone largely restricted to wooded watercourses.
Food and Feeding. Omnivorous predator and scavenger, strongly granivorous. Feeds mainly on invertebrates, small birds, eggs, nestlings, also carrion, including beachcast marine life; sometimes frogs and reptiles (lizards, turtle hatchlings), rarely fish. Also seeds, fruit, other plant material, occasionally nectar. Sometimes attacks weak or moribund lambs. Opportunistic, feeding mainly on the ground in open habitats, sometimes in trees and standing crops. Forages mainly by walking and gleaning from the ground or low vegetation, sometimes gleaning and snatching prey from foliage. Commonly patrols roads, sheep paddocks, rubbish dumps and human habitation for carrion and refuse. Sometimes dunks food in water before eating. Sometimes drops prey from height; robs raptors of prey. Avoids poisonous dorsal glands of cane toad (*Bufo marinus*) by turning carcass on its back and eating from belly. Caches or buries surplus food in such places as hole in cliff, or under soil, grass or leaves, later retrieving stored food. Forages in pairs and in small to large flocks.
Breeding. Recorded in all months in Australia, with eggs Aug–Jun in N and Jun–Dec in S of range; in New Guinea active nests Sept–Oct, eggs in Jan and Mar, and juveniles and large fledglings in Jan and early Apr; failed pairs renest. Monogamous. Solitarily breeder in well-dispersed pairs. Nest a bowl 38 cm wide and 19 cm deep, made from sticks, lined with plant fibres, wool, hair or cotton waste, built 3–45 m (usually more than 10 m) above ground in fork of tree or in artificial structure such as utility pole, tower or windmill platform. Clutch 1–7 eggs, usually 5; incubation by female, period 19–20 days; chicks fed by both sexes, nestling period 38–48 days (mean 41 days); young remain in natal territory for 2–3 months, or occasionally until following breeding season. Nests often parasitized by Channel-billed Cuckoo (*Scythrops novaehollandiae*). For 138 eggs in 30 clutches, hatching success 70% and fledging success 22%; other samples gave 77% hatching success from 43 eggs in ten nests, and 17 young from nine successful attempts out of 15 nests. First breeding when at least 2 years old (only white-eyed individuals recorded as breeding).
Movements. Resident. In humid areas juveniles, immatures and non-breeding adults form mobile, dispersive flocks of typically 20–150 individuals that congregate at large communal roosts; four such non-breeders (adult and immature, of indeterminate social status) used home ranges of up to 2250 ha (mean 700 ha). Some birds move between islands in Torres Strait.
Status and Conservation. Not globally threatened. Generally abundant and widespread; has increased in range and numbers with spread of agriculture and urbanization. Adult breeding pairs have large home range of c. 130 ha. In arid areas flocks tend to be both rare and small, numbering fewer than 20 birds. Roosts contain up to 1000 individuals. Benefits from artificial food sources, and is common in modified habitats. Perceived as a pest in sheep-rearing lands, orchards, crops, around poultry and in cities, and consequently is legally unprotected and is persecuted by shooting, trapping and poisoning in farmland (with little apparent effect on numbers). Well represented in protected areas.

110. Little Crow

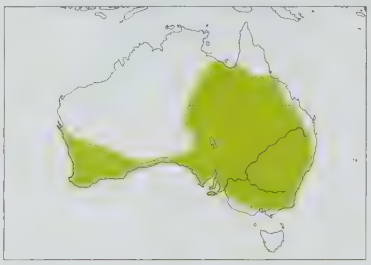
Corvus bennetti

French: Corbeau du désert **German**: Bennettkrähe **Spanish**: Cuervo de Bennett
Other common names: Bennett's/Small-billed Crow

Taxonomy. *Corvus bennetti* North, 1901, Moolah, western New South Wales, Australia.
Proposed race *bonhoti* (described from Murchison, in Western Australia) considered inadequately differentiated to warrant recognition; putative race *queenslandicus* (from Dawson R, in E Queensland), ascribed to present species, was based on misidentified *C. orru*. Monotypic.
Distribution. Inland and W Australia.

Descriptive notes. 45–48 cm; male 345–500 g, female 290–490 g, unsexed 282–525 g. Rather small and slender, short-legged crow with small bill, short throat hackles; compact, blunt-winged and agile in flight. Plumage is entirely glossy black, with white feather bases on head and neck; iris white; bill and legs black. Sexes similar. Juvenile is duller than adult, with pink gape, eyes blue-grey (fledgling) to brown; immature has eyes brown, becoming hazel. Voice. Series of rather deep (baritone), flat, hoarse, nasal and rapid caws (although notes slurred, rather than clipped), monotonous, of up to 15 notes, terminal note rarely prolonged; similar to voice of *C. mellori* but more nasal, and deeper and hoarser than that of *C. orru*. Also rapid, high-pitched caw of 3 notes, low bubbling and creaking calls, and single guttural notes.
Habitat. Most terrestrial habitat types in arid and semi-arid zones, but avoids dense tropical grassland. Commonly in low or open woodland, shrubland, pastoral land and towns. Wooded habitats typically dominated by eucalypts (*Eucalyptus*) and *Acacia*. Breeds only where surface water available.
Food and Feeding. Omnivorous predator and scavenger, strongly insectivorous. Feeds mainly on invertebrates, lizards, small birds, eggs, nestlings and carrion; occasionally frogs, small mammals; also seeds, fruit, other plant material, occasionally nectar. Occasionally attacks moribund lambs. Opportunistic, feeding mainly on the ground in open habitats, occasionally in trees and shrubs. Forages mainly by walking and gleaning from the ground or low vegetation, occasionally gleaning from foliage. Commonly patrols roads, sheep paddocks, rubbish dumps and human habitation for carrion and refuse. Sometimes dunks carrion in water before eating. Caching observed in captivity. Highly sociable, generally in large flocks.
Breeding. In S Australia laying mainly in late winter to spring, mostly mid-Jul to late Oct (peak late Aug and early Sept), occasionally to late summer (Feb), and sometimes in autumn (Mar–May), opportunistically after heavy rain; in N Australia lays Jan–Sept; failed pairs renest, and successful pairs sometimes attempt second brood. Monogamous. Nests colonially, as clumped pairs in small territories (0·5 ha) used only for breeding, or as more dispersed pairs where tree cover sparse. Nest a large bowl 30–36 cm wide and 23–37 cm deep, made from sticks, lined with bark, grass, feathers, wool, hair or pieces of cloth, often with clay layer beneath the lining, built 2–20 m (commonly less than 10 m) above ground in fork of tree or shrub or in artificial structure such as utility pole, tower or windmill platform. Clutch 1–8 eggs, usually 4–6; incubation by female, period 16–18 days; chicks fed by both sexes, nestling period 29–31 days; young remain in nest area for a few days, after which family departs from nest area with mobile flock. Nests occasionally parasitized by Channel-billed Cuckoo (*Scythrops novaehollandiae*). Breeding success during drought measured as 73% hatching success and 3% fledging success for 240 eggs in 56 clutches; other samples gave 43% hatching success and 20% fledging success from 79 eggs in 18 nests, 50% hatching success from 95 eggs in 22 nests, and 57% success in rearing young for 56 nests. Age at first breeding 3 years.
Movements. Apparently nomadic. Adult breeding pairs resident only for duration of breeding cycle; after breeding, apparently all birds (juveniles, immatures and adults) form mobile flocks of typically 50–300 birds, sometimes up to 500 or exceptionally thousands, that congregate at gluts of food and disperse or migrate up to 700 km. These movements take them to non-breeding areas outside the main breeding range, e.g. to far SW Australia. No evidence that adults return to traditional nesting territories, or that juveniles return to natal site to breed.
Status and Conservation. Not globally threatened. Abundant and widespread. Has increased in range and numbers with spread of agriculture and artificial water sources in rangelands; may have declined locally at S limit of range. Benefits from artificial food sources, and is common in modified habitats, although may be displaced by *C. mellori* in SE agricultural zone. Considered a pest in sheep-rearing lands, orchards, crops and around poultry, and consequently is legally unprotected and is occasionally shot, trapped or poisoned in farmland. Well represented in protected areas.
Bibliography. Debus (1982, 1996), Higgins *et al.* (2006a), Hobbs (1980), Klapste (1979), Lawrence (2005), Madge & Burn (1994), Morcombe (2000), Pizzey & Knight (1998), Rowley (1969a, 1970, 1973a, 1973b, 1973c, 1974, 2002a), Rowley & Vestjens (1973), Rowley *et al.* (1973), Schodde & Mason (1999), Schodde & Tidemann (1986), Simpson & Day (1996), Slater *et al.* (2003).

111. Australian Raven



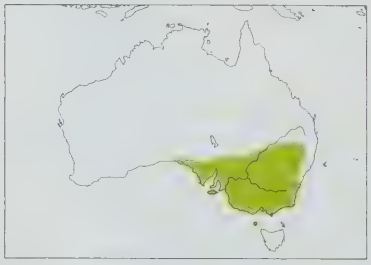
Corvus coronoides

French: Corbeau d'Australie **German**: Neuhollandkrähe **Spanish**: Cuervo Australiano

Taxonomy. *Corvus Coronoides* Vigors and Horsfield, 1827, Parramatta, New South Wales, Australia.
Much early confusion over correct specific name of this species; originally called *C. australis*, but identity and provenance of type specimen were suspect and the name was preoccupied; as a consequence, was named *C. marianae*, but that name is a synonym for the earlier *C. coronoides*, which takes priority. Purported taxon *difficilis* was based on an aberrant, immature specimen of present species and is invalid. Two subspecies recognized.

On following pages: 112. Little Raven (*Corvus mellori*); 113. Forest Raven (*Corvus tasmanicus*); 114. Collared Crow (*Corvus pectoralis*); 115. Hawaiian Crow (*Corvus hawaiiensis*); 116. Chihuahuan Raven (*Corvus cryptoleucus*); 117. Pied Crow (*Corvus albus*); 118. Ethiopian Raven (*Corvus edithae*); 119. Brown-necked Raven (*Corvus ruficollis*); 120. Common Raven (*Corvus corax*); 121. Fan-tailed Raven (*Corvus rhipidurus*); 122. White-necked Raven (*Corvus albicollis*); 123. Thick-billed Raven (*Corvus crassirostris*).

Subspecies and Distribution.
C. c. perplexus Mathews, 1912 – SW Australia.
C. c. coronoides Vigors & Horsfield, 1827 – E & SE Australia, including some major offshore islands (e.g. Kangaroo I, in South Australia).



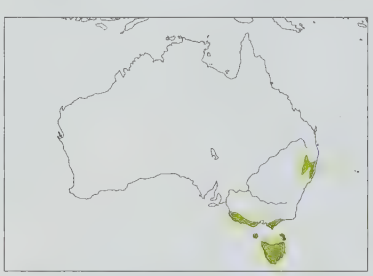
Descriptive notes. 48–54 cm; male 540–820 g, female 500–780 g. Large crow with stout bill, long, lanceolate throat hackles; tapered wings and rather long, slender tail in flight. Plumage is entirely glossy black, with grey feather bases on head and neck; iris white; bill black; extensive bare grey inter-ramal skin on side of chin; legs black. Sexes similar. Juvenile is duller than adult, with shorter hackles, pink gape and gular skin, eyes blue-grey (fledgling) to brown; older immature (in 2nd–3rd year) has eyes brown, becoming hazel. Race *perplexus* is slightly smaller than nominate, and has slightly shorter hackles. Voice. Utters series of high-pitched (tenor), slow and wailing caws (with throat hackles held prominently fanned), typically of 3 or 4 notes, terminal note drawn out and descending. Also gives shorter, sharper caws, sometimes antiphonally, low rattling and creaking note, and single long mournful notes.
Habitat. All terrestrial habitat types within range, from alpine (2000 m) to littoral and arid, but avoiding the most dense forest types such as rainforest. Most common in woodland, pastoral land and urban areas; often on edge between wooded and open areas. Habitats typically dominated by eucalypts (*Eucalyptus*), but occurs also in other vegetation types, including exotic pine (*Pinus*) plantations.
Food and Feeding. Omnivorous predator and scavenger; strongly carnivorous. Feeds mainly on invertebrates, small birds, eggs, nestlings, small mammals and carrion; occasionally frogs and lizards, rarely fish. Also seeds, some fruit, other plant material, occasionally nectar. Sometimes attacks weak or moribund lambs. Opportunistic, feeding mainly on the ground in open habitats, occasionally in trees. Forages mainly by walking and gleaning from the ground or low vegetation, occasionally snatching prey from foliage or in the air. Commonly patrols roads, sheep paddocks, rubbish dumps and parks for carrion and refuse. Often dunks carrion and household food scraps in water before eating. Caches or buries surplus food in terrestrial sites, such as under soil, bark or other debris, or in grass tussocks, later retrieving stored items. Forages singly, in pairs and in family parties; sometimes in small flocks in non-breeding season.
Breeding. Laying mainly in late winter to spring, mostly early Jul to late Oct (peak early Aug), but occasional breeding records in all other months (those from late summer and autumn referring to fledglings); failed pairs renest, but second attempt in a season rarely successful. Monogamous. Solitary, in well-dispersed pairs. Nest a large bowl 40 cm wide and 48 cm deep, made from sticks, lined with bark, grass, wool or hair, built 3–42 m (usually more than 10 m) above ground in fork of tree or on artificial structure such as utility pole, tower or windmill platform. Clutch 1–6 eggs, usually 4 or 5; incubated by female, period 19–21 days (mean 20 days); chicks fed by both sexes, nestling period 40–45 days (mean 43 days); young dependent on parents for a further three months. Nest occasionally parasitized by Channel-billed Cuckoo (*Scythrops novaehollandiae*). Breeding success measured as 73% hatching success and 35% fledging success for 1144 eggs in 260 clutches; 28% of clutches failed, giving 1–4 (mean 1·5) fledglings per successful pair, and 0·9–1·8 fledglings per pair per year. Age at first breeding 3 years.
Movements. Adult breeding pairs sedentary; occasionally short-range excursions of up to 5 km beyond territories to local gluts of food. Juveniles, immatures and non-breeding adults form mobile flocks of typically 10–30 birds that disperse up to hundreds of kilometres, though usually less than 150 km from natal site.
Status and Conservation. Not globally threatened. Abundant and widespread. Pair lives in large home range of c. 120 ha. Has increased in range and numbers with spread of agriculture, artificial water sources in rangelands, and urbanization. Benefits from artificial food sources, and is common in modified habitats. Considered a pest species in sheep-rearing lands, orchards, around poultry and in cities, and consequently is legally unprotected and is persecuted by shooting, trapping and poisoning in farmland (with little apparent effect on numbers). Well represented in protected areas.
Bibliography. Debus (1982, 1996), Higgins *et al.* (2006a), Kotler *et al.* (1998), Lawrence (2005), Lepschi (1994), Madge & Burn (1994), Meinertzhagen (1926), Mitchell & Attwood (2000), Morcombe (2000), Pizzey & Knight (1998), Rogers & Rogers (1999), Rowley (1969a, 1970, 1973a, 1973b, 1973c, 1974), Rowley & Vestjens (1973), Rowley *et al.* (1973), Schodde & Mason (1999), Schodde & Tidemann (1986), Simpson & Day (1996), Slater *et al.* (2003).

112. Little Raven

Corvus mellori

French: Petit Corbeau **German**: Gesellschaftskrähe **Spanish**: Cuervo de Mellor

Taxonomy. *Corvus mariana mellori* Mathews, 1912, Angas Plains South Australia.
Originally described as a race of *C. coronoides* (then known as *C. marianae*), although validity was not widely accepted; recognized as a distinct species in 1967. Proposed race *halmaturinus* (from Kangaroo I, off South Australia) considered indistinguishable from birds in rest of species' range. Monotypic.
Distribution. SE Australia, including Kangaroo I (off South Australia) and King I (in Bass Strait).



Descriptive notes. 48–50 cm; male 407–660 g, female 365–660 g. Medium-sized crow with rather slender bill, medium-length bifurcated throat hackles. Plumage is entirely glossy black, with grey feather bases on head and neck; iris white; bill and legs black. Sexes similar. Juvenile is duller than adult, with shorter hackles, pink gape, blue-grey (fledgling) to brown eyes; second-year has eyes brown, becoming hazel. Voice. Series of rather deep (baritone), usually rapid and clipped caws, typically of 7 notes (when perched, flicks closed wings upwards with each "bark"), deeper, harsher and more rapid than that of *C. coronoides*, although terminal note occasionally prolonged (and much shorter throat hackles less noticeable). Also various guttural caws and long creaky note.
Habitat. All terrestrial habitat types within range, from alpine (2000 m) to littoral and semi-arid, but avoids the most dense forest types such as rainforest. Most common in low or open woodland, pastoral land and urban areas; foraging flocks often in treeless grassland. Wooded habitats typically dominated by eucalypts (*Eucalyptus*), though occurs also in other vegetation types, including exotic trees.
